## Cover Photographs

**Foreground:** The first walking microrobot with a Swedish wasp relishing a ride on its back. The out-of-plane rotation of the eight legs is obtained by thermal shrinkage of polyimide in V-grooves (PVG). Leg movements are effected by sending heating pulses via integrated heaters causing the polyimide joints to expand. The size of the silicon legs is  $1000 \times 600 \times 30 \mu\text{m}$ , and the overall chip size of the robot is  $15 \times 5 \times 0.5 \text{ mm}$ . The walking speed is 6 mm/s and the robot can carry 50 times its own weight. (Photograph by Per Westergård, Vetenskapsjournalisterna, Sweden, courtesy of Thorbjörn Ebefors, Royal Institute of Technology, Sweden.)

**Background:** A 12-layer microchain fabricated in nickel using the Electrochemical Fabrication (EFAB) technology. Overall height of the chain is approximately  $100 \mu\text{m}$  and the width of a chain link is about  $290 \mu\text{m}$ . All horizontal links are free to move, while the vertical links are attached to the substrate. By simply including a sacrificial layer beneath the links, the entire chain can be released from the substrate. The microchain is fabricated in a pre-assembled state, without the need for actual assembly. A humble, picnic-loving ant would tower over the microchain shown here. (The two scanning electron micrographs courtesy of Adam L. Cohen, MEMGen Corporation, Torrance, California.)

# Preface

---

*In a little time I felt something alive moving on my left leg, which advancing gently forward over my breast, came almost up to my chin; when bending my eyes downward as much as I could, I perceived it to be a human creature not six inches high, with a bow and arrow in his hands, and a quiver at his back. ...I had the fortune to break the strings, and wrench out the pegs that fastened my left arm to the ground; for, by lifting it up to my face, I discovered the methods they had taken to bind me, and at the same time with a violent pull, which gave me excessive pain, I a little loosened the strings that tied down my hair on the left side, so that I was just able to turn my head about two inches. ...These people are most excellent mathematicians, and arrived to a great perfection in mechanics by the countenance and encouragement of the emperor, who is a renowned patron of learning. This prince has several machines fixed on wheels, for the carriage of trees and other great weights.*

(From *Gulliver's Travels—A Voyage to Lilliput*, by Jonathan Swift, 1726.)

The length-scale of man, at slightly more than  $10^0$  m, amazingly fits right in the middle of the smallest subatomic particle, which is approximately  $10^{-26}$  m, and the extent of the observable universe, which is of the order of  $10^{26}$  m. Toolmaking has always differentiated our species from all others on Earth. Aerodynamically correct wooden spears were carved by *archaic Homo sapiens* close to 400,000 years ago. Man builds things consistent with his size, typically in the range of two orders of magnitude larger or smaller than himself. But humans have always strived to explore, build and control the extremes of length and time scales. In the *Voyages to Lilliput* and *Brobdingnag* of *Gulliver's Travels*, Jonathan Swift speculates on the remarkable possibilities that diminution or magnification of physical dimensions provides. The Great Pyramid of Khufu was originally 147 m high when completed around 2600 B.C., while the Empire State Building, constructed in 1931, is 449 m tall. At the other end of the spectrum of manmade artifacts, a dime is slightly less than 2 cm in diameter. Watchmakers have practiced the art of miniaturization since the 13th century. The invention of the microscope in the 17th century opened the way for direct observation of microbes and plant and animal cells. Smaller things were manmade in the latter half of the 20th century. The transistor in today's integrated circuits has a size of 0.18  $\mu\text{m}$  in production and approaches 10 nm in research laboratories.

Microelectromechanical systems (MEMS) refer to devices that have a characteristic length of less than 1 mm but more than 1  $\mu\text{m}$ , that combine electrical and mechanical components and that are fabricated using integrated circuit batch-processing technologies. Current manufacturing techniques for MEMS include surface silicon micromachining; bulk silicon micromachining; lithography, electrodeposition and plastic molding; and electrodischarge machining. The multidisciplinary field has witnessed explosive growth during the last decade, and the technology is progressing at a rate that far exceeds that of our understanding of the physics involved. Electrostatic, magnetic, electromagnetic, pneumatic and thermal actuators, motors, valves, gears, cantilevers, diaphragms and tweezers of less than 100- $\mu\text{m}$  size have been fabricated. These have been used as sensors for pressure, temperature, mass flow, velocity, sound and

chemical composition; as actuators for linear and angular motions; and as simple components for complex systems such as robots, micro heat engines and micro heat pumps. Worldwide market projections for MEMS devices tend to be optimistic, reaching \$30 billion by the year 2004.

This handbook covers several aspects of microelectromechanical systems or, more broadly, the art and science of electromechanical miniaturization. MEMS design, fabrication and application as well as the physical modeling of their materials, transport phenomena and operations are all discussed. Chapters on the electrical, structural, fluidic, transport and control aspects of MEMS are included. Other chapters cover existing and potential applications of microdevices in a variety of fields including instrumentation and distributed control. The book is divided into four parts: Part I provides background and physical considerations, Part II discusses the design and fabrication of microdevices, Part III reviews a few of the applications of microsensors and microactuators, and Part IV ponders the future of the field. There are 36 chapters written by the world's foremost authorities on this multidisciplinary subject. The contributing authors come from the U.S., China (Hong Kong), Israel, Korea, Sweden and Taiwan and are affiliated with academia, government and industry. Without compromising rigorousness, the text is designed for maximum readability by a broad audience having an engineering or science background. As expected when several authors are involved, and despite the editor's best effort, the different chapters vary in length, depth, breadth and writing style.

*The Handbook of MEMS* should be useful as a reference book to scientists and engineers already experienced in the field or as a primer to researchers and graduate students just getting started in the art and science of electromechanical miniaturization. The editor-in-chief is very grateful to all the contributing authors for their dedication to this endeavor and selfless, generous giving of their time with no material reward other than the knowledge that their hard work may one day make the difference in someone else's life. Ms. Cindy Renee Carelli has been our acquisition editor and lifeline to CRC Press. Cindy's talent, enthusiasm and indefatigability were highly contagious and percolated throughout the entire endeavor.

**Mohamed Gad-el-Hak**

Notre Dame, Indiana

# Editor-in-Chief

---

**Mohamed Gad-el-Hak** received his B.Sc. (*summa cum laude*) in mechanical engineering from Ain Shams University in 1966 and his Ph.D. in fluid mechanics from the Johns Hopkins University in 1973. Dr. Gad-el-Hak has since taught and conducted research at the University of Southern California, University of Virginia, Institut National Polytechnique de Grenoble, Université de Poitiers and Friedrich-Alexander-Universität Erlangen-Nürnberg and has lectured extensively at seminars in the U.S. and overseas. Dr. Gad-el-Hak is currently Professor of Aerospace and Mechanical Engineering at the University of Notre Dame. Prior to that, he was a Senior Research Scientist and Program Manager at Flow Research Company in Seattle, WA, where he managed a variety of aerodynamic and hydrodynamic research projects.

Dr. Gad-el-Hak is world renowned for advancing several novel diagnostic tools for turbulent flows, including the laser-induced fluorescence (LIF) technique for flow visualization; for discovering the efficient mechanism via which a turbulent region rapidly grows by destabilizing a surrounding laminar flow; for introducing the concept of targeted control to achieve drag reduction, lift enhancement and mixing augmentation in boundary-layer flows; and for developing a novel viscous pump suited for microelectromechanical systems (MEMS) applications. Gad-el-Hak's work on Reynolds number effects in turbulent boundary layers, published in 1994, marked a significant paradigm shift in the subject. He holds two patents: one for a drag-reducing method for airplanes and underwater vehicles and the other for a lift-control device for delta wings. Dr. Gad-el-Hak has published over 340 articles, authored/edited eight books and conference proceedings, and presented 195 invited lectures. He is the author of the book *Flow Control: Passive, Active, and Reactive Flow Management*, and editor of the books *Frontiers in Experimental Fluid Mechanics*, *Advances in Fluid Mechanics Measurements*, and *Flow Control: Fundamentals and Practices*.

Dr. Gad-el-Hak is a fellow and life member of the American Physical Society, a fellow of the American Society of Mechanical Engineers, an associate fellow of the American Institute of Aeronautics and Astronautics, a member of the American Academy of Mechanics, a research fellow of the American Biographical Institute and a member of the European Mechanics Society. From 1988 to 1991, Dr. Gad-el-Hak served as Associate Editor for *AIAA Journal*. He is currently serving as Associate Editor for *Applied Mechanics Reviews* as well as Contributing Editor for Springer-Verlag's *Lecture Notes in Engineering* and *Lecture Notes in Physics*, for McGraw-Hill's *Year Book of Science and Technology*, and for CRC Press' *Mechanical Engineering Series*.

Dr. Gad-el-Hak serves as consultant to the governments of Egypt, France, Germany, Sweden and the U.S., the United Nations, and numerous industrial organizations. During the 1991/1992 academic year, he was a visiting professor at Institut de Mécanique de Grenoble, France. During the summers of 1993, 1994 and 1997, Dr. Gad-el-Hak was, respectively, a distinguished faculty fellow at Naval Undersea Warfare Center, Newport, RI; a visiting exceptional professor at Université de Poitiers, France; and a Gastwissenschaftler (guest scientist) at Forschungszentrum Rossendorf, Dresden, Germany. In 1998, Professor Gad-el-Hak was named the Fourteenth ASME Freeman Scholar. In 1999, Gad-el-Hak was awarded the prestigious Alexander von Humboldt Prize—Germany's highest research award for senior U.S. scientists and scholars in all disciplines.

## Introduction

---

Mohamed Gad-el-Hak

University of Notre Dame

*How many times when you are working on something frustratingly tiny, like your wife's wrist watch, have you said to yourself, "If I could only train an ant to do this!" What I would like to suggest is the possibility of training an ant to train a mite to do this. What are the possibilities of small but movable machines? They may or may not be useful, but they surely would be fun to make.*

(From the talk "There's Plenty of Room at the Bottom," delivered by Richard P. Feynman at the annual meeting of the American Physical Society, Pasadena, CA, December 29, 1959.)

Tool making has always differentiated our species from all others on Earth. Aerodynamically correct wooden spears were carved by *archaic Homo sapiens* close to 400,000 years ago. Man builds things consistent with his size, typically in the range of two orders of magnitude larger or smaller than himself, as indicated in [Figure 1.1](#). Though the extremes of the length scale are outside the range of this figure, man, at slightly more than  $10^0$  m, amazingly fits right in the middle of the smallest subatomic particle, which is approximately  $10^{-26}$  m, and the extent of the observable universe, which is of the order of  $10^{26}$  m (15 billion light years)—neither geocentric nor heliocentric but rather an egocentric universe! But humans have always striven to explore, build and control the extremes of length and time scales. In the voyages to Lilliput and Brobdingnag of *Gulliver's Travels*, Jonathan Swift (1726) speculates on the remarkable possibilities which diminution or magnification of physical dimensions provides.<sup>1</sup> The Great Pyramid of Khufu was originally 147 m high when completed around 2600 B.C., while the Empire State Building constructed in 1931 is currently—after the addition of a television antenna mast in 1950—449 m high. At the other end of the spectrum of man-made artifacts, a dime is slightly less than 2 cm in diameter. Watchmakers have practiced the art of miniaturization since the 13th century. The invention of the microscope in the 17th century opened the way for direct observation of microbes and plant and animal cells. Smaller things were man-made in the latter half of the 20th century. The transistor—invented in 1947—in today's integrated circuits has a size<sup>2</sup> of 0.18  $\mu\text{m}$  (180 nm) in production and approaches 10 nm in research laboratories using electron beams. But what about the miniaturization of mechanical parts—machines—envisioned by Feynman (1961) in his legendary speech quoted above?

---

<sup>1</sup>*Gulliver's Travels* was originally designed to form part of a satire on the abuse of human learning. At the heart of the story is a radical critique of human nature in which subtle ironic techniques work to part the reader from any comfortable preconceptions and challenge him to rethink from first principles his notions of man.

<sup>2</sup>The smallest feature on a microchip is defined by its smallest linewidth, which in turn is related to the wavelength of light employed in the basic lithographic process used to create the chip.

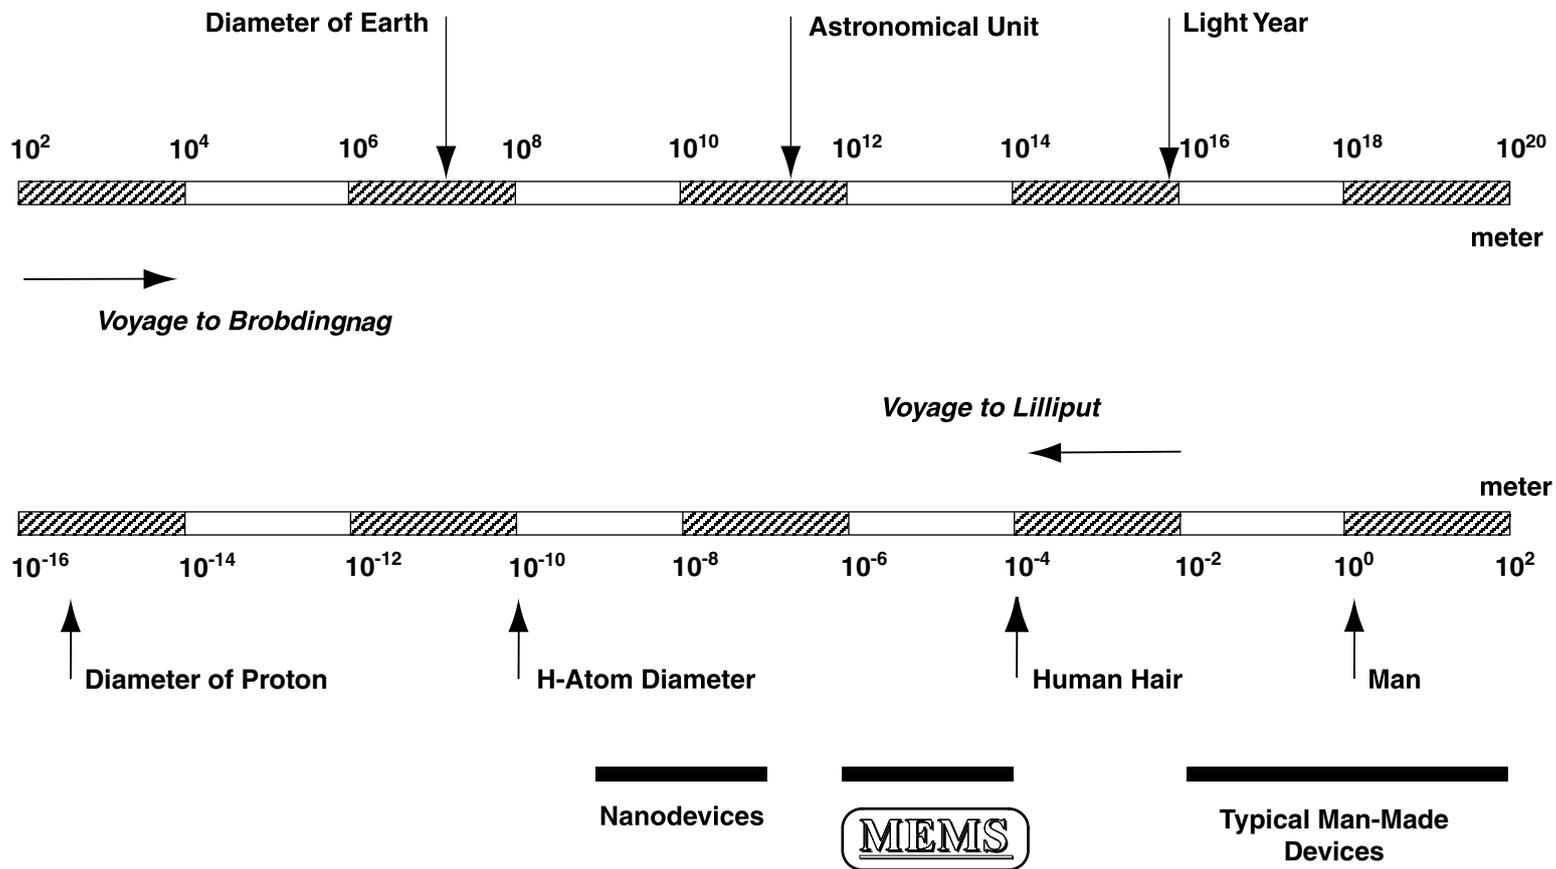

FIGURE 1.1 Scale of things, in meters. Lower scale continues in the upper bar from left to right. One meter is  $10^6 \mu\text{m}$ ,  $10^9 \text{nm}$  or  $10^{10} \text{\AA}$ .

Manufacturing processes that can create extremely small machines have been developed in recent years [Angell et al., 1983; Gabriel et al., 1988; 1992; O'Connor, 1992; Gravesen et al., 1993; Bryzek et al., 1994; Gabriel, 1995; Ashley, 1996; Ho and Tai, 1996; 1998; Hogan, 1996; Ouellette, 1996; Paula, 1996; Robinson et al., 1996a; 1996b; Madou, 1997; Tien, 1997; Amato, 1998; Busch-Vishniac, 1998; Kovacs, 1998; Knight, 1999; Epstein, 2000; Goldin et al., 2000; O'Connor and Hutchinson, 2000; Chalmers, 2001; Tang and Lee, 2001]. Electrostatic, magnetic, electromagnetic, pneumatic and thermal actuators, motors, valves, gears, cantilevers, diaphragms and tweezers less than 100  $\mu\text{m}$  in size have been fabricated. These have been used as sensors for pressure, temperature, mass flow, velocity, sound and chemical composition; as actuators for linear and angular motions; and as simple components for complex systems such as robots, micro-heat-engines and micro-heat-pumps [Lipkin, 1993; Garcia and Sniegowski, 1993; 1995; Sniegowski and Garcia, 1996; Epstein and Senturia, 1997; Epstein et al., 1997].

Microelectromechanical systems (MEMS) refer to devices that have a characteristic length of less than 1 mm but more than 1  $\mu\text{m}$ , that combine electrical and mechanical components and that are fabricated using integrated circuit batch-processing technologies. The books by Madou (1997) and Kovacs (1998) provide excellent sources for microfabrication technology. Current manufacturing techniques for MEMS include surface silicon micromachining; bulk silicon micromachining; lithography, electrodeposition and plastic molding (or, in its original German, *lithographie galvaniformung abformung*, LIGA); and electrodischarge machining (EDM). As indicated in Figure 1.1, MEMS are more than four orders of magnitude larger than the diameter of the hydrogen atom, but about four orders of magnitude smaller than the traditional man-made artifacts. Microdevices can have characteristic lengths smaller than the diameter of a human hair. Nanodevices (some say NEMS) further push the envelope of electromechanical miniaturization [Roco, 2001].

The famed physicist Richard P. Feynman delivered a mere two, but profound, lectures<sup>3</sup> on electromechanical miniaturization: “There’s Plenty of Room at the Bottom,” quoted above, and “Infinitesimal Machinery,” presented at the Jet Propulsion Laboratory on February 23, 1983. He could not see a lot of use for micromachines, lamenting in 1959: “[Small but movable machines] may or may not be useful, but they surely would be fun to make,” and, 24 years later, “There is no use for these machines, so I still don’t understand why I’m fascinated by the question of making small machines with movable and controllable parts.” Despite Feynman’s demurring regarding the usefulness of small machines, MEMS are finding increased applications in a variety of industrial and medical fields, with a potential worldwide market in the billions of dollars (\$30 billion by 2004). Accelerometers for automobile airbags, keyless entry systems, dense arrays of micromirrors for high-definition optical displays, scanning electron microscope tips to image single atoms, micro-heat-exchangers for cooling of electronic circuits, reactors for separating biological cells, blood analyzers and pressure sensors for catheter tips are but a few in current use. Microducts are used in infrared detectors, diode lasers, miniature gas chromatographs and high-frequency fluidic control systems. Micropumps are used for ink-jet printing, environmental testing and electronic cooling. Potential medical applications for small pumps include controlled delivery and monitoring of minute amounts of medication, manufacturing of nanoliters of chemicals and development of an artificial pancreas.

This multidisciplinary field has witnessed explosive growth during the last decade. Several new journals are dedicated to the science and technology of MEMS—for example, *Journal of Microelectromechanical Systems*, *Journal of Micromechanics and Microengineering* and *Microscale Thermophysical Engineering*. Numerous professional meetings are devoted to micromachines—for example, Solid-State Sensor and Actuator Workshop, International Conference on Solid-State Sensors and Actuators (Transducers), Micro Electro Mechanical Systems Workshop, Micro Total Analysis Systems, Eurosenors, etc.

This handbook covers several aspects of microelectromechanical systems, or more broadly the art and science of electromechanical miniaturization. MEMS design, fabrication and application as well as the physical modeling of their materials, transport phenomena and operations are discussed. Chapters on

---

<sup>3</sup>Both talks have been reprinted in the *Journal of Microelectromechanical Systems* 1(1), pp. 60–66, 1992; 2(1), pp. 4–14, 1993.

the electrical, structural, fluidic, transport and control aspects of MEMS are included. Other chapters cover existing and potential applications of microdevices in a variety of fields including instrumentation and distributed control. Physical understanding of the different phenomena unique to micromachines is emphasized throughout this book. The handbook is divided into four parts: Part I provides background and physical considerations, Part II discusses the design and fabrication of microdevices, Part III reviews a few of the applications of microsensors and microactuators, and Part IV ponders the future of the field. The 36 chapters are written by the world's foremost authorities on this multidisciplinary subject. The contributing authors come from academia, government and industry. Without compromising rigorously, the text is designed for maximum readability by a broad audience having an engineering or science background. The nature of the book—being a handbook and not an encyclopedia—and its size limitation dictate the exclusion of several important topics in the MEMS area of research and development.

Our objective is to provide a current overview of the fledgling discipline and its future developments for the benefit of working professionals and researchers. The handbook will be a useful guide and reference to the explosive literature on MEMS and should provide the definitive word for the fundamentals and applications of microfabrication and microdevices. Glancing at the table of contents, the reader may rightly sense an overemphasis on the physics of microdevices. This is consistent with the strong conviction of the editor-in-chief that the MEMS technology is moving too fast relative to our understanding of the unconventional physics involved. This technology can certainly benefit from a solid foundation of the underlying fundamentals. If the physics is better understood, better, less expensive and more efficient microdevices can be designed, built and operated for a variety of existing and yet-to-be-dreamed applications. Consistent with this philosophy, chapters on control theory, distributed control and soft computing are included as the backbone of the futuristic idea of using colossal numbers of microsensors and microactuators in reactive control strategies aimed at taming turbulent flows to achieve substantial energy savings and performance improvements of vehicles and other man-made devices.

I shall leave you now for the many wonders of the small world you are about to encounter when navigating through the various chapters that follow. May your voyage to Lilliput be as exhilarating, enchanting and enlightening as *Lemuel Gulliver's Travels into Several Remote Nations of the World*. *Hekinah degul!* Jonathan Swift may not have been a good biologist and his scaling laws were not as good as those of William Trimmer (see Chapter 2 of this book), but Swift most certainly was a magnificent storyteller. *Hnuv illa nyha majah Yahoo!*

2.3 [Scaling of Mechanical Systems](#)

---

### 2.1 Introduction

---

A revolution in understanding and utilizing micromechanical devices is starting. The utility of these devices will be enormous, and with time these microdevices will fill the niches of our lives as pervasively as electronics. What form will these microdevices take? What will actuate them, and how will they interact with their environment? We cannot foresee where the developing technology will take us.

How, then, do we start to design this world of the micro? As you will discover in this book, there are a large number of ways to fabricate microdevices and a vast number of designs. The number of possible things we could try is beyond possibility. Should we just start trying approaches until something works? Perhaps there is a better way.

Scaling theory is a valuable guide to what may work and what will not. By understanding how phenomena behave and change, as the scale size changes, we can gain some insight and better understand the profitable approaches. This chapter examines how things change with size and will develop mathematics that helps find the profitable approaches.

Three general scale sizes will be discussed: astronomical objects; the normal objects we deal with, called *macro-objects*; and very small objects, called *micro-objects*. Things effective at one of these scale sizes often are insignificant at another scale size. As an example, gravitational forces dominate on an astronomical scale. The motion of our planet around the sun and our sun around the galaxy is driven mostly by gravitational forces. Yet, on the macroscale of my desk top, the gravitational force between two objects, such as my tape dispenser and stapler, is insignificant. A few simple scaling calculations later in this chapter will tell us this: On astronomical scales, be concerned with gravity; on smaller scales, look to other forces to move objects.

What is obvious on an astronomical-scale size or on a macroscale size is often not obvious on the microscale. For example, take the case of an electric motor. It is really a magnetic motor, and almost all macrosized electric actuators use magnetic fields to generate forces. Hence, one's first intuition would be to use magnetic motors in designing microdevices. However, most of the common micromotor designs use electrostatic fields instead of magnetic. The reasons for this will become obvious in the following discussion of how forces scale.

This field of micromechanical devices is extremely broad. It encompasses all of the traditional science and engineering disciplines, only on a smaller scale. Try to think of a traditional science or engineering discipline that does not have a microequivalent. What we are about in our new discipline is replicating the macroscience and engineering on a microscale. As a result, technical people from all science and engineering disciplines can make important contributions to this field.

The time scale from conception to utilization has been collapsing. Alessandro Volta and Andre Marie Ampere developed the basic concepts of electricity. About a hundred years later, Nikola Tesla and Thomas Alva Edison developed practical electric generators and motors. In contrast, the microcomb drive motor was described in 1989 and currently is being used in automobiles as an airbag sensor [Tang et al., 1989]. Volta and Ampere's ideas took a hundred years to culminate in practical implementation, but the microcomb drive motor took less than a dozen years from conception to full-scale implementation.

One of the marvelous things about nature is the widely varying scale sizes available to us. Section 2.2 will discuss this broad range of scales. Section 2.3 will show how scaling theory can be used as a guide to understand how phenomena change with scale. We hope the material that follows encourages you to explore the broad scope of this new field.

## 2.2 The Log Plot

---

As the scale, or size, of a system changes by several orders of magnitude, the system tends to behave differently. Consider, for example, a glass of water that is about 5 cm on a side. Pour the glass of water onto a table, and notice how the water flows and runs off the edge of the table. If the size of the glass is decreased by two orders of magnitude, or a factor of 100, the glass is now 0.05 cm (or half a millimeter) on a side. Pour this glass onto the table, and see that the surface tension pulls the water into a drop that sticks to the table. Turn the table on its side, and observe that it is difficult to make the drop flow to the edge of the table. In each case, the substance is the same, water, and it is the same table, but changing the scale size makes the water behave very differently.

By decreasing the size of the glass again by two orders of magnitude, the glass is now 0.0005 cm, or 5  $\mu\text{m}$ , on a side. If you pour a drop this size onto the table, it most likely will not even reach the table. Some air current will entrain the drop and carry it away like mist flowing through the city at night. Again, the behavior of the water is dramatically different because of its size. Even the act of pouring the glass over the table is different. The 5-cm glass pours, whereas water in the 0.05- and 0.0005-cm glasses is constrained by surface tension. Different physical effects manifest themselves differently because of the system size.

Figure 2.1 shows the full range of sizes available to us, from atoms to the Universe. Atoms are the smallest mechanical system we will manipulate in the near future; their size is several Angstroms ( $10^{-10}$  of a meter). The Universe is the largest mechanical system we can observe. Depending upon the particular astronomical theory, the Universe is about  $10^{37}$  m in diameter. Hence, the full range available for us to investigate and use is about  $10^{47}$  m or 47 orders of magnitude.

Along the horizontal axis in Figure 2.1 is plotted the size of the system. The short vertical lines in the center of the plot represent a factor of 10 change in the system size. The long vertical lines represent a change of 100,000, or five orders of magnitude. Along the top, the size of the system is given in meters, and in the central band the size of the system is given in Angstroms. Figure 2.1 is plotted as a log plot for two reasons: (1) to enable everything to be depicted on the same piece of paper, and (2) to easily visualize the different size domains.

One can get a sense of the size of things by looking at the Ant, Man and Whale. These familiar objects span about five orders of magnitude. Several orders of magnitude smaller than the Ant are Bacteria and Virus. Going to larger systems, the U.S. road system is about five orders or magnitude larger than the Whale, and the Earth's orbit is about five orders of magnitude larger than the U.S. road system. Increasing another five or six orders of magnitude brings us to interstellar distances.

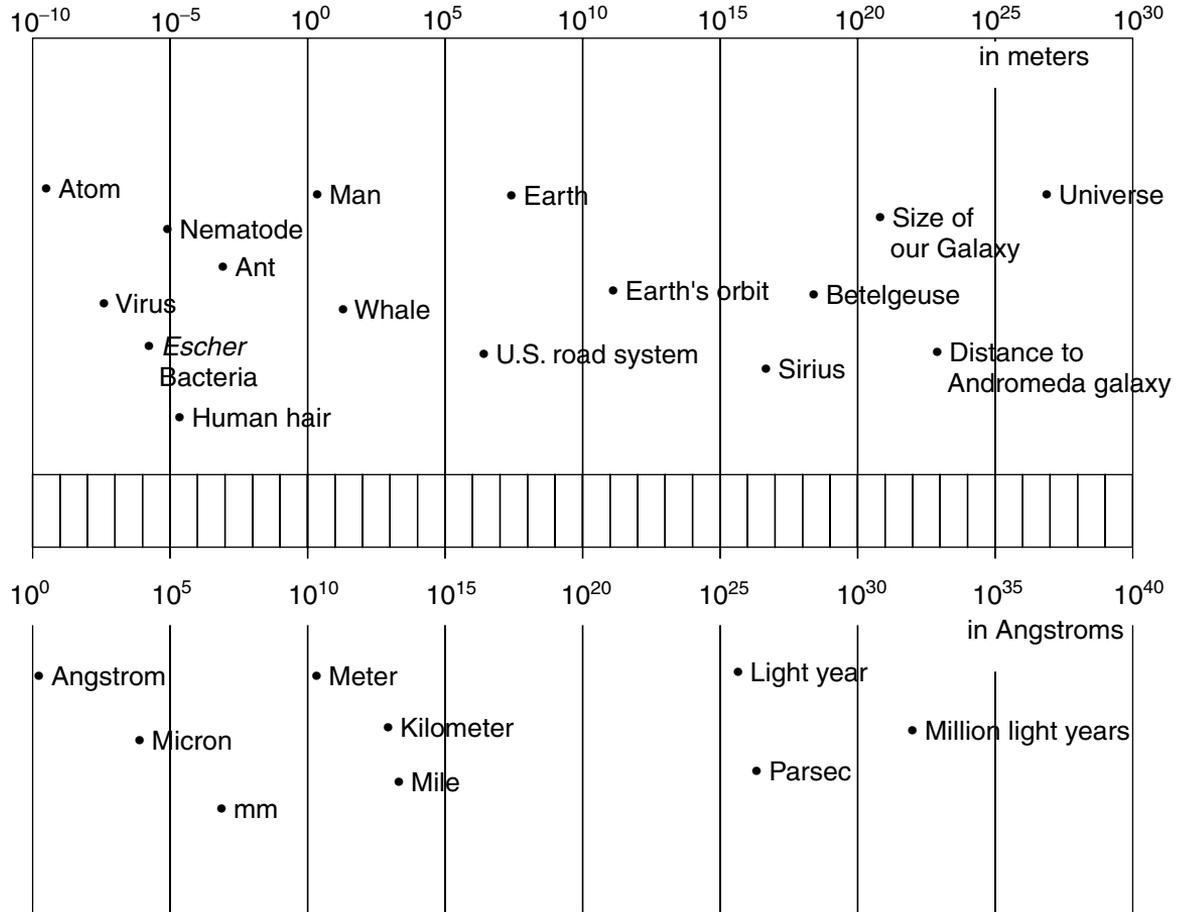

FIGURE 2.1 Log plot of all mechanical systems available for exploration.

The bottom portion of [Figure 2.1](#) shows the units we use to measure things. The Angstrom, micron, millimeter, meter, kilometer, and mile are familiar units, but then we see a gap of about a dozen orders of magnitude before the astronomical units of light year and parsec are reached.

The microregion of interest to this chapter ranges from about a millimeter to an Angstrom (from about  $10^{-3}$  to  $10^{-10}$  meters). This region comprises roughly a fifth of the full range of domains available for us to explore and may seem like a small portion, but consider that the U.S. roadway system is one of the largest mechanical systems we will build for quite a while. Buildings and ships are probably the largest self-contained mechanical systems we will construct in the near future. Most of the larger domains are so large, they simply are not accessible to us. Thus, the microregion represents the majority of the new domains available for exploration!

This microdomain is enticing. Part of the charm is that conventional designs do not work well, and ingenuity is needed to make new designs. For example, macro- and microdevices that transfer water tend to use different physical principles. An open ditch works at one scale, and a capillary works at a smaller scale. Because microdesigners are left without the conventional solutions, they have the opportunity to find their own solutions.

## 2.3 Scaling of Mechanical Systems

---

As the size of a system changes, the physical parameters change, often in a dramatic way [Trimmer et al., 1989; Madou, 1997]. To understand how these parameters change, consider the scale factor  $S$ . This scale factor is similar to the small notation on the corner of a mechanical drawing which might say the scale of the drawing is 1:10. The actual object to be made is 10 times the size of the drawing. A scale of 1:100 means the actual object is 100 times larger. In the microdomain, the scale might be 100:1, meaning the object is 100 times smaller than the drawing. When the scale size changes, all the dimensions of the object change by exactly the same amount  $S$  such that  $1:S$ .

This scale factor  $S$  can be used to describe how physical phenomena change. All the lengths of the drawing scale by the factor  $S$ , but other parameters such as the volume scale differently. Volume  $V$  is length  $L$  times width  $W$  times height  $H$ , or

$$V = L \cdot W \cdot H \quad (2.1)$$

When the scale changes by 1/100 (that is, decreases by a factor of 100), the length and width and height all change by 1/100, and the volume decreases by  $(1/100)^3$  or 1/1,000,000. The volume decreases by a factor of a million when the scale size decreases by a factor of a hundred. Volume is an example of a parameter that scales as  $S^3$ . The force due to surface tension scales as  $S^1$ , the force due to electrostatics scales as  $S^2$ , the force due to certain magnetic forces scales as  $S^3$ , and gravitational forces scale as  $S^4$ . Now, if the size of the system decreases from a meter to a millimeter, this is a decrease in size of a factor of a thousand,  $S = 1/1000$ . The surface tension force decreases by a factor of a thousand,  $S^1 = (1/1000)^1$ ; the electrostatic force decreases by a factor of a million,  $S^2 = (1/1000)^2 = 1/1,000,000$ ; the magnetic force decreases by a factor of a billion,  $S^3 = (1/1000)^3 = 1/1,000,000,000$ ; and the gravitational force decreases by a factor of a trillion,  $S^4 = (1/1000)^4 = 1/1,000,000,000,000$ . Indeed, changing the size of a mechanical system changes what forces are important.

Knowing how a physical phenomenon scales, whether it scales as  $S^1$  or  $S^2$  or  $S^3$  or  $S^4$  or some other power of  $S$ , guides our understanding of how to design small mechanical systems. As an example, consider a water bug. The weight of the water bug scales as the volume, or  $S^3$ , while the force used to support the bug scales as the surface tension ( $S^1$ ) times the distance around the bug's foot ( $S^1$ ), and the force on the bug's foot scales as  $S^1 \times S^1 = S^2$ . When the scale size,  $S$ , decreases, the weight decreases more rapidly than the surface tension forces. Changing from a 2-m-sized man to a 2-mm-sized bug decreases the weight by a factor of a billion, while the surface tension force decreases by only a factor of a million. Hence, the bug can walk on water.

Scaling provides a good guide to how things behave and helps us gain insight into small systems, but scaling is just that, a good guide. It usually does not provide exact solutions. For example, the scaling above does not take into account the difference between the water bug's foot and a person's foot. Water bug's feet are designed for water, and we expect superior performance. Creativity and intuition are what make an excellent design; scaling is a guide to understanding what is important.

A mathematical notation is now discussed that captures the different scaling laws into a convenient form. This notation shows many different scaling laws at once and can be used to easily understand what happens to the different terms and parameters of an equation as the scale size is changed.

Consider four different forces laws,  $F = S^1$ ,  $F = S^2$ ,  $F = S^3$ ,  $F = S^4$ , and collect these different cases into a vertical Trimmer bracket:

$$F = \begin{bmatrix} S^1 \\ S^2 \\ S^3 \\ S^4 \end{bmatrix} \quad (2.2)$$

The top-most element of this bracket refers to the case where the force scales as  $S^1$ , the next element down refers to the case where the force scales as  $S^2$ , etc.

To continue, let us do something with this bracket. Work  $W$  is force  $F$  times distance  $D$ , or

$$W = F \cdot D \quad (2.3)$$

and, extending our notation,

$$W = F \cdot D = \begin{bmatrix} S^1 \\ S^2 \\ S^3 \\ S^4 \end{bmatrix} \begin{bmatrix} S^1 \\ S^1 \\ S^1 \\ S^1 \end{bmatrix} = \begin{bmatrix} S^2 \\ S^3 \\ S^4 \\ S^5 \end{bmatrix} \quad (2.4)$$

or

$$W = \begin{bmatrix} S^2 \\ S^3 \\ S^4 \\ S^5 \end{bmatrix} \quad (2.5)$$

Note that distance  $D$ , shown above, always scales as  $S^1$ , and its bracket consists of all  $S^1$ 's. In the top case where the force scales as  $S^1$ , the distance scales as  $S^1$ , and their product scales as  $S^2$ . In the second element down, the force scales as  $S^2$ , the distance scales as  $S^1$ , and their product scales as  $S^3$ . Here in one notation we have shown how the work scales for the four different force laws. For example, the gravitational force between an object and the Earth scales as  $S^3$  (the Earth's mass remains constant in this example, and the mass of the object scales as its volume,  $S^3$ ), and looking at the third element down we see that a force scaling of  $S^3$  gives us a work, or energy, scaling of  $S^4$ . If the size of a system decreases by a factor of a thousand (say, from 10 cm to 0.10 mm), the gravitational energy required to move an object from the bottom to the top of the machine under consideration decreases by  $(1/1000)^4 = 1/1,000,000,000,000$ . The gravitational

work decreases by a factor of a trillion. We know this intuitively: Drop an ant from ten times his height, and he walks away. Please do not try this with a horse.

How do the acceleration and transit times change for the different force scaling laws? Acceleration  $a$  is equal to force  $F$  divided by the mass  $m$ :

$$a = \frac{F}{m} = F \cdot m^{-1} \quad (2.6)$$

and we know the mass scales as  $S^3$ , and  $m^{-1}$  scales as  $S^{-3}$ , giving:

$$a = \begin{bmatrix} S^1 \\ S^2 \\ S^3 \\ S^4 \end{bmatrix} \begin{bmatrix} S^3 \\ S^3 \\ S^3 \\ S^3 \end{bmatrix}^{-1} = \begin{bmatrix} S^1 \\ S^2 \\ S^3 \\ S^4 \end{bmatrix} \begin{bmatrix} S^{-3} \\ S^{-3} \\ S^{-3} \\ S^{-3} \end{bmatrix} = \begin{bmatrix} S^{-2} \\ S^{-1} \\ S^0 \\ S^1 \end{bmatrix} \quad (2.7)$$

This is an interesting result. When the force scales as  $S^1$ , the acceleration scales as  $S^{-2}$ . If the size of the system decreases by a factor of 100, the acceleration increases by  $(1/100)^{-2} = 10,000$ . And, as the system becomes smaller, the acceleration increases. A predominance of the forces we use in the microdomain scale as  $S^2$ . For these forces, the acceleration scales as  $S^{-1}$ , and decreasing the size by a factor of 100 increases the acceleration by a factor of 100, still a nice increase in acceleration. In general, small systems tend to accelerate very rapidly. For the case where the force scales as  $S^3$ , the acceleration remains constant,  $(1/100)^0 = 1$ , and the acceleration decreases for forces that scale as  $S^4$ .

The transit time  $t$  to move from point  $A$  to  $B$  in our scalable drawing can be calculated as:

$$x = \frac{1}{2}at^2 \quad (2.8)$$

$$t = \sqrt{\frac{2x}{a}} = \sqrt{2} \cdot (x)^{0.5} \cdot (a)^{-0.5} \quad (2.9)$$

and

$$t = \begin{bmatrix} S^0 \\ S^0 \\ S^0 \\ S^0 \end{bmatrix} \begin{bmatrix} S^1 \\ S^1 \\ S^1 \\ S^1 \end{bmatrix}^{0.5} \begin{bmatrix} S^{-2} \\ S^{-1} \\ S^0 \\ S^1 \end{bmatrix}^{-0.5} = \begin{bmatrix} S^0 \\ S^0 \\ S^0 \\ S^0 \end{bmatrix} \begin{bmatrix} S^{0.5} \\ S^{0.5} \\ S^{0.5} \\ S^{0.5} \end{bmatrix} \begin{bmatrix} S^1 \\ S^{0.5} \\ S^0 \\ S^{-0.5} \end{bmatrix} = \begin{bmatrix} S^{1.5} \\ S^1 \\ S^{0.5} \\ S^0 \end{bmatrix} \quad (2.10)$$

$$t = \begin{bmatrix} S^{1.5} \\ S^1 \\ S^{0.5} \\ S^0 \end{bmatrix} \quad (2.11)$$

For the case where the force scales as  $S^2$ , transit time  $t$  scales as  $S^1$ . If the system decreases by a factor of 100, the transit time decreases by a factor of 100. Again, we know this intuitively; small things tend to be fast.

Depending upon the equation and variables of interest, the Trimmer brackets can be configured differently. To continue the above example, one might be interested in how things behave if the acceleration, instead of the force, scales in different ways. One could write:

$$a = \begin{bmatrix} S^1 \\ S^2 \\ S^3 \\ S^4 \end{bmatrix} \quad (2.12)$$

From above:

$$t = \sqrt{\frac{2x}{a}} = \sqrt{2} \cdot (x)^{0.5} \cdot (a)^{-0.5} \quad (2.13)$$

and

$$t = \begin{bmatrix} S^0 \\ S^0 \\ S^0 \\ S^0 \end{bmatrix} \begin{bmatrix} S^1 \\ S^1 \\ S^1 \\ S^1 \end{bmatrix}^{0.5} \begin{bmatrix} S^1 \\ S^2 \\ S^3 \\ S^4 \end{bmatrix}^{-0.5} = \begin{bmatrix} S^0 \\ S^0 \\ S^0 \\ S^0 \end{bmatrix} \begin{bmatrix} S^{0.5} \\ S^{0.5} \\ S^{0.5} \\ S^{0.5} \end{bmatrix} \begin{bmatrix} S^{-0.5} \\ S^{-1} \\ S^{-1.5} \\ S^{-2} \end{bmatrix} = \begin{bmatrix} S^0 \\ S^{-0.5} \\ S^{-1} \\ S^{-1.5} \end{bmatrix} \quad (2.14)$$

$$t = \begin{bmatrix} S^0 \\ S^{-0.5} \\ S^{-1} \\ S^{-1.5} \end{bmatrix} \quad (2.15)$$

The top element in this bracket describes how time scales when the acceleration scales as  $S^1$ . (In the earlier discussion, the top element describes how time scales when the *force* scales as  $S^1$ .) These brackets can be arranged for the convenience of the problem at hand. We need not even use integer exponents. For example, we could have defined the acceleration as:

$$a = \begin{bmatrix} S^{0.1} \\ S^{0.2} \\ S^{0.3} \\ S^2 \\ S^4 \end{bmatrix} \quad (2.16)$$

and then calculated the transit times for these five new scaling functions.

Let us examine the gravitational example in the introduction. As you will see in a moment, gravitational forces scale as  $S^4$  and are a dominant force in large systems, but not small systems. The force between two objects is

$$F = G \frac{M_1 \cdot M_2}{r^2} \quad (2.17)$$

where  $F$  is the force;  $G$  is the gravitational constant ( $= 6.670 \times 10^{-11} \text{ N m}^2 \text{ kg}^{-2}$ ), which does not change with scale size;  $M_1$  and  $M_2$  are the masses of the two objects; and  $r$  is the separation. The masses scale as:

$$M = \rho \cdot V = S^0 \cdot S^3 = S^3 \quad (2.18)$$

where the density,  $\rho$ , is assumed constant ( $S^0$ ), and  $V$  is the volume ( $S^3$ ). Now, force  $F$  scales as:

$$F = S^0 \frac{S^3 \cdot S^3}{S^2} = S^4 \quad (2.19)$$

Now, let's make a different assumption and suppose the density is not constant with scale size. The density could be represented as:

$$\rho = \begin{bmatrix} S^0 \\ S^{-1} \\ S^{-2} \\ S^{-3} \end{bmatrix} \quad (2.20)$$

and force  $F$  becomes:

$$F = G \frac{M_1 \cdot M_2}{r^2} = G \frac{\rho \cdot V_1 \cdot \rho V_2}{r^2} = G \cdot \rho^2 \cdot V_1 \cdot V_2 \cdot R^{-2} \quad (2.21)$$

$$F = S^0 \begin{bmatrix} S^0 \\ S^{-1} \\ S^{-2} \\ S^{-3} \end{bmatrix}^2 S^3 S^3 S^{-2} = S^0 \begin{bmatrix} S^0 \\ S^{-2} \\ S^{-4} \\ S^{-6} \end{bmatrix} S^3 S^3 S^{-2} = \begin{bmatrix} S^4 \\ S^2 \\ S^0 \\ S^{-2} \end{bmatrix} \quad (2.22)$$

From the top element, where the density does not change with size, the force scales as  $S^4$ . From the third element down, when the density scales as  $S^{-2}$ , the gravitational force remains constant as the scale size changes. That is, if astronomical objects become less dense as they become larger (as  $\rho = S^{-2}$ ), then the gravitational force between objects remains constant ( $F = S^0$ ) as one considers different-sized astronomical systems.

It is useful to understand how different forces scale. A more complete listing of forces and their scaling is given below,

$$F = \begin{bmatrix} S^1 \\ S^2 \\ S^3 \\ S^4 \end{bmatrix} = \begin{bmatrix} \text{Surface tension} \\ \text{Electrostatic, Pressure, Biological, Magnetic } (J = S^{-1}) \\ \text{Magnetic } (J = S^{-0.5}) \\ \text{Gravitational, Magnetic } (J = S^0) \end{bmatrix} \quad (2.23)$$

Surface tension has the delightful scaling of  $S^1$  and increases rapidly relative to other forces as a system becomes smaller. However, changing the surface tension usually requires changing the temperature, adding a surfactant, or changing some other parameter that is usually difficult to control. Most forces

currently used by microdesigners scale as  $S^2$ . These include electrostatic forces, forces generated by pressures, and biological forces (the force an animal can exert generally depends upon as the cross section of the muscle). How magnetic forces scale depends upon how the current density (current per unit area of the coils) scales. If the current density,  $J$ , in the coil remains constant ( $S^0$ ), the magnetic force between two coils scales as  $S^4$ , and in this case the magnetic forces become weak in the microdomain. However, one can remove heat much more efficiently from a small volume, and the current density of a microcoil can be much higher than in a large coil. If the current density scales as  $S^{-1}$  when the system decreases by a factor of ten, the current density increases by a factor of ten. In this case, the coil has much higher resistive losses, but the force scales much more advantageously as  $S^2$ .

### 3.1 Introduction

---

New technologies tend to originate with new materials and manufacturing processes, which are used for new products. In the early stages, the emphasis is on novel devices and systems as well as ways of making them. Studies of fundamental issues such as mechanical properties and design procedures come later. For example, in 1830 there were 23 miles of railroad track in the U.S., but by 1870 there were 53,000 miles of track. However, the Bessemer steelmaking process did not originate until 1856, and the American Society for Testing and Materials (ASTM) was not organized until 1898.

The same is true for microelectromechanical systems (MEMS). The emphasis over the past dozen or so years has been on new materials, new manufacturing processes, and new microdevices—and rightfully so. These technological advances have been paralleled by an increasing interest in mechanical testing of materials used in MEMS. More researchers are becoming involved, with the topic appearing in symposia sponsored by the Society for Experimental Mechanics, the American Society of Mechanical Engineers, and the Materials Research Society. Further, the November 2000 ASTM symposium, “Mechanical Testing of Structural Films,” was an important first step toward standardization of test methods. This increase in MEMS material testing has occurred over the past ten or so years, and this chapter is a review of the current status of the field.

Mechanical properties of interest fall into three general categories: elastic, inelastic, and strength. The designer of a microdevice needs to know the elastic properties in order to predict the amount of deflection from an applied force, or vice versa. If the material is ductile and the deformed structure does not need to return to its initial state, then the inelastic material behavior is necessary. The strength of the material must be known so that the allowable operating limits can be set. The manufacturer of a MEMS device needs to understand the relation between the processing and the properties of the material.

The importance of mechanical properties was recognized early on by a leader in the MEMS field, Richard Muller, who wrote in 1990, “Research on the mechanical properties of the electrical materials forming microdynamic structures (which previously had exclusively electrical uses), on the scaling of mechanical design, and on the effective uses of computer aids is needed to provide the engineering base that will make it possible to exploit fully this technology” [Muller, 1990]. Later, and expanded, conclusions and recommendations were made in a 1997 report of a National Research Council committee, of which Muller was chair [Muller, 1997]. One conclusion was, “Test-and-characterization methods and metrologies are required to (1) help fabrication facilities define MEMS materials for potential users, (2) facilitate consistent evaluations of material and process properties at the required scales, and (3) provide a basis for comparisons among materials fabricated at different facilities.” One recommendation was, “Studies that address fundamental mechanical properties (e.g., Young’s modulus, fatigue strength, residual stress, internal friction) and the engineering physics of long-term reliability, friction, and wear are vitally needed.” These rather obvious statements are part of the development of a new technology.

There have been other reviews of the topic. The first on freestanding thin films by Menter and Pashley (1959) is interesting to read from a historical point of view. This author reviewed existing techniques and introduced new ones in 1996 [Sharpe et al., 1996] and looked at the variation in the mechanical properties of polysilicon as tested by several researchers in 1997 [Sharpe et al., 1997b]. Obermeier (1996) reviewed test methods for mechanical and thermophysical properties. Ballarini (1998) prepared a report for the Air Force Research Laboratory, which reviewed pertinent experimental and theoretical work up until then. Yi and Kim (1999a) published a review article, “Measurement of Mechanical Properties for MEMS Materials” on just this topic. Schweitz and Ericson (1999) reviewed the state of the art and offered some interesting conclusions and advice. Chang and Sharpe (1999) wrote an introductory chapter on the subject, and Spearing (2000) wrote a comprehensive exposition from a materials aspect. This chapter is intended to be a comprehensive survey focusing on both the test methods and the properties that have been measured.

After brief definitions of the mechanical properties of interest, the current test methods for MEMS materials are reviewed. Then, the properties of the various materials are summarized in a comprehensive set of tables. In almost all cases, these properties are not yet firmly established with the same confidence one is accustomed to when looking in a handbook, so a final table of initial design values completes this chapter as an aid to initial consideration and design of MEMS.

If the reader is interested in the experimental methods, then the review of test methods will guide him or her to the appropriate references. If details about mechanical properties of specific materials are desired, then the tables and the references will prove useful. Finally, if one wants only typical properties for an initial design concept, the last section provides a succinct answer.

## 3.2 Mechanical Property Definitions

---

The properties of interest here are *material properties*; that is, the measured value is independent of the test method. Implicit is the understanding that the property is also independent of the size of the specimen, but that may not necessarily be the case for MEMS materials. The fabrication process for, say, thin-film silicon carbide is completely different from that of bulk silicon carbide, and it is reasonable to expect different mechanical behavior. The question of specimen size effect needs to be considered at the appropriate length scale—in this case, whether a  $200 \times 200\text{-}\mu\text{m}$  cross-section tensile specimen behaves the same way as a  $2 \times 2\text{-}\mu\text{m}$  one. That question is not very easy to answer until test methods exist with sufficient sensitivity and reproducibility to differentiate the material behavior.

The American Society for Testing Materials defines standard test procedures through a lengthy process of draft and review. Many of the common standards for structural materials were set in the early part of the twentieth century. However, new ones appear to meet the demands of new technologies, and a complete set of standards is issued each year. For example, the field of fracture mechanics as a usable measure of material and structural response emerged in the early 1950s. The first draft of a standard measure of fracture toughness did not appear until 1965, with the first complete standard appearing in 1970 [ASTM, 1970]. It will be some time before standards for measuring the mechanical properties of MEMS materials are

established, but it is useful to be guided by the accepted definitions of mechanical properties. The pertinent standards for testing the mechanical properties of metals appear in [ASTM, 2000a] and those for ceramics in [ASTM, 2000b]. ASTM Standard E-8 gives directions for tension testing of metals, while E-9 covers compression testing. ASTM Standards C-1273 and C-1161 cover the tension and creep testing of ceramics. Once the stress–strain curve is obtained, various approximations or curve-fits can be used to insert the material behavior into the design process.

*Young's modulus* is the slope of the linear part of the stress–strain curve of a material; it is a measure of its stiffness. ASTM E-111 specifies that, “The test specimen is loaded uniaxially and load and strain are measured, either incrementally or continuously.” It then goes on to prescribe how the slope is determined along with a myriad of other details. *Poisson's ratio* is a measure of the lateral contraction or expansion of a material when subjected to an axial stress within the elastic region. ASTM E-132 requires that, “In this test method, the value of Poisson's ratio is obtained from strains resulting from uniaxial stress only.” Note that these elastic properties are defined for isotropic materials only. Neither of these is easy to measure at the MEMS material size scale as will be seen in the next section. When a material is inelastic (and nonlinear), one needs the complete stress–strain curve to specify the material behavior.

The strength of a material enables one to determine how much force can be applied to a component or structure. ASTM E-6 defines *fracture strength* as “the normal stress at the beginning of fracture”; it is the useful measure for brittle materials. ASTM C-1161 defines *flexural strength* as “a measure of the ultimate strength of a specified beam in bending”; note the linking of the strength measure to a particular size and shape of specimen. If the material is inelastic, then *yield strength* (defined by a prescribed deviation from initial linearity) is the one that defines the departure from elastic response, and *tensile strength* denotes the maximum stress the material will support before complete failure. *Compressive strength* is more difficult to establish unless the material is brittle.

*Fracture toughness* is a generic term for various measures of resistance to extension of a crack. The most familiar version is plane-strain fracture toughness, ASTM E-399, which requires that the test specimen be thick enough to produce a state of plane strain at the tip of the crack. In this case, the value measured is indeed a material property that is independent of specimen size. Perhaps a more appropriate measure for MEMS is plane-stress fracture toughness, ASTM E-561, but it requires that one either measure or infer the actual crack extension. Implicit in all fracture testing is the condition that the radius at the tip of the crack be very small relative to other dimensions; this is a difficult requirement at the MEMS size scale.

The response of a material to cyclic loading is presented as the *S–N curve*, which is a plot of the applied stress,  $S$ , on the ordinate vs. the number of cycles to failure,  $N$ , on the abscissa. One obtains such a plot by testing many samples at various levels of applied stress and recording the number of cycles until the specimen breaks in two. ASTM E-466 gives the detailed procedures for metals; this is obviously an expensive kind of test.

*Creep* is the time-dependent increase in strain under applied stress. Although important in systems operating at high temperature, there is no ASTM standard for creep testing of metals. ASTM C-1291 defines procedures for testing ceramics. As in fatigue testing, results are usually presented in the form of plots.

### 3.3 Test Methods

---

Measuring mechanical properties of materials manufactured by processes used in MEMS is not easy. One must be able to: (1) obtain and mount a specimen, (2) measure its dimensions, (3) apply force or displacement to deform it, (4) measure the force, and (5) measure the displacement, or preferably, measure the strain. All of these steps are fully developed and standardized for common structural materials where the minimum dimension of the gauge section of a tensile specimen is 2 mm or so. ASTM E-345 does describe procedures for testing metallic foils that are less than 150  $\mu\text{m}$  thick, but the rest of the dimensions are large. ASTM E-8 includes wires and even describes special grips, but does not state a minimum diameter. One can get guidance from these two standards, but neither is completely appropriate for small MEMS specimens.

One would prefer to determine mechanical properties by *direct methods* similar to the approaches of ASTM. To obtain Young's modulus, a uniform stress is applied, which is calculated from direct measurements of the applied force and the dimensions of the specimen. Strain is measured directly as the force is applied. The specimen is designed to have a uniform gauge section, which is long enough to assure that the stress field is not affected by the grip ends and to permit strain measurement.

This is not always possible for MEMS materials; in fact, it is most often neither possible nor practical. It is then necessary to resort to *inverse methods* in which a model (simple or complex) is constructed of the test structure. Force is applied to the test structure and displacement is measured with the elastic, inelastic, or strength properties then extracted from the model. A simple example, and one that has been widely used in MEMS material testing, is a cantilever beam. If it is sufficiently long and thin, then only the Young's modulus enters as a material property into the formula relating force and displacement. Other examples are resonant structures and bulge tests with pressurized membranes; these are described later. If more than one material property appears in the model, then different geometries must be tested.

The formulas for determining Young's modulus,  $E$ , by various methods are

Static Beam	Resonant Beam	Bulge Test	Tensile Test
$\frac{4PL^3}{\delta bh^3}$	$\frac{ML^3 \omega^2}{2bh^3}$	$\frac{p(1-\nu)a^4}{\delta^3 h c(\nu)}$	$\frac{P}{bh \epsilon}$

where  $h$ ,  $b$  and  $L$  are the thickness, width and length of the specimen;  $P$  and  $p$  are the applied force and pressure;  $M$  is the effective mass;  $\omega$  is the resonant frequency;  $a$  is the dimension of a square membrane; and  $\delta$  and  $\epsilon$  are the measured deflection and strain, respectively. The function of Poisson's ratio,  $c(\nu)$ , depends upon the geometry and is often approximated. The simplicity of the tensile test is an obvious advantage.

Johnson et al. (1999) have compared the uniaxial and bending tests and point out that uncertainty in specimen dimensions are more of a problem in bending tests, while overall elongation is difficult to measure in a tension test. However, if strain can be measured directly, the overall elongation does not need to be measured. They also point out that strength due to misalignment is more of a problem in tension than in bending.

As will be seen later in this chapter, there is an alarming variability among measured values of even such a basic property as Young's modulus for the most widely studied MEMS material—polysilicon. Senturia (1998) attributes this to two primary reasons: "insufficiently precise models used to interpret the data and metrology errors in establishing the geometry of the test devices." He is referring to inverse methods in the first point; whether the boundary conditions of the actual structure actually match the model is a real question. The point on metrology applies to all test methods—direct or inverse.

It is useful to distinguish between *on-chip* test methods and *property tests*. It is very important in this technology to be able to obtain a measure of mechanical properties from *test structures* that are on the same chip (or die) as the manufactured MEMS. That usually precludes a direct property measurement on a *specimen*, which must be larger to allow gripping and pulling even though the size of the gauge section is the same size scale as the microdevice. This is not an issue in mechanical and civil engineering fields where the required specimen size is smaller than the system or structure. One may regard property tests as basic or baseline and on-chip tests as practical. Obviously, direct comparisons of the two approaches with specimens and test structures on the same die are required for completeness.

### 3.3.1 Specimen and Test Structure Preparation

One does not take a billet of bulk material and shape it into the final MEMS product as is common for most manufacturing processes. Rather, the microdevice is produced by deposition and etching processes. This means that the specimen or test structure cannot be cut from the bulk material but must be produced by the same processes as the product. A tensile specimen must be designed so that one end remains fixed

to the die and the other end accommodates some sort of gripping mechanism. A test structure must be designed so that the boundaries are indeed fixed and must incorporate some sort of actuating mechanism to produce force and a sensor to determine displacement or perhaps strain.

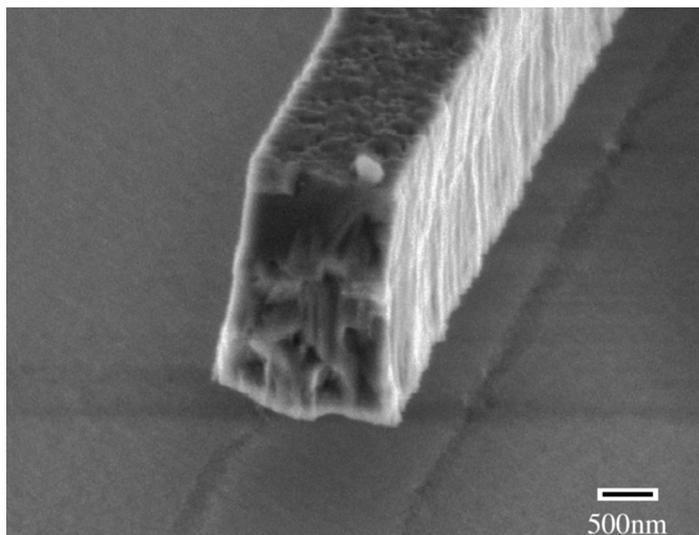

An early and interesting approach to producing tensile specimens of thin foils was conceived by Neugebauer (1960), who deposited gold films onto oriented rocksalt crystals. The gold film was glued to the grips of a test machine and the test section covered with sealing wax while the salt was dissolved away. These specimens ranged in thickness from 0.05 to 1.5  $\mu\text{m}$  and were 1 to 2 mm wide and approximately 1 cm long. He found the tensile strength to be 2 to 4 times higher than for annealed bulk material but observed no dependence on film thickness. The Young's modulus values agreed with those of the bulk material.

This is a simple example of specimen preparation, but it is illustrative of the methods used in the mechanical test methods for MEMS materials. One deposits the material of interest and removes the unwanted portions of the supporting substrate. An additional step is the patterning of the test material through photolithography.

### 3.3.2 Dimension Measurement

Minimum features in MEMS are usually on the order of 1  $\mu\text{m}$ —a bit larger than in microelectronics. One would think that measuring the  $2 \times 2\text{-}\mu\text{m}$  cross section of a tensile specimen or the equivalent dimensions of a test structure is easy, but it is not. The thickness of a layer is well controlled and measured by the manufacturer. Lengths are large enough to measure with sufficient accuracy in an optical microscope. It is the width of the specimens or test structure components that is difficult to determine when it is small.

A major problem is the fact that the cross section is not sharply defined or even rectangular as expected. [Figure 3.1](#) is a scanning electron microscope (SEM) photograph of the end of a polysilicon tensile specimen after testing. This specimen is from the MUMPs process at Cronos, which deposits a first layer of polysilicon that is 2.0  $\mu\text{m}$  thick and then a second layer that is 1.5  $\mu\text{m}$  thick. The interface between these two layers is visible in the photograph. The designed width is 2.0  $\mu\text{m}$ , which is approximately the case at the bottom. The fact that the cross section is not a perfect rectangle contributes to the uncertainty in the area. One can also see that the corners are somewhat rounded, which makes it difficult to establish the edges when making a plan-view measurement.

**FIGURE 3.1** Scanning electron micrograph of the end of a broken tensile specimen [Sharpe et al., 1999a]. The specimen is 3.5  $\mu\text{m}$  thick and 2  $\mu\text{m}$  wide at the bottom.

The dimensions of a specimen or test structure are normally established before the experiment, but a more accurate measurement may be made after the specimen is broken. Optical or scanning electron microscopy, mechanical or optical profilometry, and interferometry are possible measurement techniques, but some of these can be quite time consuming and expensive. Johnson et al. (1999) state that it is typical to assign an uncertainty of between  $\pm 0.05$  and  $\pm 0.10$   $\mu\text{m}$  to width measurements. A 2  $\mu\text{m}$ -wide specimen would therefore have at most  $\pm 5\%$  relative uncertainty in its width, which is actually quite reasonable for such small specimens. This short discussion reinforces the statement by Senturia (1998) that metrology is a major problem in determining mechanical properties.

### 3.3.3 Force and Displacement Measurement

Johnson et al. (1999) explain that tensile tests require the measurement of larger forces and smaller overall displacements, while the opposite is true for bending tests. A polysilicon tensile specimen  $2 \times 2$   $\mu\text{m}$  square with a fracture strength of 2 GPa requires a force of 8 mN to break it. If that same specimen is 50  $\mu\text{m}$  long, fixed at one end, and with a transverse point load at the other end, a force of only 0.05 mN is required to break it. If that material has a modulus of 160 GPa, the elongation of a tensile specimen is 0.62  $\mu\text{m}$ , while the deflection at the end of a bending specimen is 10.4  $\mu\text{m}$ .

Commercial force transducers are readily available with a range of  $\pm 5$  g (50 mN) and a resolution of 0.001 g. This author prefers to use the lower range of a  $\pm 100$ -g-load cell because it is stiffer relative to a tensile specimen and to calibrate it with weights. A resolution of 0.01 g with a full-scale uncertainty of  $\pm 1\%$  is achieved [Sharpe et al., 1999a]. Howard and Fu (1997) review suitable force transducers, and others such as Greek et al. (1995) and Saif and MacDonald (1996) construct their own.

Commercial capacitance-based displacement transducers can be used to measure the overall displacement of a test system to a resolution of 0.01  $\mu\text{m}$  and full-scale uncertainty of  $\pm 1\%$  [Sharpe et al., 1999a]. Schemes to measure mechanical deflections at the optical microscope level are attractive, and Pan and Hsu (1999) present a vernier gauge approach to measure residual stress. This approach can be electrically instrumented with differential capacitance measurement as shown by Que et al. (1999).

### 3.3.4 Strain Measurement

It is, of course, preferable to measure strain directly whether the test arrangement is bending or tension; this is difficult to do on such small specimens. The author and his colleagues have developed a laser-based strain measurement system in which two reflective lines are deposited on the gauge section of a tensile specimen during manufacture. These lines are perpendicular to the loading axis, and when they are illuminated with a low-power laser beam interference fringe patterns are formed. These fringes move as the lines separate when the specimen is strained; the motion is tracked with diode arrays and a computer system to enable real-time strain measurement on specimens as narrow as 20  $\mu\text{m}$ . A set of four lines on wider specimens permits one to measure Poisson's ratio. Details are given in Sharpe et al. (1997c; 1997d), and the resolution is approximately  $\pm 5$  microstrain with a relative uncertainty of 5% at 0.5% strain.

Detailed full-field strain measurements at the MEMS size scale are desirable but difficult. Micro-Raman spectroscopy can probe very small areas, on the order of 1  $\mu\text{m}$  in diameter, on thin films. Analysis of frequency shifts as force is applied to a specimen leads to local strain measurements [Benrakkad et al., 1995; Pinardi et al., 1997; Zhang et al., 1997; Amimoto et al., 1998]. The Moiré method using e-beam lithography to write high-frequency line and dot gratings at a small scale has been demonstrated by Dally and Read (1993), but this is a very challenging process. Chasiotis and Knauss (1998) are developing digital image correlation methods to measure strains in tensile specimens; the resolution is 300 to 500 microstrain. Mazza et al. (1996a) have demonstrated this to be a viable technique on single-crystal silicon specimens. Laser speckle methods can give full-field results and have been demonstrated by Anwander et al. (2000) and Chang et al. (2000). None of these techniques has been applied to extensive studies of mechanical properties of MEMS materials.

### 3.3.5 Tensile Tests

There are three arrangements used in tensile tests of MEMS materials: specimen in a supporting frame, specimen fixed to die at one end, and separate specimen. A fourth clever approach was introduced early on by Koskinen et al. (1993) but has not been continued. They deposited a grid of long, thin tensile specimens, which were all fastened to larger portions at each end; the appearance was similar to a foil resistance strain gage. One end of the arrangement was fixed and the other attached to a movable grip that could be rotated about an axis perpendicular to the grid. This caused all of the specimens to buckle, each a different amount than its neighbor. When the grip moved, each specimen in turn was straightened and pulled. The recorded force-displacement record enabled measurement of modulus and strength.

#### 3.3.5.1 Specimen in Frame

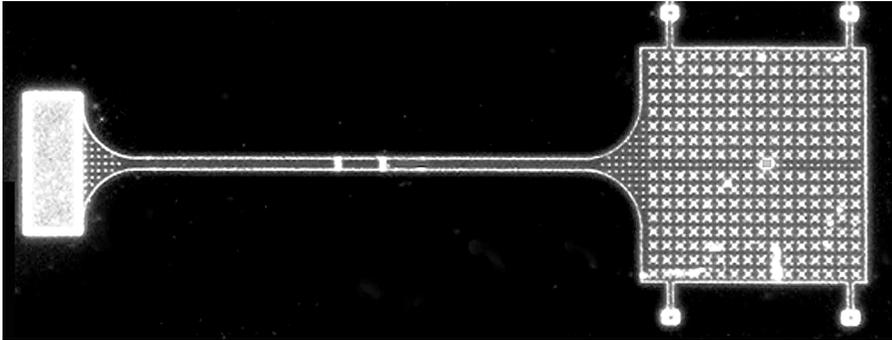

Read and Dally (1992) introduced a very effective way of handling thin-film specimens in 1992. The tensile specimen is patterned onto the surface of a wafer and then a window is etched in the back of the wafer to expose the gauge section. The result is a specimen suspended across a rectangular frame, which can be handled easily and placed into a test machine. The two larger ends of the frame are fastened to grips, and the two narrower sides are cut to completely free the specimen. This is an extension of the much earlier approach by Neugebauer (1960) and has been adopted by others [Cunningham et al., 1995; Emery et al., 1997; Ogawa et al., 1997; Sharpe et al., 1997c; Cornella et al., 1998; Yi and Kim, 1999b]. A SEM photograph of such a specimen while still in the frame is shown in [Figure 3.2](#).

#### 3.3.5.2 Specimen Fixed at One End

Tsuchiya introduced the concept of a tensile specimen fixed to the die at one end and gripped with an electrostatic probe at the other end [Tsuchiya et al., 1998]. This approach has been adopted by this author and his students [Sharpe et al., 1998a], and [Figure 3.3](#) is a photograph of this type of specimen. The gauge section is 3.5  $\mu\text{m}$  thick, 50  $\mu\text{m}$  wide, and 2 mm long. The fixed end is topped with a gold layer for electrical contact. The grip end is filled with etch holes, as are the two curved transition regions from the grips to the gauge section. The large grip end is held in place during the etch release process by four anchor straps, which are broken before testing.

**FIGURE 3.2** Scanning electron micrograph of a polysilicon tensile specimen in a supporting single-crystal silicon frame. (From Sharpe, W.N., Jr., Yuan, B., Vaidyanathan, R., and Edwards, R.L. (1996) *Proc. SPIE* **2880**, pp. 78–91. With permission.)

**FIGURE 3.3** A tensile specimen fixed at the left end with a free grip end at the right end. (From Sharpe, W.N., Jr., and Jackson, K. (2000) *Microscale Systems: Mechanics and Measurements Symposium*, Society for Experimental Mechanics, pp. ix–xiv. With permission.)

Chasiotis and Knauss (2000) have developed procedures for gluing the grip end of a similar specimen to a force/displacement transducer, which enables application of larger forces. A different approach is to fabricate the grip end in the shape of a ring and insert a pin into it to make the connection to the test system. Greek et al. (1995) originated this with a custom-made setup, and LaVan et al. (2000a) use the probe of a nanoindenter for the same purpose.

It is possible to build the deforming mechanism onto or into the wafer, although it can be difficult to get an accurate measure of the forces and deflections. Biebl and von Philipsborn (1995) stretched polysilicon specimens in tension with residual stresses in the structure. Yoshioka et al. (1996) etched a hinged paddle in the silicon wafer, which could be deflected to pull a thin single crystal specimen. Nieva et al. (1998) produced a framed specimen and heated the frame to pull the specimen, as did Kapels et al. (2000).

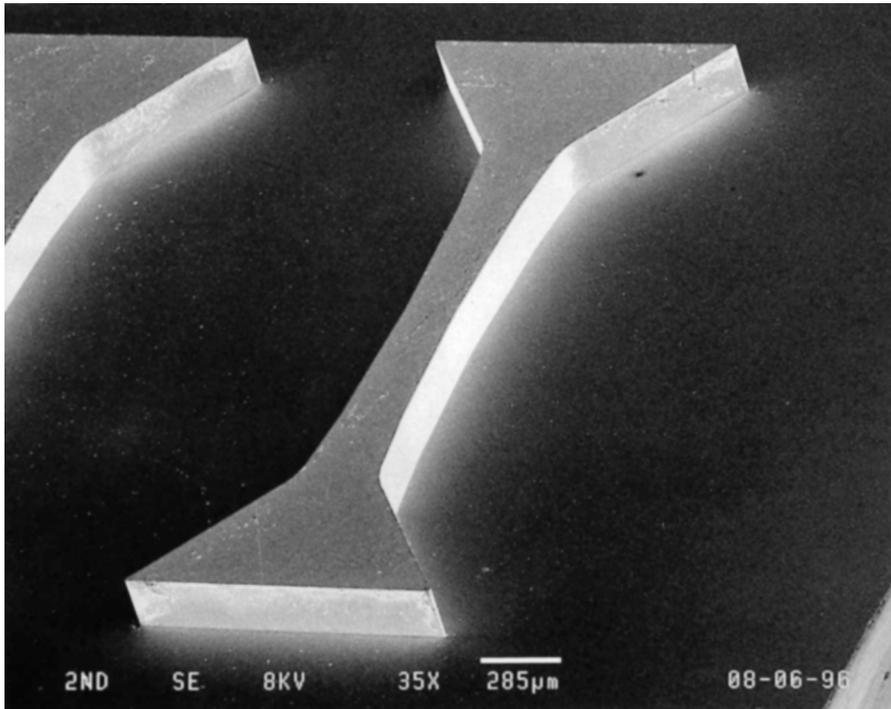

### 3.3.5.3 Separate Specimen

The challenge of picking up a tensile specimen only a few microns thick and placing it into a test machine is formidable. However, if the specimens are on the order of tens or hundreds of microns thick, as they are for LIGA-deposited materials, it is perfectly possible. This author and students developed techniques to test steel microspecimens having submillimeter dimensions [Sharpe et al., 1998b]. The steel dog biscuit-shaped specimens were obtained by cutting thin slices from the bulk material and cutting them out with a small CNC mill. Electroplated nickel specimens can be patterned into a similar shape in LIGA molds as shown in Figure 3.4. These specimens are released from the substrate by etching, picked up, and put into grips with inserts that match the wedge-shaped ends [Sharpe et al., 1997e].

McAleavey et al. (1998) used the same sort of specimen to test SU-8 polymer specimens. Mazza et al. (1996b) prepared nickel specimens of similar size in the gauge section, but with much larger grip ends. Christenson et al. (1998) fabricated LIGA nickel specimens of a more conventional shape that were approximately 2 cm long with flat grip ends; these were large enough to test in a commercial table-top electrohydraulic test machine.

### 3.3.5.4 Smaller Specimens

All of the above may appear impressive to the materials test engineer accustomed to common structural materials, but there is a continuing push toward smaller structural components at the nanoscale. Yu et al. (2000) have successfully attached the ends of carbon nanotubes as small as 20 nm in diameter and a few microns long to atomic force microscopy (AFM) probes. As the probes are moved apart inside a SEM, their deflections are measured and used to extract both the force in the tube and its overall elongation. They report strengths up to 63 GPa and modulus values up to 950 GPa.

**FIGURE 3.4** Nickel microspecimen produced by the LIGA method. The overall length is 3.1 mm, and the width of the specimen at the center is 200  $\mu\text{m}$ . (From Sharpe, W.N., Jr., et al. (1997) *Proc. Int. Solid State Sensors and Actuators Conf.—Transducers '97*, pp. 607–610. © 1997 IEEE. With permission.)

### 3.3.6 Bend Tests

Three arrangements are also used in bend tests of structural films: out-of-plane bending of cantilever beams, beams fastened at both ends, and in-plane bending of beams. Larger specimens, which can be individually handled, can also be tested in bending fixtures similar to those used for ceramics.

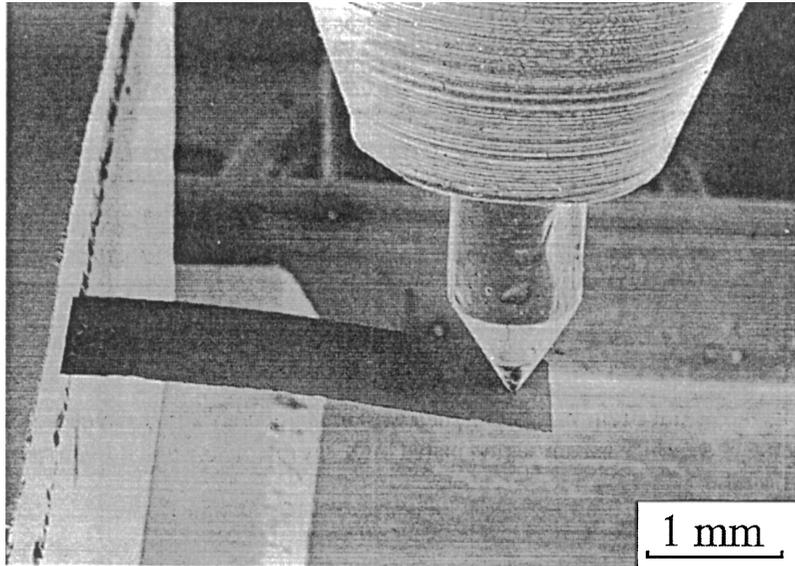

#### 3.3.6.1 Out-of-Plane Bending

The approach here is simple. One patterns long, narrow, and thin beams of the test material onto a substrate and then etches away the material underneath to leave a cantilever beam hanging over the edge. By measuring the force vs. deflection at or near the end of the beam, one can extract Young's modulus via the formula in Section 3.3. However, this is not so easy because if the beams are long and thin, the deflections can be large, but the forces are small. The converse is true if the beam is short and thick, but then the applicability of simple beam theory comes into question. If the beam is narrow enough, Poisson's ratio does not enter the formula; otherwise, beams of different geometries must be tested to determine it.

Weihls et al. (1988) introduced this method in 1988 by measuring the force and deflection with a nanoindenter having a force resolution of 0.25  $\mu\text{N}$  and a displacement resolution of 0.3 nm. Typical specimens had a thickness, width and length of 1.0, 20 and 30  $\mu\text{m}$ , respectively. Figure 3.5 shows a cantilever beam deflected by a nanoindenter tip in a later investigation [Hollman et al., 1995].

Biebl et al. (1995a) attracted the end of a cantilever down to the substrate with electrostatic forces and recorded the capacitance change as the voltage was increased to pull more of the beam into contact. Fitting these measurements to an analytical model permitted a determination of Young's modulus.

Krulevitch (1996) proposed a technique for measuring Poisson's ratio of thin films fabricated in the shapes of beams and plates by comparing the measured curvatures. These were two-layer composite

**FIGURE 3.5** A cantilever microbeam deflected out of plane by a diamond stylus. The beam was cut from a free-standing diamond film. (Reprinted from Hollman, P., et al. (1995) *Thin Solid Films* 270, pp. 137–142. With permission from Elsevier Science.)

structures, so the properties of the substrate must be known. Kraft et al. (1998) also tested composite beams by measuring the force-deflection response with a nanoindenter. Bi-layer cantilever beams have been tested by Tada et al. (1998) who heated the substrate and measured the curvature.

More sensitive measurements of force and displacement on smaller cantilever beams can be made by using an AFM probe, as shown by Serre et al. (1998), Namazu et al. (2000), Comella and Scanlon (2000) and Kazinczi et al. (2000). A specially designed test machine using an electromagnetic actuator has been developed by Komai et al. (1998).

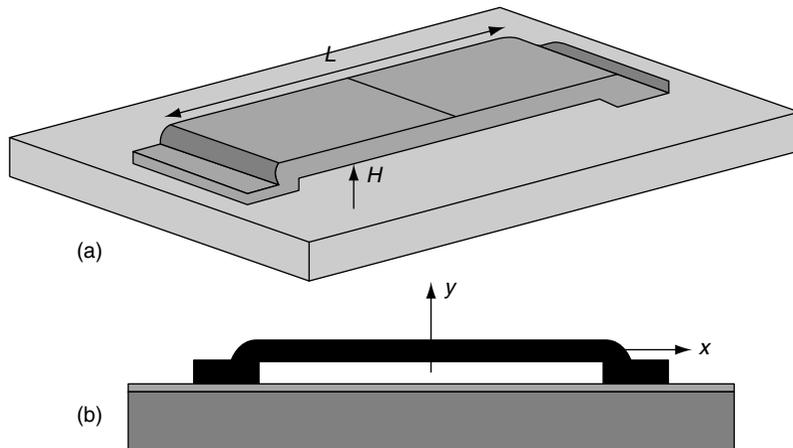

### 3.3.6.2 Beams with Fixed Ends

It is somewhat easier to work with a beam that is fixed at both ends; it is stiffer and more robust. Tai and Muller (1990) used a surface profilometer to trace the shapes of fixed–fixed beams at various load settings. By comparison of measured traces and using a finite element analysis of the structure, they were able to determine Young’s modulus.

A promising on-chip test structure has been developed over the years by Senturia and his students; it is shown schematically in Figure 3.6. A voltage is applied between the conductive polysilicon beam and the substrate to pull the beam down, and the voltage that causes the beam to make contact is a measure of its stiffness. This concept was introduced early on by Petersen and Guarnieri (1979) and further developed by Gupta et al. (1996). A similar approach and analysis were described by Zou et al. (1995). The considerable advantage here is that the measurements can be made entirely with electrical probing in a manner similar to that used to check microelectronic circuits. This opens the opportunity for process monitoring and quality control.

It is clear that the “fixed” ends exert a major influence on the stiffness of the test structure. Kobrinsky et al. (1999) have thoroughly examined this effect and shown its importance. The problem is that a particular manufacturing process, or even variations within the same process, may etch the substrate slightly differently and change the rigidity of the ends. Nevertheless, this is a potentially very useful method for monitoring the consistency of MEMS materials and processes.

Zhang et al. (2000) recently conducted a thorough study of silicon nitride in which microbridges (fixed–fixed beams) were deflected with a nanoindenter with a wedge-shaped indenter. By fitting the

**FIGURE 3.6** Schematic of a fixed-fixed beam. (From Kobrinisky, M., et al. (1999) *MEMS Microelectromechanical System 1*, pp. 3–10, ASME, New York. With permission.)

measured force-deflection records to their analytical model, they extracted both Young’s modulus and residual stress.

### 3.3.6.3 In-Plane Bending

In-plane bending may be a more appropriate test method in that the structural supports of MEMS accelerometers are subjected to that mode of deformation. Jaecklin et al. (1994) pushed long, thin cantilever beams with a probe until they broke; optical micrographs gave the maximum deflections from which the fracture strain was determined. Jones et al. (1996) constructed a test structure consisting of cantilever beams of different lengths fastened to a movable shuttle. As the shuttle was pushed, the beams contacted fixed stops on the substrate; the deformed shape was videotaped and the fracture strain determined. Figure 3.7 is a photograph of one of their deformed specimens.

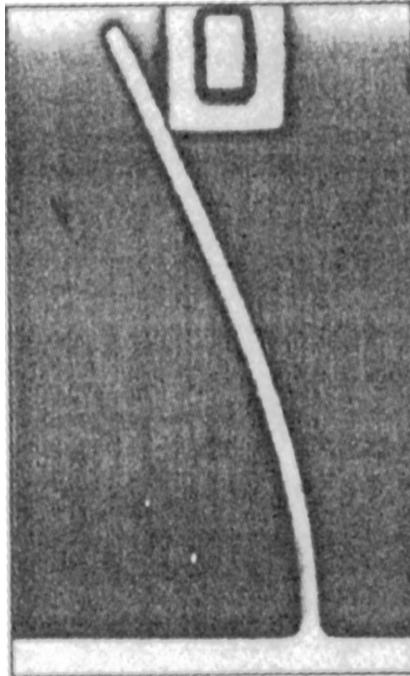

Kahn et al. (1996) developed a double cantilever beam arrangement to measure the fracture toughness of polysilicon and used the measured displacement between the two beams to determine Young’s modulus via a finite element model. The beams were separated by forcing a mechanical probe between them and pushing it toward the notched end. A similar approach has been taken by Fitzgerald et al. (1998) to measure crack growth and fracture toughness in single crystal silicon, but they use a clever structure that permits opening the beams by compression of cantilever extensions.

### 3.3.6.4 Bending of Larger Specimens

Microelectromechanical technology is not restricted to only thin-film structures, although they are far-and-away the predominant type. Materials fabricated with thicknesses on the order of tens or hundreds of microns are of current interest and likely to become more important in the future.

Ruther et al. (1995) manufactured a microtesting system by the LIGA process to test electroplated copper. The interesting feature is that the in-plane cantilever beam and the test system are fabricated together on the die; however, this requires a rather complex assembly. Stephens et al. (1998) fabricated rows of LIGA nickel beams sticking up from the substrate and then measured the force applied near the upper tip of the beam while displacing the substrate. The resulting force-displacement curve permitted extraction of Young’s modulus, and the recorded maximum force gave a modulus of rupture.

Larger structures, such as the microengine under development at MIT, have thicknesses on the order of several millimeters. It is then necessary to test specimens of similar sizes in what is sometimes called the “mesoscale” region—dimensions from 0.1 mm to 1 cm for a general definition. Single-crystal silicon is the material of interest for initial versions and Chen et al. (1998) have developed a method for bend

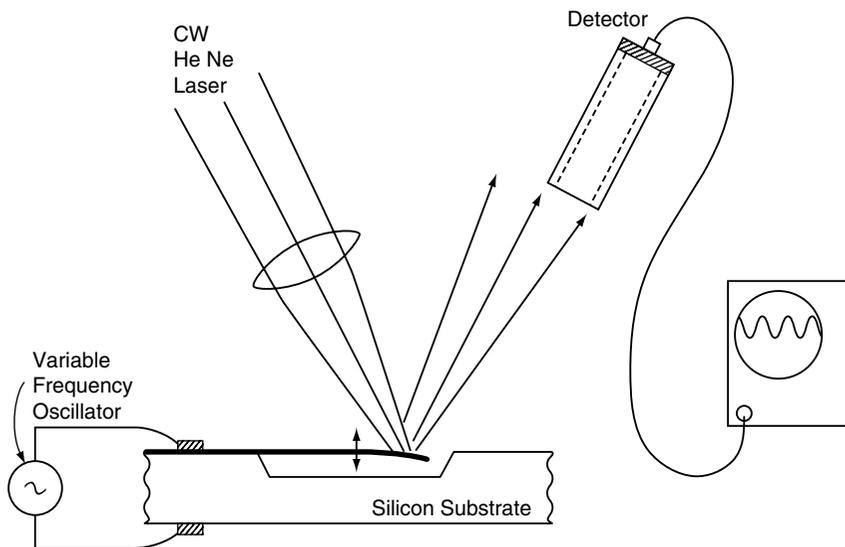

**FIGURE 3.7** A polysilicon cantilever beam subjected to in-plane bending. The beam is  $2.8\ \mu\text{m}$  wide, and the vertical distance between the fixed end at the bottom and the deflected end at the top is  $70\ \mu\text{m}$ . (From Sharpe, W.N., Jr., et al. (1998) *Microelectromechanical Structures for Materials Research Symposium*, pp. 56–65. With permission.)

testing square plates simply supported over a circular hole and recording the force as a small steel ball is pushed into the center of the plate. Fracture strengths are obtained, and this efficient arrangement permits study of the effects of various manufacturing processes on the load-carrying capability of the material.

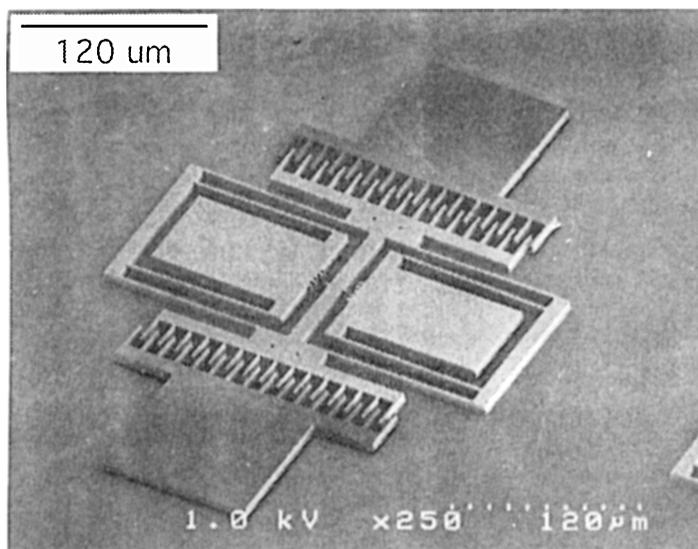

### 3.3.7 Resonant Structure Tests

Frequency and changes in frequency can be measured precisely, and elastic properties of modeled structures can be determined. The microstructures can be very small and excited by capacitive comb drives, which require only electrical contact. This makes this approach suitable for on-chip testing; in fact, the MUMPs process at Cronos includes a resonant structure on each die. That microstructure moves parallel to the substrate, but others vibrate perpendicularly.

Petersen and Guarnieri (1979) introduced the resonant structure concept in 1979 by fabricating arrays of thin, narrow cantilever beams of various lengths extending over an anisotropically etched pit in the substrate. The die containing the beams was excited by variable frequency electrostatic attraction between the substrate and the beams, and the vibration perpendicular to the substrate was measured by reflection from an incident laser beam, as shown by the schematic in [Figure 3.8](#). Yang and Fujita (1997) took a similar approach to study the effect of resistive heating on U-shaped beams. Commercial AFM cantilevers were tested in a similar manner by Hoummady et al. (1997), who measured the higher resonant modes of a cantilever beam with a mass on the end. Zhang et al. (1991) measured vibrations of a beam fixed at both ends by using laser interferometry. An elaborate and carefully modeled micromirror that was excited by electrostatic attraction was developed by Michalicek et al. (1995). Deflection was also measured by laser interferometry, and experiments determined Young's modulus over a range of temperatures as well as validated the model.

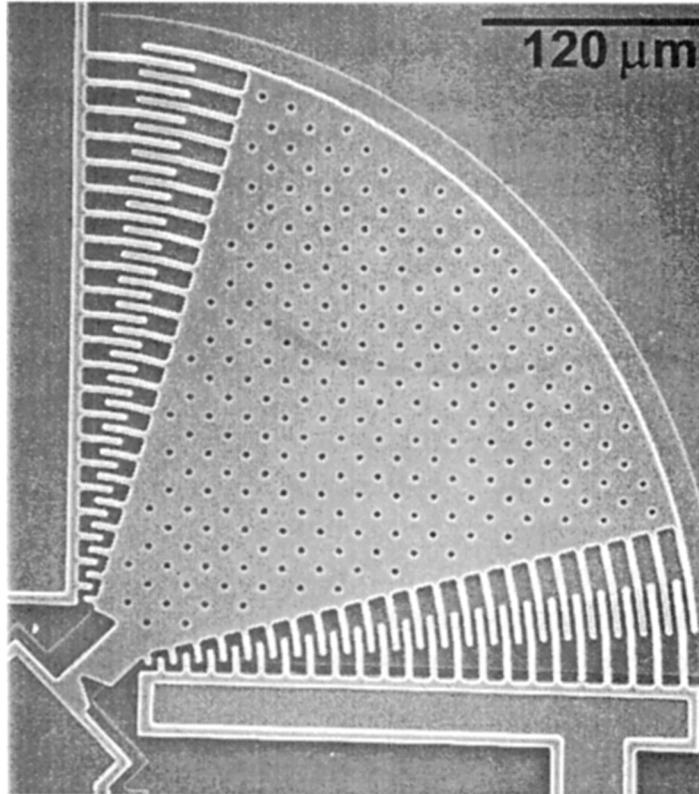

**FIGURE 3.8** Schematic of the resonant structure system of Petersen and Guarnieri (1979). (Reprinted from Petersen, K.E., and Guarnieri, C.R. (1979) *J. Appl. Phys.* **50**, pp. 6761–6766. With permission from American Institute of Physics.)

**FIGURE 3.9** Scanning electron micrograph of the in-plane resonant structure of Kahn et al. (1998). (From Kahn, H., et al. (1998) *Microelectromechanical Structures for Materials Research Symposium*, pp. 33–38. With permission.)

Microstructures that vibrate parallel to the plane of the substrate require less processing; the substrate does not have to be removed. Biebl et al. (1995b) introduced this concept, and Kahn et al. (1998) have used a more recent version to study the effects of heating on the Young's modulus of films sputtered onto the structure. Figure 3.9 is a SEM image of their structure, which is easy to model. Pads A, B, C and D are fixed to the substrate; the rest of the structure is free. Electrostatic comb drives excite the two symmetrical substructures, which consist of four flexural springs and a rigid mass. The resonant frequency of this device is around 47 kHz. A different approach in which a small notched specimen is fabricated as part of a large resonant fan-shaped component has been developed by Brown et al. (1997).

**FIGURE 3.10** Scanning electron micrograph of the in-plane resonant structure of Brown et al. (1997). (From Brown, S.B., et al. (1997) *Proc. Int. Solid-State Sensors and Actuators Conf.—Transducers '97*, pp. 591–593. © 1997 IEEE. With permission.)

This resonant structure, shown in [Figure 3.10](#), has been primarily used for fatigue and crack growth studies, but Young's modulus of polysilicon has been extracted from its finite element model [Sharpe et al., 1998c].

### 3.3.8 Membrane Tests

It is relatively easy to fabricate a thin membrane of test material by etching away the substrate; the membrane is then pressurized and the measured deflection can be used to determine the biaxial modulus. An advantage of this approach is that tensile residual stress in the membrane can be measured, but the value of Poisson's ratio must be assumed. This method, often called bulge testing, was first introduced by Beams (1959), who tested thin films of gold and silver and measured the center deflection of the circular membrane as a function of applied pressure. Jacodine and Schlegel (1966) used this approach to measure Young's modulus of silicon oxide. Tabata et al. (1989) tested rectangular membranes whose deflections were measured by observations of Newton's rings, as did Maier-Schneider et al. (1995). The variation of Hong et al. (1990) used circular membranes with force deflection measured at the center with a nanoindenter. Pressurized square membranes with the deflection measured by a stage-mounted microscope were tested by Walker et al. (1990) to study the effect of hydrofluoric acid exposure on polysilicon; a similar approach to determine biaxial modulus, residual stress and strength was used by Cardinale and Tustison (1992). Vlassak and Nix (1992) eliminated the need to assume a value of Poisson's ratio by testing rectangular silicon nitride films with different aspect ratios. More recently, Jayaraman et al. (1998) took this same approach to measure Young's modulus and Poisson's ratio of polysilicon.

### 3.3.9 Indentation Tests

A nanoindenter is, in the fewest words, simply a miniature and highly sensitive hardness tester. Both force and displacement are measured, and modulus and strength can be obtained from the resulting plot. Penetration depths can be very small (a few nanometers), and automated machines permit multiple measurements to enhance confidence in the results and also to scan small areas for variations in properties.

Weihls et al. (1989) measured the Young's modulus of an amorphous silicon oxide film and a nontextured gold film with a nanoindenter and obtained only limited agreement with their microbeam deflection experiments. The modulus measured by indentation was consistently higher and the large pressure of the indenter tip was the probable cause. Taylor (1991) used nanoindenter measurements restricted to penetrations of 200 nm into 1- $\mu\text{m}$ -thick silicon nitride films to study the effects of processing on mechanical properties. Young's modulus decreased with decreasing density of the films.

Bhushan and Li (1997) and Li and Bhushan (1999) have studied the tribological properties of MEMS materials and used a nanoindenter to measure the modulus and a microhardness tester to measure the fracture toughness of thin films. Measurements of Young's modulus of polysilicon showed a wide scatter. Bucheit et al. (1999) examined the mechanical properties of LIGA-fabricated nickel and copper by using a nanoindenter as one of the tools. In most cases, Young's modulus from nanoindenter measurements were higher than from tension tests, but the nanoindenter does allow one to look at both sides of the thin film as well as sectioned areas.

### 3.3.10 Other Test Methods

The readily observed buckling of a column-like structure under compression can be used to measure forces in specimens; if the specimen breaks, an estimate of the fracture strength can be made. Tai and Muller (1988) fabricated long, thin polysilicon specimens with one end fixed and the other enclosed in slides. The movable end was pushed with a micromanipulator, and its displacement when the structure buckled was used to determine the strain (not stress) at fracture. Ziebart and colleagues have analyzed thin films with various boundary conditions ranging from fixed along two sides [Ziebart et al., 1997] to fixed on all four sides [Ziebart et al., 1999]. The first arrangement permitted the measurement of Poisson's ratio when the side supports were compressed, and the second determined prestrains induced by processing. Beautiful patterns are obtained, but the analysis and the specimen preparation can be time consuming.

Another clever approach based on buckling is described by Cho et al. (1997). They etched away the silicon substrate under an overhanging strip of diamond-like carbon film and used the buckled pattern to determine the residual stress in the film. A more traditional creep test was used by Teh et al. (1999) to study creep in  $2 \times 2 \times 100\text{-}\mu\text{m}$  polysilicon strips fixed at each end. As current passed through the specimens, they heated up and their buckled deflection over time at a constant current was used to extract a strain vs. time creep curve. This approach is complicated by the nonuniformity of the strain in the specimen.

Although torsion is an important mode of deformation in certain MEMS such as digital mirrors, few test methods have been developed. Saif and MacDonald (1996) introduced a system to twist very small (10  $\mu\text{m}$  long and 1  $\mu\text{m}$  on a side) pillars of single-crystal silicon and measure both the force and deflection. Larger (300  $\mu\text{m}$  long with side dimensions varying from 30 to 180  $\mu\text{m}$ ) of both silicon and LIGA nickel were tested by Schiltges et al. (1998). Emphasis was on the elastic properties only with the shear modulus values agreeing with expected bulk values.

Nondestructive measurements of elastic properties of thin films can be accomplished with laser-induced ultrasonic surface waves. An impulse is generated in the film by a laser pulse, and the surface wave is sensed by a piezoelectric transducer. In principle, Young's modulus, density and thickness can be determined, but this cannot be achieved for all combinations of film and substrate materials. Schneider and Tucker (1996) describe this test method and present results for a wide range of films; the Young's modulus values generally agree with other thin-film measurements. A drawback here is the planar size of the film; the input and output must be several millimeters apart. A related technique uses Brillouin scattering as described in Monteiro et al. (1996).

### 3.3.11 Fracture Tests

Single-crystal silicon and polysilicon are both brittle materials, and it is therefore natural to want to measure their fracture toughness. This is even more difficult than measuring their fracture strength because of the need for a crack with a tip radius small relative to the specimen dimensions.

Photolithography processes for typical thin films have a minimum feature radius of approximately 1  $\mu\text{m}$ . Fan et al. (1990), Sharpe et al. (1997f) and Tsuchiya et al. (1998) have tested polysilicon films in tension using edge cracks, center cracks and edge cracks, respectively. Kahn et al. (1999) modeled a double-cantilever specimen with a long crack and wedged it open with an electrostatic actuator.

Fitzgerald et al. (1999) prepared sharp cracks in double-cantilever silicon crystal specimens by etching, and Suwito et al. (1997) modeled the sharp corner of a tensile specimen to measure the fracture toughness. Van Arsdell and Brown (1999) introduced cracks at notches in polysilicon with a diamond indenter. A promising new approach using a focused ion beam (FIB) can prepare cracks with tip radii of 30 nm according to K. Jackson (pers. comm.).

### 3.3.12 Fatigue Tests

Many MEMS operate for billions of cycles, but that kind of testing is conducted on microdevices such as digital mirrors instead of the more basic reversed bending or push–pull tests so familiar to the metal fatigue community. Brown and his colleagues have developed a fan-shaped, electrostatically driven notched specimen that has been used for fatigue and crack growth studies [Brown et al., 1993; 1997; Van Arsdell and Brown, 1999]. Minoshima et al. (1999) have tested single crystal silicon in bending fatigue, and Sharpe et al. (1999) reported some preliminary tension–tension tests on polysilicon. As noted earlier, fatigue data are reported as stress vs. life plots, and Kapels et al. (2000) present a plot that looks much like one would expect for a metal; the allowable applied stress decreases from 2.9 GPa for a monotonic test to 2.2 GPa at one million cycles.

### 3.3.13 Creep Tests

Some MEMS are thermally actuated, so the possibility of creep failure exists. No techniques similar to the familiar dead-weight loading to produce strain vs. time curves exist. Teh et al. (1999) have observed the buckling of heated fixed-end polysilicon strips.

### 3.3.14 Round Robin Tests

Mechanical testing of MEMS materials presents unique challenges as the above review shows. Convergence of test methods into a standard is still far in the future, but progress in that direction usually begins with a “round robin” program in which a common material is tested by the method-of-choice in participating laboratories. That first step was taken in 1997/1998 with the results reported at the Spring 1998 meeting of the Materials Research Society [Sharpe et al., 1998c]. Polysilicon from the MUMPs 19 and 21 runs of Cronos were tested in bending (Figure 3.7), resonance (Figure 3.10) and tension (Figure 3.3). Young’s modulus was measured as  $174 \pm 20$  GPa in bending,  $137 \pm 5$  GPa in resonance and  $139 \pm 20$  GPa in tension. Strengths in bending were  $2.8 \pm 0.5$  GPa, in resonance  $2.7 \pm 0.2$  GPa and in tension  $1.3 \pm 0.2$  GPa. These variations were alarming, but in retrospect perhaps not too surprising given the newness of the test methods at that time.

A more recent interlaboratory study of the fracture strength of polysilicon manufactured at Sandia has been arranged by LaVan et al. (2000b). Strengths measured on similar tensile specimens by Tsuchiya in Japan and at Johns Hopkins were  $3.23 \pm 0.25$  and  $2.85 \pm 0.40$  GPa, respectively. LaVan tested in tension with a different approach and obtained  $4.27 \pm 0.61$  GPa. It seems clear that more effort needs to be devoted to the development of test methods that can be used in a standardized manner by anyone who is interested.

### 3.4 Mechanical Properties

This section lists in tabular form the results of measurements of mechanical properties of materials used in MEMS structural components. The intent of this section is to provide the reader not only values of mechanical properties but also access to references on materials and test methods of interest. Because there is as yet no standard test method and such a wide variety in the values is obtained for supposedly identical materials, the reader with a strong interest in the mechanical behavior of a particular material can use the tables to identify pertinent references.

Almost all the data listed comes from experiments directly related to free-standing structural films. The only exceptions are the results from ultrasonic measurements by Schneider and Tucker (1996) because they tested a number of materials of interest. It proved too cumbersome to include information on the processing conditions for each reference, but it is hoped the short comments in the tables will be useful. Many of the results are average values of multiple replications, and the standard deviations are included when they are available. Most of the materials used in MEMS are ceramics and show linear and brittle behavior, in which case only the fracture strength is listed. The tables for ductile materials show both yield and ultimate strengths. It should also be noted that the values in the tables are edited from a larger list. Some of the same values had been presented in two different venues (e.g., a conference publication and a journal paper), in which case the more archival version was referenced. A limited number of studies have been conducted on the effects of environment (temperature, hydrofluoric acid, saltwater, etc.) on MEMS materials, but that area of research is in its infancy and is not included.

First, typical stress-strain curves are plotted in Figure 3.11 to compare the mechanical behavior of MEMS materials with a common structural steel, A533-B, which is moderately strong (yield strength of 440 MPa) but ductile and tough. Polysilicon is linear and brittle and much stronger. LIGA nickel is ductile and considerably stronger than bulk pure nickel; one must test materials as they are produced for MEMS instead of relying on bulk material values.

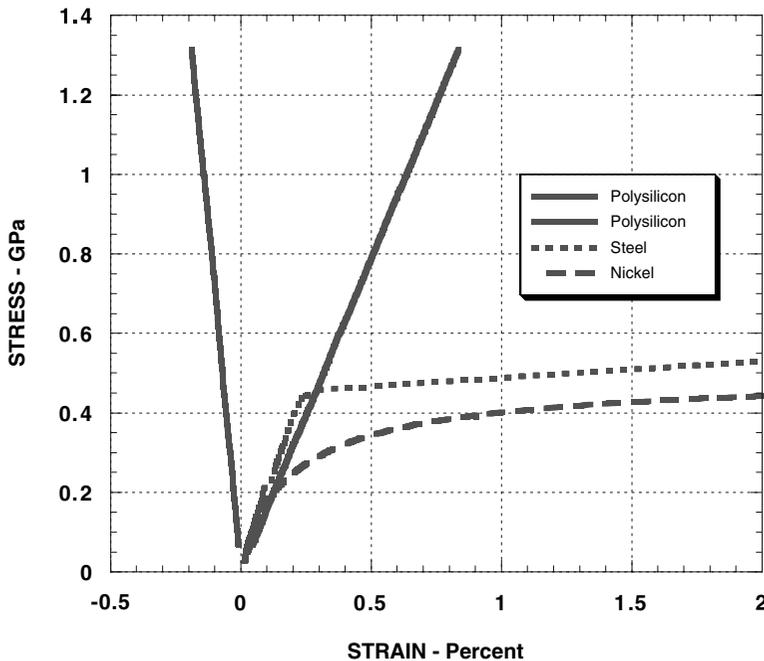

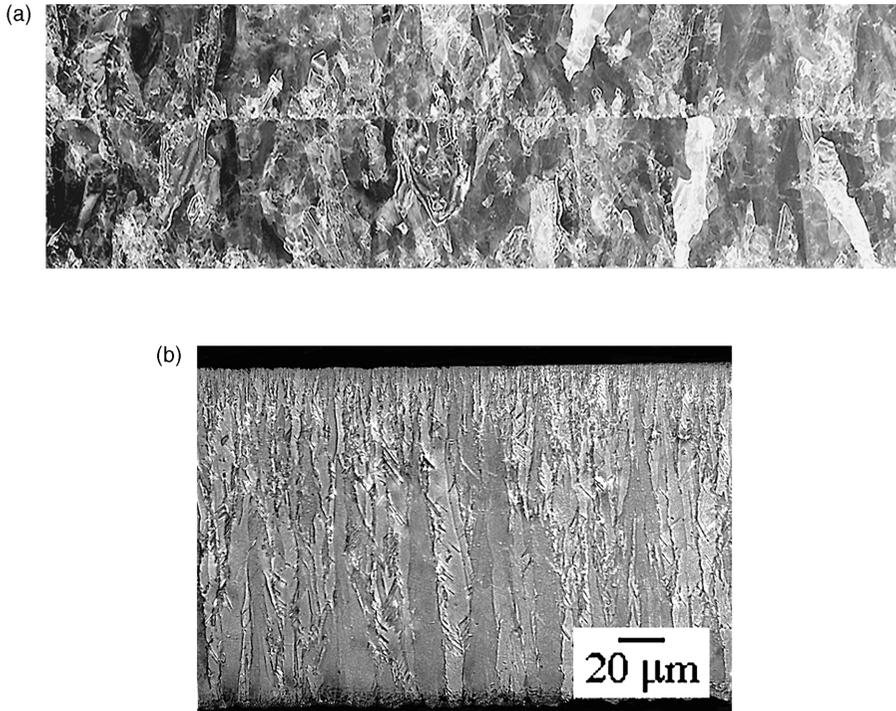

FIGURE 3.11 Representative stress-strain curves of polysilicon, electroplated nickel and A-533B steel. These are from microspecimens tested in the author's laboratory.

**FIGURE 3.12** Microstructure of two common MEMS materials. Note the columnar grain structure perpendicular to the plane of the film. (a) Polysilicon deposited in two layers; the bottom layer is 2.0  $\mu\text{m}$  thick and the top one is 1.5  $\mu\text{m}$  thick. (Reprinted from Sharpe et al. (1998c). © 1998 IEEE. With permission.) (b) Nickel electroplated into LIGA molds. (Reprinted from Sharpe et al. (1997d). © 1998 IEEE. With permission.)

The microstructure of these MEMS materials is also different from bulk materials. The physics of the thin-film deposition process cause the grains to be columnar in a direction perpendicular to the film as shown in Figure 3.12. The result is similar to the cross section of a piece of bamboo or wood, and the material is transversely isotropic. Test methods are not sensitive enough to measure the anisotropic constants.

Table 3.1 lists metal films tested in a free-standing manner such that they would be appropriate for use in MEMS. Only aluminum is currently used in that fashion, but these are materials commonly used in the electronics industry and may be of interest. Note that all of these are ductile materials; the complete stress–strain curves are included in many of the references. The values of Young’s modulus as measured for pure bulk materials are listed for reference.

Carbon can be deposited to form an amorphous or crystalline structure, which is often referred to as diamond-like carbon, or DLC. Diamond itself has a very high stiffness and strength as well as a low coefficient of friction, and for these reasons DLC offers exciting possibilities in MEMS. The very limited results to date, shown in Table 3.2, support this line of reasoning although they are far too sparse to be conclusive.

Electroplated nickel and nickel–iron MEMS, usually manufactured via the LIGA process, offer the possibility of larger and stronger actuators and connectors. The microstructure and mechanical properties of an electroplated material are highly dependent upon the composition of the plating bath along with the current and temperature. Similarly, the composition of a nickel–iron alloy makes a big difference. Young’s modulus and strength values are listed in Tables 3.3 and 3.4 for nickel and nickel–iron, respectively. The modulus of bulk nickel is around 200 GPa, and the yield strength of pure fine-grained nickel is approximately 60 MPa [ASM, 1990]. Table 3.3 shows that the modulus of nickel is generally somewhat lower and the strength considerably higher. Nickel–iron has a smaller modulus as expected, but can be a very strong material as seen from the few results in Table 3.4.

The most common MEMS material is polysilicon, and it is also the most tested, as [Table 3.5](#) demonstrates. The stiffness coefficients of single-crystal silicon are well established, and the modulus in different directions can vary from 125 to 180 GPa [Sato et al., 1997]. Aggregate theories predict that randomly oriented polycrystalline silicon should have a Young's modulus between 163 and 166 GPa [Guo et al., 1992; Jayaraman et al., 1999]. Most of the modulus values in [Table 3.5](#) are near or within this range, but some vary widely, especially when a test method is first used. An estimate of what the fracture strength should be is more difficult as it depends on the flaws in the material. Even though strength is easier to measure than modulus (one only needs to measure force), there are fewer entries. This is because many of the bending, resonance and bulge tests do not lead to failure in the specimen.

Single-crystal silicon has also been studied extensively, as [Table 3.6](#) shows. The modulus values there are measured along particular crystallographic directions, so they should not be expected to compare with the polysilicon values.

Silicon carbide holds promise for MEMS because of its expected high stiffness, strength and chemical and temperature stability, and Sarro (2000) provides a thorough overview of its potential. Bulk silicon carbide is commonly available, but manufacturing processes for thin, free-standing films are still in development. [Table 3.7](#) lists results from the few tests to date; note that no strength values appear.

Silicon nitride commonly appears in both MEMS and in microelectronics as an insulating layer. There is growing interest in it as a structural material, and [Table 3.8](#) lists its properties. Silicon oxide is also

typically included in a MEMS or microelectronics process but is less likely to be used as a structural component because of its low stiffness and strength, as shown in [Table 3.9](#).

The main application to date of the polymer SU-8 is as a mask material for thicker electroplated metal MEMS. The use of it as a structural component is possible, but the values of stiffness and strength in [Table 3.10](#) are very low.

Fracture toughness values have been measured for polysilicon, and [Table 3.11](#) lists the results. Note that this is not the plane-strain fracture toughness that is a materials property; one must be careful, as some authors list this value as  $K_{Ic}$ .

Poisson's ratio is an important materials property when the stress state is bi-axial, but only a very limited number of measurements have been made. Those are listed in the "Comments" column of the tables.

The question is often asked about the effect of size on the strength of MEMS materials. It is well known that fine single-crystal "whiskers" of materials can have very high strengths, the premise being that they

have fewer imperfections. MEMS structural components can be on the same size scale, which leads to the question being asked. However, there are no dramatic increases in strength because the materials still have fine grains relative to the specimen size. Tsuchiya et al. (1998) found an increase in the tensile strength of 2.0-μm-thick polysilicon specimens as their length increased from 30 to 300 μm, but that was only a 30% increase. Recent results show that the modulus of polysilicon does not vary with specimen size, but the strength increases from 1.21 to 1.65 GPa with decreasing specimen size [Sharpe et al., 2001].

From a practical point of view, one does not need to worry about the effect of size on strength for common MEMS structural components.

On the other hand, Namazu et al. (2000) tested silicon crystal beams ranging in size from widths, thicknesses and lengths of 0.2, 0.25 and 6 μm to 1.04, 0.52 and 9.85 mm, respectively. These were prepared by anisotropic etching; the smallest ones were tested using an atomic force microscope, and the largest ones with a microhardness tester. The mean bending strengths covered an astonishing range from 0.47 to 17.5 GPa—a factor of 37!

### 3.5 Initial Design Values

If the manufacturing and testing technology for materials used in MEMS were as fully developed as those associated with common structural materials, such as aluminum, for example, then this entire chapter could have been reduced to a one-page table. However, that is not the case; the materials themselves are actually new, and the test methods are still in their infancy.

It may be useful to list “best guesses” at the material properties of MEMS materials to be used in an initial design, and that is done in [Table 3.12](#). The reader is cautioned that these are only estimates and that the actual properties resulting from a particular manufacturing process may be quite different from these nominal values.

Aluminum, copper and gold have essentially the same modulus values as the bulk materials, but the ultimate strengths are slightly higher than those found for commercially pure materials. Young’s modulus for thin-film nickel can vary depending upon the deposition parameters, but it is conservative to assume that it will be lower (at 180 GPa) than the 200 GPa expected for bulk pure nickel. There are fewer results for nickel–iron, so the modulus of 120 GPa is only a rough estimate. However, it is clear that thin-film nickel and nickel–iron alloys are quite a bit stronger than one would expect from knowledge of bulk behavior.

The values listed for diamond-like carbon are only an optimistic guide. There are many variations of this material, and very few tests. These properties are included because such a material would be very attractive if it could be realized.

Polysilicon has certainly been thoroughly tested and is widely used, so one must wonder why there is no “standard” value—at least for Young’s modulus—by now. The explanation is, of course, the difficulty in testing at this size scale, but there is a clear trend toward a modulus in the neighborhood of 160 GPa. An assumption of that number  $\pm 10$  GPa can be used with confidence in the initial design of a microdevice. It is also clear that the strength can vary depending upon the manufacturing process, but will fall in the range of 1.2 to 3.0 GPa.

Single-crystal silicon has been thoroughly characterized, to the point that it has been used as a “standard material” to validate test systems. The modulus depends on orientation, and the strength range is enormous, with some extremely high values being reported.

Silicon carbide is widely promoted as a MEMS material, but conclusive measurements of its modulus have yet to be made and there are no measurements of strength. One should use the modulus value with caution. The situation is better for silicon nitride, as it has been more widely used and tested.

Although numbers to three significant figures are listed in [Table 3.12](#), the reader will surely appreciate their unreliability and wonder as to their value. But, there are many other uncertainties that occur between the initial design and the product. Dimensions may not come out as specified, and that can have a profound effect on the stiffnesses of small components. Boundary conditions may not be as specified

**TABLE 3.12** Initial Design Values

Material	Young’s Modulus (GPa)	Poisson’s Ratio	Yield Strength (GPa)	Ultimate or Fracture Strength (GPa)
Aluminum	70	—	—	0.15
Copper	120	—	0.15	0.35
Gold	70	—	—	0.30
Nickel	180	—	0.30	0.50
Nickel–Iron	120	—	0.70	1.60
Diamond-like carbon	800	0.22	—	8.0
Polysilicon	160	0.22	—	1.2–3.0
Silicon crystal	125–180	—	—	>1.0
Silicon carbide	400	0.25	—	—
Silicon nitride	250	0.23	—	6.0
Silicon oxide	70	—	—	1.0

either, due to variations in etch release processes. Nevertheless, one must start somewhere, and the values in Table 3.12 enable that. A user should certainly look at the more detailed information in the other tables and probably should consult some of the appropriate references.

## Acknowledgments

---

The author is grateful for the interactions with students and colleagues over the past five years that has provided the background for this chapter. The assistance of Vanessa Coleman with the preparation is appreciated. Effort sponsored by the Defense Advanced Research Projects Agency (DARPA) and Air Force Research Laboratory, Air Force Materiel Command, USAF, under agreement number F30602-99-2-0553. The U.S. government is authorized to reproduce and distribute reprints for governmental purposes notwithstanding any copyright annotation thereon.

*One of the first men who speculated on the remarkable possibilities which magnification or diminution of physical dimensions provides was Jonathan Swift, who, in Gulliver's Travels, drew some conclusions as to what dwarfs and giants would really look like, and what sociological consequences size would have. Some time ago Florence Moog (Scientific American, November 1948) showed that Swift was a "bad biologist," or Gulliver a "poor liar." She showed that a linear reduction in size would carry with it a reduction in the number of brain cells, and hence a reduction in intellectual capacity in Lilliputians, whereas the enormous Brobdingnagians were physically impossible; they could have had physical reality only if their necks and legs had been short and thick. These 90-ton monsters could never have walked on dry land, nor could their tremendous weight have been carried on proportionately-sized feet.*

*Even though Swift, in his phantasy, committed a number of physical errors, because he was not sufficiently aware of the fact that some physical properties of a body are proportional to the linear dimensions (height), whereas others vary with the third power of linear size (such as weight and cell number), yet he surpassed his medieval predecessors in many respects and drew a number of excellent conclusions, bringing both giants and dwarfs close to physical reality.*

(From "The Size of Man," by F.W. Went, *American Scientist* 56(4), pp. 400–413, 1968.)

### 4.1 Introduction

---

In this chapter, we review the status of our understanding of fluid flow physics particular to microdevices. The chapter is an update of an earlier publication by the same author [Gad-el-Hak, 1999]. The coverage here is broad, leaving the details to other chapters in the handbook that treat specialized problems in microscale fluid mechanics. Not all microelectromechanical systems (MEMS) devices involve fluid flows, of course, but this chapter will focus on the ones that do. Microducts, micronozzles, micropumps, microturbines and microvalves are examples of small devices involving the flow of liquids

and gases. MEMS can also be related to fluid flows in an indirect way. The availability of inexpensive, batch-processing-produced microsensors and microactuators provides opportunities for targeting small-scale coherent structures in macroscopic turbulent shear flows. Flow control using MEMS promises a quantum leap in control system performance [Gad-el-Hak, 2000]. Additionally, the extremely small sensors made possible by microfabrication technology allow measurements with spatial and temporal resolutions not achievable before. For example, high-Reynolds-number turbulent flow diagnoses are now feasible down to the Kolmogorov scales [Löfdahl and Gad-el-Hak, 1999]. Those indirect topics are also left to other chapters in the book.

## 4.2 Flow Physics

---

The rapid progress in fabricating and utilizing microelectromechanical systems during the last decade has not been matched by corresponding advances in our understanding of the unconventional physics involved in the manufacture and operation of small devices [Madou, 1997; Kovacs, 1998; Gad-el-Hak, 1999; Knight, 1999]. Providing such understanding is crucial to designing, optimizing, fabricating and utilizing improved MEMS devices. This chapter focuses on the physics of fluid flows in microdevices.

Fluid flows in small devices differ from those in macroscopic machines. The operation of MEMS-based ducts, nozzles, valves, bearings, turbomachines, etc. cannot always be predicted from conventional flow models such as the Navier–Stokes equations with a no-slip-boundary condition at a fluid–solid interface, as is routinely and successfully applied for larger flow devices. Many questions have been raised when the results of experiments with microdevices could not be explained via traditional flow modeling. The pressure gradient in a long microduct was observed to be nonconstant and the measured flowrate was higher than that predicted from the conventional continuum flow model. Load capacities of micro-bearings were diminished and electric currents necessary to move micromotors were extraordinarily high. The dynamic response of micromachined accelerometers operating at atmospheric conditions was observed to be over-damped.

In the early stages of development of this exciting new field, the objective was to build MEMS devices as productively as possible. Microsensors were reading something, but not many researchers seemed to know exactly what. Microactuators were moving, but conventional modeling could not precisely predict their motion. After a decade of unprecedented progress in MEMS technology, perhaps the time is now ripe to take stock, slow down a bit and answer the many questions that have arisen. The ultimate aim of this long-term exercise is to achieve rational-design capability for useful microdevices and to be able to characterize definitively and with as little empiricism as possible the operations of microsensors and microactuators.

In dealing with fluid flow-through microdevices, one is faced with the question of which model to use, which boundary condition to apply and how to proceed to obtain solutions to the problem at hand. Obviously surface effects dominate in small devices. The surface-to-volume ratio for a machine with a characteristic length of 1 m is  $1 \text{ m}^{-1}$ , while that for a MEMS device having a size of  $1 \mu\text{m}$  is  $10^6 \text{ m}^{-1}$ . The millionfold increase in surface area relative to the mass of the minute device substantially affects the transport of mass, momentum and energy through the surface. The small length scale of microdevices may invalidate the continuum approximation altogether. Slip flow, thermal creep, rarefaction, viscous dissipation, compressibility, intermolecular forces and other unconventional effects may have to be taken into account, preferably using only first principles such as conservation of mass, Newton's second law, conservation of energy, etc.

In this chapter, we discuss continuum as well as molecular-based flow models and the choices to be made. Computing typical Reynolds, Mach and Knudsen numbers for the flow through a particular device is a good start to characterize the flow. For gases, microfluid mechanics has been studied by incorporating slip-boundary conditions, thermal creep and viscous dissipation, as well as compressibility effects, into the continuum equations of motion. Molecular-based models have also been attempted for certain ranges of the operating parameters. Use is made of the well-developed kinetic theory of gases, embodied in the Boltzmann equation, and direct simulation methods such as Monte Carlo. Microfluid mechanics of

liquids is more complicated. The molecules are much more closely packed at normal pressures and temperatures, and the attractive or cohesive potential between the liquid molecules as well as between the liquid and solid ones plays a dominant role if the characteristic length of the flow is sufficiently small. In cases when the traditional continuum model fails to provide accurate predictions or postdictions, expensive molecular dynamics simulations seem to be the only first-principle approach available to rationally characterize liquid flows in microdevices. Such simulations are not yet feasible for realistic flow extent or number of molecules. As a consequence, the microfluid mechanics of liquids is much less developed than that for gases.

### 4.3 Fluid Modeling

A flowfield can be modeled either as the fluid really is—a collection of molecules—or as a continuum where the matter is assumed continuous and indefinitely divisible. The former modeling is subdivided into deterministic methods and probabilistic ones, while in the latter approach the velocity, density, pressure, etc. are defined at every point in space and time, and conservation of mass, energy and momentum lead to a set of nonlinear partial differential equations (Euler, Navier–Stokes, Burnett, etc.). Fluid modeling classification is depicted schematically in Figure 4.1.

The continuum model, embodied in the Navier–Stokes equations, is applicable to numerous flow situations. The model ignores the molecular nature of gases and liquids and regards the fluid as a continuous medium describable in terms of the spatial and temporal variations of density, velocity, pressure, temperature and other macroscopic flow quantities. For dilute gas flows near equilibrium, the Navier–Stokes equations are derivable from the molecularly based Boltzmann equation but can also be derived independently of that for both liquids and gases. In the case of direct derivation, some empiricism is necessary to close the resulting indeterminate set of equations. The continuum model is easier to handle mathematically (and is also more familiar to most fluid dynamicists) than the alternative molecular models. Continuum models should therefore be used as long as they are applicable. Thus, careful considerations of the validity of the Navier–Stokes equations and the like are in order.

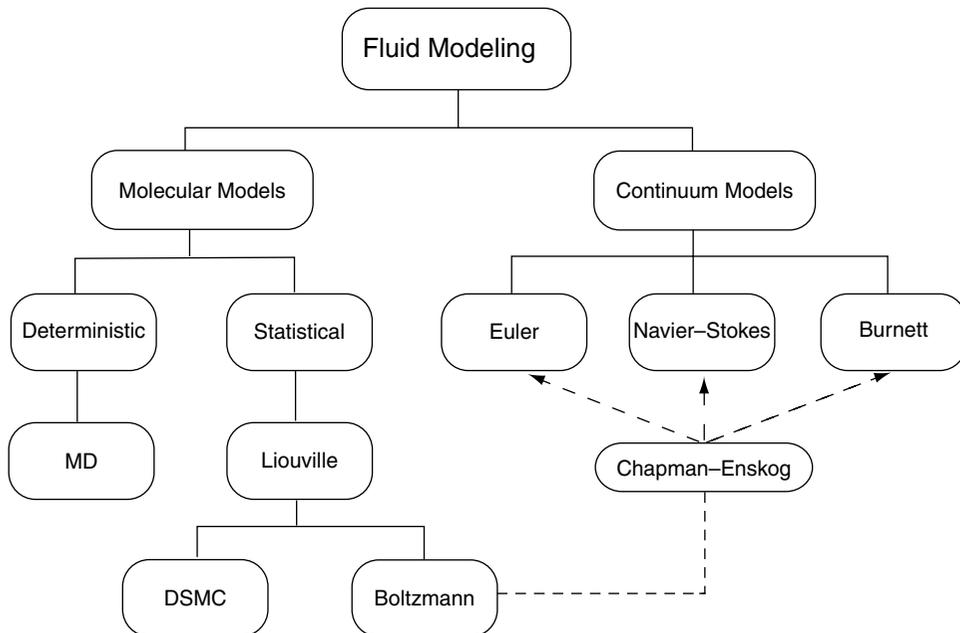

FIGURE 4.1 Molecular and continuum flow models. (From Gad-el-Hak, M. (1999) *J. Fluids Eng.* **121**, pp. 5–33, ASME, New York. With permission.)

Basically, the continuum model leads to fairly accurate predictions as long as local properties such as density and velocity can be defined as averages over elements large compared with the microscopic structure of the fluid but small enough in comparison with the scale of the macroscopic phenomena to permit the use of differential calculus to describe them. Additionally, the flow must not be too far from thermodynamic equilibrium. The former condition is almost always satisfied, but it is the latter which usually restricts the validity of the continuum equations. As will be seen in the following section, the continuum flow equations do not form a determinate set. The shear stress and heat flux must be expressed in terms of lower order macroscopic quantities such as velocity and temperature, and the simplest (i.e., linear) relations are valid only when the flow is near thermodynamic equilibrium. Worse yet, the traditional no-slip-boundary condition at a solid–fluid interface breaks down even before the linear stress–strain relation becomes invalid.

To be more specific, we temporarily restrict the discussion to gases where the concept of mean free path is well defined. Liquids are more problematic and we defer their discussion to a later section. For gases, the mean free path  $\mathcal{L}$  is the average distance traveled by molecules between collisions. For an ideal gas modeled as rigid spheres, the mean free path is related to temperature  $T$  and pressure  $p$  as follows:

$$\mathcal{L} = \frac{1}{\sqrt{2}\pi n\sigma^2} = \frac{kT}{\sqrt{2}\pi p\sigma^2} \quad (4.1)$$

where  $n$  is the number density (number of molecules per unit volume),  $\sigma$  is the molecular diameter, and  $k$  is the Boltzmann constant ( $1.38 \times 10^{-23}$  J/K · molecule).

The continuum model is valid when  $\mathcal{L}$  is much smaller than a characteristic flow dimension  $L$ . As this condition is violated, the flow is no longer near equilibrium and the linear relation between stress and rate of strain and the no-slip-velocity condition are no longer valid. Similarly, the linear relation between heat flux and temperature gradient and the no-jump temperature condition at a solid–fluid interface are no longer accurate when  $\mathcal{L}$  is not much smaller than  $L$ .

The length scale  $L$  can be some overall dimension of the flow, but a more precise choice is the scale of the gradient of a macroscopic quantity, as, for example, the density  $\rho$ ,

$$L = \frac{\rho}{\left|\frac{\partial\rho}{\partial y}\right|} \quad (4.2)$$

The ratio between the mean free path and the characteristic length is known as the Knudsen number:

$$Kn = \frac{\mathcal{L}}{L} \quad (4.3)$$

and generally the traditional continuum approach is valid, albeit with modified boundary conditions, as long as  $Kn < 0.1$ .

There are two more important dimensionless parameters in fluid mechanics, and the Knudsen number can be expressed in terms of those two. The Reynolds number is the ratio of inertial forces to viscous ones:

$$Re = \frac{v_o L}{\nu} \quad (4.4)$$

where  $v_o$  is a characteristic velocity, and  $\nu$  is the kinematic viscosity of the fluid. The Mach number is the ratio of flow velocity to the speed of sound:

$$Ma = \frac{v_o}{a_o} \quad (4.5)$$

The Mach number is a dynamic measure of fluid compressibility and may be considered as the ratio of inertial forces to elastic ones. From the kinetic theory of gases, the mean free path is related to the viscosity

as follows:

$$\mathbf{v} = \frac{\mu}{\rho} = \frac{1}{2} \mathcal{L} \bar{v}_m \quad (4.6)$$

where  $\mu$  is the dynamic viscosity, and  $\bar{v}_m$  is the mean molecular speed which is somewhat higher than the sound speed  $a_o$ ,

$$\bar{v}_m = \sqrt{\frac{8}{\pi\gamma}} a_o \quad (4.7)$$

where  $\gamma$  is the specific heat ratio (i.e., the isentropic exponent). Combining Eqs. (4.3) to (4.7), we reach the required relation:

$$Kn = \sqrt{\frac{\pi\gamma}{2}} \frac{Ma}{Re} \quad (4.8)$$

In boundary layers, the relevant length scale is the shear-layer thickness  $\delta$ , and for laminar flows:

$$\frac{\delta}{L} \sim \frac{1}{\sqrt{Re}} \quad (4.9)$$

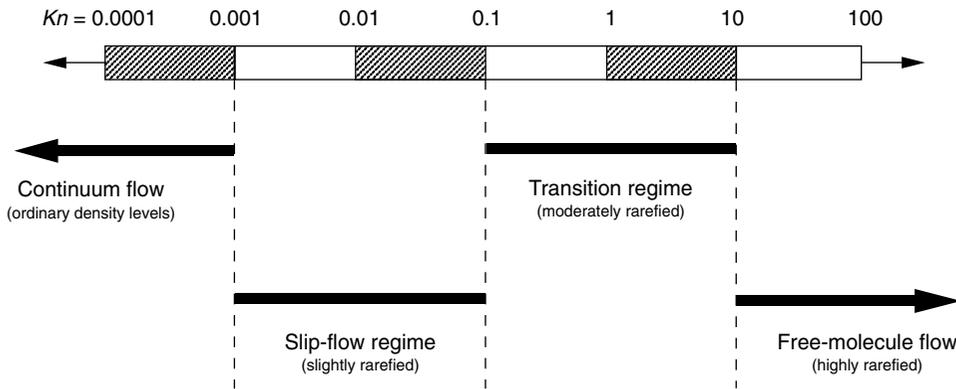

$$Kn \sim \frac{Ma}{Re_\delta} \sim \frac{Ma}{\sqrt{Re}} \quad (4.10)$$

where  $Re_\delta$  is the Reynolds number based on the freestream velocity  $v_o$  and the boundary layer thickness  $\delta$ , and  $Re$  is based on  $v_o$  and the streamwise length scale  $L$ .

Rarefied gas flows are in general encountered in flows in small geometries such as MEMS devices and in low-pressure applications such as high-altitude flying and high-vacuum gadgets. The local value of Knudsen number in a particular flow determines the degree of rarefaction and the degree of validity of the continuum model. The different Knudsen number regimes are determined empirically and are therefore only approximate for a particular flow geometry. The pioneering experiments in rarefied gas dynamics were conducted by Knudsen in 1909. In the limit of zero Knudsen number, the transport terms in the continuum momentum and energy equations are negligible and the Navier–Stokes equations then reduce to the inviscid Euler equations. Both heat conduction and viscous diffusion and dissipation are negligible, and the flow is then approximately isentropic (i.e., adiabatic and reversible) from the continuum viewpoint, while the equivalent molecular viewpoint is that the velocity distribution function is everywhere of the local equilibrium or Maxwellian form. As  $Kn$  increases, rarefaction effects become more important, and eventually the continuum approach breaks down altogether. The different Knudsen number regimes are depicted in [Figure 4.2](#), and can be summarized as follows:

Euler equations (neglect molecular diffusion):	$Kn \rightarrow 0$ ( $Re \rightarrow \infty$ )
Navier–Stokes equations with no-slip boundary conditions:	$Kn < 10^{-3}$
Navier–Stokes equations with slip boundary conditions:	$10^{-3} \leq Kn < 10^{-1}$
Transition regime:	$10^{-1} \leq Kn < 10$
Free-molecule flow:	$Kn \geq 10$

As an example, consider air at standard temperature ( $T = 288$  K) and pressure ( $p = 1.01 \times 10^5$  N/m<sup>2</sup>). A cube 1  $\mu\text{m}$  on a side contains  $2.54 \times 10^7$  molecules separated by an average distance of 0.0034  $\mu\text{m}$ . The gas is considered dilute if the ratio of this distance to the molecular diameter exceeds 7, and in the current example this ratio is 9, barely satisfying the dilute gas assumption. The mean free path computed from Eq. (1) is  $\mathcal{L} = 0.065$   $\mu\text{m}$ . A microdevice with characteristic length of 1  $\mu\text{m}$  would have  $Kn = 0.065$ , which is in the slip-flow regime. At lower pressures, the Knudsen number increases. For example, if the

**FIGURE 4.2** Knudsen number regimes. (From Gad-el-Hak, M. (1999) *J. Fluids Eng.* **121**, pp. 5–33, ASME, New York. With permission.)

pressure is 0.1 atm and the temperature remains the same,  $Kn = 0.65$  for the same 1- $\mu\text{m}$  device, and the flow is then in the transition regime. There would still be over 2 million molecules in the same 1- $\mu\text{m}$  cube, and the average distance between them would be 0.0074  $\mu\text{m}$ . The same device at 100 km altitude would have  $Kn = 3 \times 10^4$ , well into the free-molecule flow regime. The Knudsen number for the flow of a light gas such as helium is about 3 times larger than that for air flow at otherwise the same conditions.

Consider a long microchannel where the entrance pressure is atmospheric and the exit conditions are near vacuum. As air goes down the duct, the pressure and density decrease while the velocity, Mach number and Knudsen number increase. The pressure drops to overcome viscous forces in the channel. If isothermal conditions prevail,<sup>1</sup> density also drops and conservation of mass requires the flow to accelerate down the constant-area tube. The fluid acceleration in turn affects the pressure gradient, resulting in a nonlinear pressure drop along the channel. The Mach number increases down the tube, limited only by choked-flow condition  $Ma = 1$ . Additionally, the normal component of velocity is no longer zero. With lower density, the mean free path increases and  $Kn$  correspondingly increases. All flow regimes depicted in Figure 4.2 may occur in the same tube: continuum with no-slip-boundary conditions, slip-flow regime, transition regime and free-molecule flow. The air flow may also change from incompressible to compressible as it moves down the microduct. A similar scenario may take place if the entrance pressure is, say, 5 atm, while the exit is atmospheric. This deceptively simple duct flow may in fact manifest every single complexity discussed in this section. In the following six sections, we discuss in turn the Navier–Stokes equations, compressibility effects, boundary conditions, molecular-based models, liquid flows and surface phenomena.

## 4.4 Continuum Model

We recall in this section the traditional conservation relations in fluid mechanics. A concise derivation of these equations can be found in Gad-el-Hak (2000). In here, we re-emphasize the precise assumptions needed to obtain a particular form of the equations. A continuum fluid implies that the derivatives of all the dependent variables exist in some reasonable sense. In other words, local properties such as density and velocity are defined as averages over elements large compared with the microscopic structure of the fluid but small enough in comparison with the scale of the macroscopic phenomena to permit the use of differential calculus to describe them. As mentioned earlier, such conditions are almost always met. For such fluids, and assuming the laws of nonrelativistic mechanics hold, the conservation of mass,

<sup>1</sup>More likely, the flow will be somewhere in between isothermal and adiabatic, Fanno flow. In that case, both density and temperature decrease downstream, the former not as fast as in the isothermal case, None of that changes the qualitative arguments made in the example.

momentum and energy can be expressed at every point in space and time as a set of partial differential equations as follows:

$$\frac{\partial \rho}{\partial t} + \frac{\partial}{\partial x_k}(\rho u_k) = 0 \quad (4.11)$$

$$\rho \left( \frac{\partial u_i}{\partial t} + u_k \frac{\partial u_i}{\partial x_k} \right) = \frac{\partial \Sigma_{ki}}{\partial x_k} + \rho g_i \quad (4.12)$$

$$\rho \left( \frac{\partial e}{\partial t} + u_k \frac{\partial e}{\partial x_k} \right) = -\frac{\partial q_k}{\partial x_k} + \Sigma_{ki} \frac{\partial u_i}{\partial x_k} \quad (4.13)$$

where  $\rho$  is the fluid density,  $u_k$  is an instantaneous velocity component ( $u, v, w$ ),  $\Sigma_{ki}$  is the second-order stress tensor (surface force per unit area),  $g_i$  is the body force per unit mass,  $e$  is the internal energy and  $q_k$  is the sum of heat flux vectors due to conduction and radiation. The independent variables are time  $t$  and the three spatial coordinates  $x_1, x_2$  and  $x_3$  or  $(x, y, z)$ .

Equations (4.11) to (4.13) constitute five differential equations for the 17 unknowns:  $\rho, u_i, \Sigma_{ki}, e$  and  $q_k$ . Absent any body couples, the stress tensor is symmetric, having only six independent components, which reduces the number of unknowns to 14. Obviously, the continuum flow equations do not form a determinate set. To close the conservation equations, the relation between the stress tensor and deformation rate, the relation between the heat flux vector and the temperature field and appropriate equations of state relating the different thermodynamic properties are needed. The stress–rate-of-strain relation and the heat-flux–temperature-gradient relation are approximately linear if the flow is not too far from thermodynamic equilibrium. This is a phenomenological result but can be rigorously derived from the Boltzmann equation for a dilute gas assuming the flow is near equilibrium. For a Newtonian, isotropic, Fourier, ideal gas, for example, those relations read:

$$\Sigma_{ki} = -p \delta_{ki} + \mu \left( \frac{\partial u_i}{\partial x_k} + \frac{\partial u_k}{\partial x_i} \right) + \lambda \left( \frac{\partial u_j}{\partial x_j} \right) \delta_{ki} \quad (4.14)$$

$$q_i = -\kappa \frac{\partial T}{\partial x_i} + \text{heat flux due to radiation} \quad (4.15)$$

$$de = c_v dT \quad \text{and} \quad p = \rho \mathcal{R} T \quad (4.16)$$

where  $p$  is the thermodynamic pressure,  $\mu$  and  $\lambda$  are the first and second coefficients of viscosity, respectively,  $\delta_{ki}$  is the unit second-order tensor (Kronecker delta),  $\kappa$  is the thermal conductivity,  $T$  is the temperature field,  $c_v$  is the specific heat at constant volume and  $\mathcal{R}$  is the gas constant given by the Boltzmann constant divided by the mass of an individual molecule  $k = m\mathcal{R}$ . The Stokes' hypothesis relates the first and second coefficients of viscosity, thus  $\lambda + \frac{2}{3}\mu = 0$ , although the validity of this assumption for other than dilute, monatomic gases has occasionally been questioned [Gad-el-Hak, 1995]. With the above constitutive relations and neglecting radiative heat transfer, Eqs. (4.11), (4.12) and (4.13), respectively, read:

$$\frac{\partial \rho}{\partial t} + \frac{\partial}{\partial x_k}(\rho u_k) = 0 \quad (4.17)$$

$$\rho \left( \frac{\partial u_i}{\partial t} + u_k \frac{\partial u_i}{\partial x_k} \right) = -\frac{\partial p}{\partial x_i} + \rho g_i + \frac{\partial}{\partial x_k} \left[ \mu \left( \frac{\partial u_i}{\partial x_k} + \frac{\partial u_k}{\partial x_i} \right) + \delta_{ki} \lambda \frac{\partial u_j}{\partial x_j} \right] \quad (4.18)$$

$$\rho \left( \frac{\partial e}{\partial t} + u_k \frac{\partial e}{\partial x_k} \right) = \frac{\partial}{\partial x_k} \left( \kappa \frac{\partial T}{\partial x_k} \right) - p \frac{\partial u_k}{\partial x_k} + \phi \quad (4.19)$$

The three components of the vector Eq. (4.18) are the Navier–Stokes equations expressing the conservation of momentum for a Newtonian fluid. In the thermal energy Eq. (4.19),  $\phi$  is the always positive dissipation function expressing the irreversible conversion of mechanical energy to internal energy as a result of the deformation of a fluid element. The second term on the right-hand side of Eq. (4.19) is the reversible work done (per unit time) by the pressure as the volume of a fluid material element changes. For a Newtonian, isotropic fluid, the viscous dissipation rate is given by:

$$\phi = \frac{1}{2}\mu\left(\frac{\partial u_i}{\partial x_k} + \frac{\partial u_k}{\partial x_i}\right)^2 + \lambda\left(\frac{\partial u_j}{\partial x_j}\right)^2 \quad (4.20)$$

There are now six unknowns:  $\rho$ ,  $u_i$ ,  $p$  and  $T$ ; the five coupled Eqs. (4.17) to (4.19); plus the equation of state relating pressure, density and temperature. These six equations together with a sufficient number of initial and boundary conditions constitute a well-posed, albeit formidable, problem. The system of Eqs. (4.17) to (4.19) is an excellent model for the laminar or turbulent flow of most fluids such as air and water under many circumstances, including high-speed gas flows for which the shock waves are thick relative to the mean free path of the molecules.

Considerable simplification is achieved if the flow is assumed incompressible, usually a reasonable assumption provided that the characteristic flow speed is less than 0.3 of the speed of sound. The incompressibility assumption is readily satisfied for almost all liquid flows and many gas flows. In such cases, the density is assumed either a constant or a given function of temperature (or species concentration). The governing equations for such flow are

$$\frac{\partial u_k}{\partial x_k} = 0 \quad (4.21)$$

$$\rho\left(\frac{\partial u_i}{\partial t} + u_k \frac{\partial u_i}{\partial x_k}\right) = -\frac{\partial p}{\partial x_i} + \frac{\partial}{\partial x_k}\left[\mu\left(\frac{\partial u_i}{\partial x_k} + \frac{\partial u_k}{\partial x_i}\right)\right] + \rho g_i \quad (4.22)$$

$$\rho c_p\left(\frac{\partial T}{\partial t} + u_k \frac{\partial T}{\partial x_k}\right) = \frac{\partial}{\partial x_k}\left(\kappa \frac{\partial T}{\partial x_k}\right) + \phi_{\text{incomp}} \quad (4.23)$$

where  $\phi_{\text{incomp}}$  is the incompressible limit of Eq. (4.20). These are now five equations for the five dependent variables  $u_i$ ,  $p$  and  $T$ . Note that the left-hand side of Eq. (4.23) has the specific heat at constant pressure  $c_p$  and not  $c_v$ . It is the convection of enthalpy—and not internal energy—that is balanced by heat conduction and viscous dissipation. This is the correct incompressible-flow limit—of a compressible fluid—as discussed in detail in Section 10.9 of Panton (1996); a subtle point perhaps but one that is frequently missed in textbooks.

For both the compressible and the incompressible equations of motion, the transport terms are neglected away from solid walls in the limit of infinite Reynolds number ( $Kn \rightarrow 0$ ). The fluid is then approximated as inviscid and nonconducting, and the corresponding equations read (for the compressible case):

$$\frac{\partial \rho}{\partial t} + \frac{\partial}{\partial x_k}(\rho u_k) = 0 \quad (4.24)$$

$$\rho\left(\frac{\partial u_i}{\partial t} + u_k \frac{\partial u_i}{\partial x_k}\right) = -\frac{\partial p}{\partial x_i} + \rho g_i \quad (4.25)$$

$$\rho c_v\left(\frac{\partial T}{\partial t} + u_k \frac{\partial T}{\partial x_k}\right) = -p \frac{\partial u_k}{\partial x_k} \quad (4.26)$$

The Euler Eq. (4.25) can be integrated along a stream line, and the resulting Bernoulli's equation provides a direct relation between the velocity and pressure.

## 4.5 Compressibility

The issue of whether to consider the continuum flow compressible or incompressible seems to be rather straightforward but is in fact full of potential pitfalls. If the local Mach number is less than 0.3, then the flow of a compressible fluid such as air can—according to the conventional wisdom—be treated as incompressible. But the well-known  $Ma < 0.3$  criterion is only a necessary not a sufficient one to allow a treatment of the flow as approximately incompressible. In other words, situations exist where the Mach number can be exceedingly small while the flow is compressible. As is well documented in heat transfer textbooks, strong wall heating or cooling may cause the density to change sufficiently and the incompressible approximation to break down, even at low speeds. Less known is the situation encountered in some microdevices where the pressure may strongly change due to viscous effects even though the speeds may not be high enough for the Mach number to go above the traditional threshold of 0.3. Corresponding to the pressure changes would be strong density changes that must be taken into account when writing the continuum equations of motion. In this section, we systematically explain all situations where compressibility effects must be considered. Let us rewrite the full continuity Eq. (4.11) as follows:

$$\frac{D\rho}{Dt} + \rho \frac{\partial u_k}{\partial x_k} = 0 \quad (4.27)$$

where  $\frac{D}{Dt}$  is the substantial derivative  $(\frac{\partial}{\partial t} + u_k \frac{\partial}{\partial x_k})$ , expressing changes following a fluid element. The proper criterion for the incompressible approximation to hold is that  $(\frac{1}{\rho} \frac{D\rho}{Dt})$  is vanishingly small. In other words, if density changes following a fluid particle are small, the flow is approximately incompressible. Density may change arbitrarily from one particle to another without violating the incompressible flow assumption. This is the case for example in the stratified atmosphere and ocean, where the variable-density/temperature/salinity flow is often treated as incompressible.

From the state principle of thermodynamics, we can express the density changes of a simple system in terms of changes in pressure and temperature:

$$\rho = \rho(p, T) \quad (4.28)$$

Using the chain rule of calculus,

$$\frac{1}{\rho} \frac{D\rho}{Dt} = \alpha \frac{Dp}{Dt} - \beta \frac{DT}{Dt} \quad (4.29)$$

where  $\alpha$  and  $\beta$  are, respectively, the isothermal compressibility coefficient and the bulk expansion coefficient—two thermodynamic variables that characterize the fluid susceptibility to change of volume—which are defined by the following relations:

$$\alpha(p, T) \equiv \frac{1}{\rho} \left. \frac{\partial \rho}{\partial p} \right|_T \quad (4.30)$$

$$\beta(p, T) \equiv -\frac{1}{\rho} \left. \frac{\partial \rho}{\partial T} \right|_p \quad (4.31)$$

For ideal gases,  $\alpha = 1/p$  and  $\beta = 1/T$ . Note, however, that in the following arguments it will not be necessary to invoke the ideal gas assumption. The flow must be treated as compressible if pressure and/or

temperature changes—following a fluid element—are sufficiently strong. Equation (4.29) must of course be properly nondimensionalized before deciding whether a term is large or small. In here, we follow closely the procedure detailed in Panton (1996).

Consider first the case of adiabatic walls. Density is normalized with a reference value  $\rho_o$ ; velocities, with a reference speed  $v_o$ ; spatial coordinates and time, with, respectively,  $L$  and  $L/v_o$ , the isothermal compressibility coefficient and bulk expansion coefficient with reference values  $\alpha_o$  and  $\beta_o$ . The pressure is nondimensionalized with the inertial pressure scale  $\rho_o v_o^2$ . This scale is twice the dynamic pressure (i.e., the pressure change as an inviscid fluid moving at the reference speed is brought to rest).

Temperature changes for the case of adiabatic walls can only result from the irreversible conversion of mechanical energy into internal energy via viscous dissipation. Temperature is therefore nondimensionalized as follows:

$$T^* = \frac{T - T_o}{\left(\frac{\mu_o v_o^2}{c_{p_o}}\right)} = \frac{T - T_o}{Pr \left(\frac{v_o^2}{c_{p_o}}\right)} \quad (4.32)$$

where  $T_o$  is a reference temperature,  $\mu_o$ ,  $\kappa_o$  and  $c_{p_o}$  are, respectively, reference viscosity, thermal conductivity and specific heat at constant pressure, and  $Pr$  is the reference Prandtl number,  $(\mu_o c_{p_o})/\kappa_o$ .

In the present formulation, the scaling used for pressure is based on the Bernoulli's equation and therefore neglects viscous effects. This particular scaling guarantees that the pressure term in the momentum equation will be of the same order as the inertia term. The temperature scaling assumes that the conduction, convection and dissipation terms in the energy equation have the same order of magnitude. The resulting dimensionless form of Eq. (4.29) reads:

$$\frac{1}{\rho^*} \frac{D\rho^*}{Dt^*} = \gamma_o Ma^2 \left\{ \alpha^* \frac{Dp^*}{Dt^*} - \frac{Pr B \beta^*}{A} \frac{DT^*}{Dt^*} \right\} \quad (4.33)$$

where the superscript  $*$  indicates a nondimensional quantity,  $Ma$  is the reference Mach number ( $v_o/a_o$ , where  $a_o$  is the reference speed of sound) and  $A$  and  $B$  are dimensionless constants defined by  $A \equiv \alpha_o \rho_o c_{p_o} T_o$  and  $B \equiv \beta_o T_o$ . If the scaling is properly chosen, the terms having the  $*$  superscript in the right-hand side should be of order one, and the relative importance of such terms in the equations of motion is determined by the magnitude of the dimensionless parameter(s) appearing to their left (e.g.,  $Ma$ ,  $Pr$ , etc.). Therefore, as  $Ma^2 \rightarrow 0$ , temperature changes due to viscous dissipation are neglected (unless  $Pr$  is very large, as, for example, in the case of highly viscous polymers and oils). Within the same order of approximation, all thermodynamic properties of the fluid are assumed constant.

Pressure changes are also neglected in the limit of zero Mach number. Hence, for  $Ma < 0.3$  (i.e.,  $Ma^2 < 0.09$ ), density changes following a fluid particle can be neglected and the flow can then be approximated as incompressible;<sup>2</sup> however, there is a caveat in this argument. Pressure changes due to inertia can indeed be neglected at small Mach numbers and this is consistent with the way we nondimensionalized the pressure term above. If, on the other hand, pressure changes are mostly due to viscous effects, as is the case in a long microduct or a micro-gas-bearing, pressure changes may be significant even at low speeds (low  $Ma$ ). In that case, the term  $\frac{Dp^*}{Dt^*}$  in Eq. (4.33) is no longer of order one and may be large regardless of the value of  $Ma$ . Density then may change significantly and the flow must be treated as compressible. Had pressure been nondimensionalized using the viscous scale  $\left(\frac{\mu_o v_o}{L}\right)$  instead of the inertial one ( $\rho_o v_o^2$ ), the revised Eq. (4.33) would have  $Re^{-1}$  appearing explicitly in the first term in the right-hand side, accentuating the importance of this term when viscous forces dominate.

<sup>2</sup>With an error of about 10% at  $Ma = 0.3$ , 4% at  $Ma = 0.2$ , 1% at  $Ma = 0.1$  and so on.

A similar result can be gleaned when the Mach number is interpreted as follows:

$$Ma^2 = \frac{v_o^2}{a_o^2} = v_o^2 \left. \frac{\partial \rho}{\partial p} \right|_s = \frac{\rho_o v_o^2}{\rho_o} \left. \frac{\partial \rho}{\partial p} \right|_s \sim \frac{\Delta p}{\rho_o} \frac{\Delta \rho}{\Delta p} = \frac{\Delta \rho}{\rho_o} \quad (4.34)$$

where  $s$  is the entropy. Again, the above equation assumes that pressure changes are inviscid; therefore, a small Mach number means negligible pressure and density changes. In a flow dominated by viscous effects—such as that inside a microduct—density changes may be significant even in the limit of zero Mach number.

Identical arguments can be made in the case of isothermal walls. Here, strong temperature changes may be the result of wall heating or cooling, even if viscous dissipation is negligible. The proper temperature scale in this case is given in terms of the wall temperature  $T_w$  and the reference temperature  $T_o$  as follows:

$$\widehat{T} = \frac{T - T_o}{T_w - T_o} \quad (4.35)$$

where  $\widehat{T}$  is the new dimensionless temperature. The nondimensional form of Eq. (4.29) now reads:

$$\frac{1}{\rho^*} \frac{D\rho^*}{Dt^*} = \gamma_o Ma^2 \alpha^* \frac{Dp^*}{Dt^*} - \beta^* B \left( \frac{T_w - T_o}{T_o} \right) \frac{D\widehat{T}}{Dt^*} \quad (4.36)$$

Here, we notice that the temperature term is different from that in Eq. (4.33).  $Ma$  is no longer appearing in this term, and strong temperature changes, i.e., large  $(T_w - T_o)/T_o$ , may cause strong density changes regardless of the value of the Mach number. Additionally, the thermodynamic properties of the fluid are not constant but depend on temperature, and as a result the continuity, momentum and energy equations all couple. The pressure term in Eq. (4.36), on the other hand, is exactly as it was in the adiabatic case and the same arguments made before apply: The flow should be considered compressible if  $Ma > 0.3$ , or if pressure changes due to viscous forces are sufficiently large.

Experiments in gaseous microducts confirm the above arguments. For both low- and high-Mach-number flows, pressure gradients in long microchannels are nonconstant, consistent with the compressible flow equations. Such experiments were conducted by, among others, Prud'homme et al. (1986), Pfahler et al. (1991), van den Berg et al. (1993), Liu et al. (1993; 1995), Pong et al. (1994), Harley et al. (1995), Piekos and Breuer (1996), Arkilic (1997) and Arkilic et al. (1995; 1997a; 1997b). Sample results will be presented in the following section.

Three additional scenarios exist in which significant pressure and density changes may take place without inertial, viscous or thermal effects. First is the case of quasistatic compression/expansion of a gas in, for example, a piston–cylinder arrangement. The resulting compressibility effects are, however, compressibility of the fluid and not of the flow. Two other situations where compressibility effects must also be considered are problems with length scales comparable to the scale height of the atmosphere and rapidly varying flows as in sound propagation [Lighthill, 1963].

## 4.6 Boundary Conditions

The continuum equations of motion described earlier require a certain number of initial and boundary conditions for proper mathematical formulation of flow problems. In this section, we describe the boundary conditions at a fluid–solid interface. Boundary conditions in the inviscid flow theory pertain only to the velocity component normal to a solid surface. The highest spatial derivative of velocity in the

inviscid equations of motion is first order, and only one velocity boundary condition at the surface is admissible. The normal velocity component at a fluid–solid interface is specified, and no statement can be made regarding the tangential velocity component. The normal-velocity condition simply states that a fluid-particle path cannot go through an impermeable wall. Real fluids are of course viscous, and the corresponding momentum equation has second-order derivatives of velocity, thus requiring an additional boundary condition on the velocity component tangential to a solid surface.

Traditionally, the no-slip condition at a fluid–solid interface is enforced in the momentum equation and an analogous no-temperature-jump condition is applied in the energy equation. The notion underlying the no-slip/no-jump condition is that within the fluid there cannot be any finite discontinuities of velocity/temperature. Those would involve infinite velocity/temperature gradients and so produce infinite viscous stress/heat flux that would destroy the discontinuity in infinitesimal time. The interaction between a fluid particle and a wall is similar to that between neighboring fluid particles; therefore, no discontinuities are allowed at the fluid–solid interface either. In other words, the fluid velocity must be zero relative to the surface and the fluid temperature must equal to that of the surface. But, strictly speaking, those two boundary conditions are valid only if the fluid flow adjacent to the surface is in thermodynamic equilibrium. This requires an infinitely high frequency of collisions between the fluid and the solid surface. In practice, the no-slip/no-jump condition leads to fairly accurate predictions as long as  $Kn < 0.001$  (for gases). Beyond that, the collision frequency is simply not high enough to ensure equilibrium and a certain degree of tangential-velocity slip and temperature jump must be allowed. This is a case frequently encountered in MEMS flows, and we develop the appropriate relations in this section.

For both liquids and gases, the linear Navier boundary condition empirically relates the tangential velocity slip at the wall  $\Delta u|_w$  to the local shear:

$$\Delta u|_w = u_{\text{fluid}} - u_{\text{wall}} = L_s \left. \frac{\partial u}{\partial y} \right|_w \quad (4.37)$$

where  $L_s$  is the constant slip length, and  $\left. \frac{\partial u}{\partial y} \right|_w$  is the strain rate computed at the wall. In most practical situations, the slip length is so small that the no-slip condition holds. In MEMS applications, however, that may not be the case. Once again we defer the discussion of liquids to a later section and focus for now on gases.

Assuming isothermal conditions prevail, the above slip relation has been rigorously derived by Maxwell (1879) from considerations of the kinetic theory of dilute, monatomic gases. Gas molecules, modeled as rigid spheres, continuously strike and reflect from a solid surface, just as they continuously collide with each other. For an idealized perfectly smooth wall (at the molecular scale), the incident angle exactly equals the reflected angle and the molecules conserve their tangential momentum and thus exert no shear on the wall. This is termed *specular reflection* and results in perfect slip at the wall. For an extremely rough wall, on the other hand, the molecules reflect at some random angle uncorrelated with their entry angle. This perfectly diffuse reflection results in zero tangential momentum for the reflected fluid molecules to be balanced by a finite slip velocity in order to account for the shear stress transmitted to the wall. A force balance near the wall leads to the following expression for the slip velocity:

$$u_{\text{gas}} - u_{\text{wall}} = \mathcal{L} \left. \frac{\partial u}{\partial y} \right|_w \quad (4.38)$$

where  $\mathcal{L}$  is the mean free path. The right-hand side can be considered as the first term in an infinite Taylor series, sufficient if the mean free path is relatively small enough. The equation above states that significant slip occurs only if the mean velocity of the molecules varies appreciably over a distance of one mean free path. This is the case, for example, in vacuum applications and/or flow in microdevices. The number of collisions between the fluid molecules and the solid in those cases is not large enough for even an approximate flow equilibrium to be established. Furthermore, additional (nonlinear) terms

in the Taylor series would be needed as  $\mathcal{L}$  increases and the flow is further removed from the equilibrium state.

For real walls some molecules reflect diffusively and some reflect specularly. In other words, a portion of the momentum of the incident molecules is lost to the wall and a (typically smaller) portion is retained by the reflected molecules. The tangential-momentum-accommodation coefficient  $\sigma_v$  is defined as the fraction of molecules reflected diffusively. This coefficient depends on the fluid, the solid and the surface finish and has been determined experimentally to be between 0.2 and 0.8 [Thomas and Lord, 1974; Seidl and Steiheil, 1974; Porodnov et al., 1974; Arkilic et al., 1997b; Arkilic, 1997], the lower limit being for exceptionally smooth surfaces while the upper limit is typical of most practical surfaces. The final expression derived by Maxwell for an isothermal wall reads:

$$u_{\text{gas}} - u_{\text{wall}} = \frac{2 - \sigma_v}{\sigma_v} \mathcal{L} \left. \frac{\partial u}{\partial y} \right|_w \quad (4.39)$$

For  $\sigma_v = 0$ , the slip velocity is unbounded, while for  $\sigma_v = 1$ , Eq. (4.39) reverts to Eq. (4.38).

Similar arguments were made for the temperature-jump-boundary condition by von Smoluchowski (1898). For an ideal gas flow in the presence of wall-normal and tangential temperature gradients, the complete (first-order) slip-flow and temperature-jump-boundary conditions read:

$$u_{\text{gas}} - u_{\text{wall}} = \frac{2 - \sigma_v}{\sigma_v} \frac{1}{\rho \sqrt{\frac{2\mathcal{R}T_{\text{gas}}}{\pi}}} \tau_w + \frac{3Pr(\gamma - 1)}{4\gamma\rho\mathcal{R}T_{\text{gas}}} (-q_x)_w = \frac{2 - \sigma_v}{\sigma_v} \mathcal{L} \left( \frac{\partial u}{\partial y} \right)_w + \frac{3}{4} \frac{\mu}{\rho T_{\text{gas}}} \left( \frac{\partial u}{\partial x} \right)_w \quad (4.40)$$

$$T_{\text{gas}} - T_{\text{wall}} = \frac{2 - \sigma_T}{\sigma_T} \left[ \frac{2(\gamma - 1)}{(\gamma + 1)} \right] \frac{1}{\rho\mathcal{R} \sqrt{\frac{2\mathcal{R}T_{\text{gas}}}{\pi}}} (-q_y)_w = \frac{2 - \sigma_T}{\sigma_T} \left[ \frac{2\gamma}{(\gamma + 1)} \right] \frac{\mathcal{L}}{Pr} \left( \frac{\partial T}{\partial y} \right)_w \quad (4.41)$$

where  $x$  and  $y$  are the streamwise and normal coordinates;  $\rho$  and  $\mu$  are, respectively, the fluid density and viscosity;  $\mathcal{R}$  is the gas constant;  $T_{\text{gas}}$  is the temperature of the gas adjacent to the wall;  $T_{\text{wall}}$  is the wall temperature;  $\tau_w$  is the shear stress at the wall;  $Pr$  is the Prandtl number;  $\gamma$  is the specific heat ratio;  $q_x$  and  $q_y$  are, respectively, the tangential and normal heat flux at the wall.

The tangential-momentum-accommodation coefficient  $\sigma_v$  and the thermal-accommodation coefficient  $\sigma_T$  are given, respectively, by:

$$\sigma_v = \frac{\tau_i - \tau_r}{\tau_i - \tau_w} \quad (4.42)$$

$$\sigma_T = \frac{dE_i - dE_r}{dE_i - dE_w} \quad (4.43)$$

where the subscripts  $i$ ,  $r$  and  $w$  stand for, respectively, incident, reflected and solid wall conditions;  $\tau$  is a tangential momentum flux;  $dE$  is an energy flux.

The second term in the right-hand side of Eq. (4.40) is the *thermal creep*, which generates slip velocity in the fluid opposite to the direction of the tangential heat flux (i.e., flow in the direction of increasing temperature). At sufficiently high Knudsen numbers, a streamwise temperature gradient in a conduit leads to a measurable pressure gradient along the tube. This may be the case in vacuum applications and MEMS devices. Thermal creep is the basis for the so-called Knudsen pump—a device with no moving parts—in which rarefied gas is hauled from one cold chamber to a hot one.<sup>3</sup> Clearly, such a pump

<sup>3</sup>The terminology *Knudsen pump* has been used by, for example, Vargo and Muntz (1996), but, according to Loeb (1961), the original experiments demonstrating such a pump were carried out by Osborne Reynolds.

performs best at high Knudsen numbers and is typically designed to operate in the free-molecule flow regime.

In dimensionless form, Eqs. (4.40) and (4.41), respectively, read:

$$u_{\text{gas}}^* - u_{\text{wall}}^* = \frac{2 - \sigma_v}{\sigma_v} Kn \left( \frac{\partial u^*}{\partial y^*} \right)_w + \frac{3}{2\pi} \frac{(\gamma - 1)}{\gamma} \frac{Kn^2 Re}{Ec} \left( \frac{\partial T^*}{\partial x^*} \right)_w \quad (4.44)$$

$$T_{\text{gas}}^* - T_{\text{wall}}^* = \frac{2 - \sigma_T}{\sigma_T} \left[ \frac{2\gamma}{(\gamma + 1)} \right] \frac{Kn}{Pr} \left( \frac{\partial T^*}{\partial y^*} \right)_w \quad (4.45)$$

where the superscript \* indicates dimensionless quantity,  $Kn$  is the Knudsen number,  $Re$  is the Reynolds number and  $Ec$  is the Eckert number defined by:

$$Ec = \frac{v_o^2}{c_p \Delta T} = (\gamma - 1) \frac{T_o}{\Delta T} Ma^2 \quad (4.46)$$

where  $v_o$  is a reference velocity,  $\Delta T = (T_{\text{gas}} - T_o)$  and  $T_o$  is a reference temperature. Note that very low values of  $\sigma_v$  and  $\sigma_T$  lead to substantial velocity slip and temperature jump even for flows with small Knudsen number.

The first term in the right-hand side of Eq. (4.44) is first order in Knudsen number, while the thermal creep term is second order, meaning that the creep phenomenon is potentially significant at large values of the Knudsen number. Equation (4.45) is first order in  $Kn$ . Using Eqs. (4.8) and (4.46), the thermal creep term in Eq. (4.44) can be rewritten in terms of  $\Delta T$  and Reynolds number. Thus,

$$u_{\text{gas}}^* - u_{\text{wall}}^* = \frac{2 - \sigma_v}{\sigma_v} Kn \left( \frac{\partial u^*}{\partial y^*} \right)_w + \frac{3}{4} \frac{\Delta T}{T_o} \frac{1}{Re} \left( \frac{\partial T^*}{\partial x^*} \right)_w \quad (4.47)$$

It is clear that large temperature changes along the surface or low Reynolds numbers lead to significant thermal creep.

The continuum Navier–Stokes equations with no-slip-/no-temperature-jump-boundary conditions are valid as long as the Knudsen number does not exceed 0.001. First-order slip-/temperature-jump-boundary conditions should be applied to the Navier–Stokes equations in the range of  $0.001 < Kn < 0.1$ . The transition regime spans the range of  $0.1 < Kn < 10$ , and second-order or higher slip-/temperature-jump-boundary conditions are applicable there. Note, however, that the Navier–Stokes equations are first-order accurate in  $Kn$  as will be shown later and are themselves not valid in the transition regime. Either higher order continuum equations (e.g., Burnett equations) should be used there or molecular modeling should be invoked, abandoning the continuum approach altogether.

For isothermal walls, Beskok (1994) derived a higher order, slip-velocity condition as follows:

$$u_{\text{gas}} - u_{\text{wall}} = \frac{2 - \sigma_v}{\sigma_v} \left[ \mathcal{L} \left( \frac{\partial u}{\partial y} \right)_w + \frac{\mathcal{L}^2}{2!} \left( \frac{\partial^2 u}{\partial y^2} \right)_w + \frac{\mathcal{L}^3}{3!} \left( \frac{\partial^3 u}{\partial y^3} \right)_w + \dots \right] \quad (4.48)$$

Attempts to implement the above slip condition in numerical simulations are rather difficult. Second-order and higher derivatives of velocity cannot be computed accurately near the wall. Based on asymptotic analysis, Beskok (1996) and Beskok and Karniadakis (1994; 1999) proposed the following alternative higher order boundary condition for the tangential velocity, including the thermal creep term:

$$u_{\text{gas}}^* - u_{\text{wall}}^* = \frac{2 - \sigma_v}{\sigma_v} \frac{Kn}{1 - b Kn} \left( \frac{\partial u^*}{\partial y^*} \right)_w + \frac{3}{2\pi} \frac{(\gamma - 1)}{\gamma} \frac{Kn^2 Re}{Ec} \left( \frac{\partial T^*}{\partial x^*} \right)_w \quad (4.49)$$

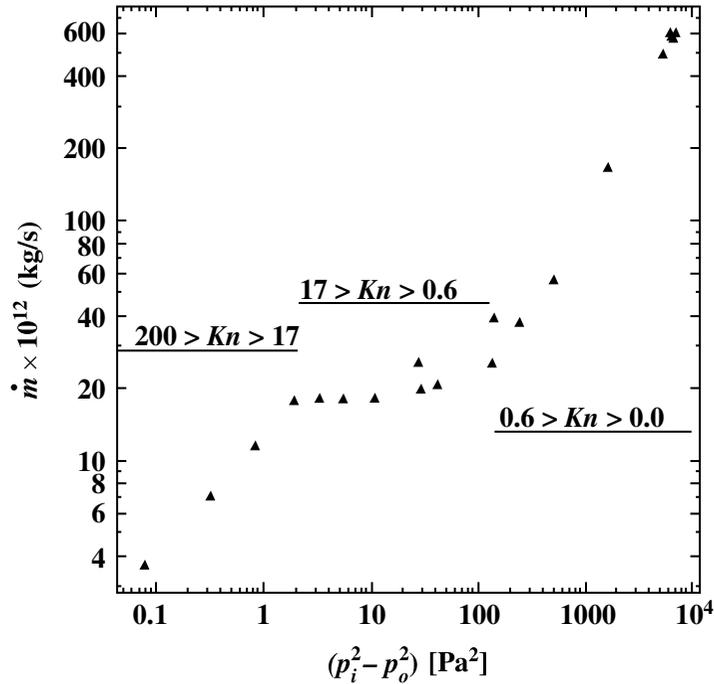

FIGURE 4.3 Variation of mass flowrate as a function of  $(p_i^2 - p_o^2)$ . (Original data acquired by S.A. Tison and plotted by Beskok et al. (1996). Figure from Gad-el-Hak, M. (1999) *J. Fluids Eng.* **121**, pp. 5–33, ASME, New York. With permission.)

where  $b$  is a high-order slip coefficient determined from the presumably known no-slip solution, thus avoiding the computational difficulties mentioned above. If this high-order slip coefficient is chosen as  $b = u_w''/u_w'$ , where the prime denotes derivative with respect to  $y$  and the velocity is computed from the no-slip Navier–Stokes equations, Eq. (4.49) becomes second-order accurate in Knudsen number. Beskok’s procedure can be extended to third and higher orders for both the slip-velocity and thermal creep terms.

Similar arguments can be applied to the temperature-jump-boundary condition, and the resulting Taylor series reads in dimensionless form (Beskok, 1996):

$$T_{\text{gas}}^* - T_{\text{wall}}^* = \frac{2 - \sigma_T}{\sigma_T} \left[ \frac{2\gamma}{(\gamma + 1)} \right] \frac{1}{Pr} \left[ Kn \left( \frac{\partial T^*}{\partial y} \right)_w + \frac{Kn^2}{2!} \left( \frac{\partial^2 T^*}{\partial y^2} \right)_w + \dots \right] \quad (4.50)$$

Again, the difficulties associated with computing second- and higher order derivatives of temperature are alleviated using a procedure identical to that utilized for the tangential velocity boundary condition.

Several experiments in low-pressure macroducts or in microducts confirm the necessity of applying the slip-boundary condition at sufficiently large Knudsen numbers. Among them are those conducted by Knudsen (1909), Pfahler et al. (1991), Tison (1993), Liu et al. (1993; 1995), Pong et al. (1994), Arkilic et al. (1995), Harley et al. (1995) and Shih et al. (1995; 1996). The experiments are complemented by the numerical simulations carried out by Beskok (1994; 1996), Beskok and Karniadakis (1994; 1999), and Beskok et al. (1996). Here we present selected examples of the experimental and numerical results.

Tison (1993) conducted pipe flow experiments at very low pressures. His pipe has a diameter of 2 mm and a length-to-diameter ratio of 200. Both inlet and outlet pressures were varied to yield Knudsen number in the range of  $Kn = 0$  to 200. Figure 4.3 shows the variation of mass flowrate as a function of  $(p_i^2 - p_o^2)$ , where  $p_i$  is the inlet pressure and  $p_o$  is the outlet pressure. The pressure drop in this rarefied pipe flow is nonlinear, characteristic of low-Reynolds-number, compressible flows. Three distinct flow

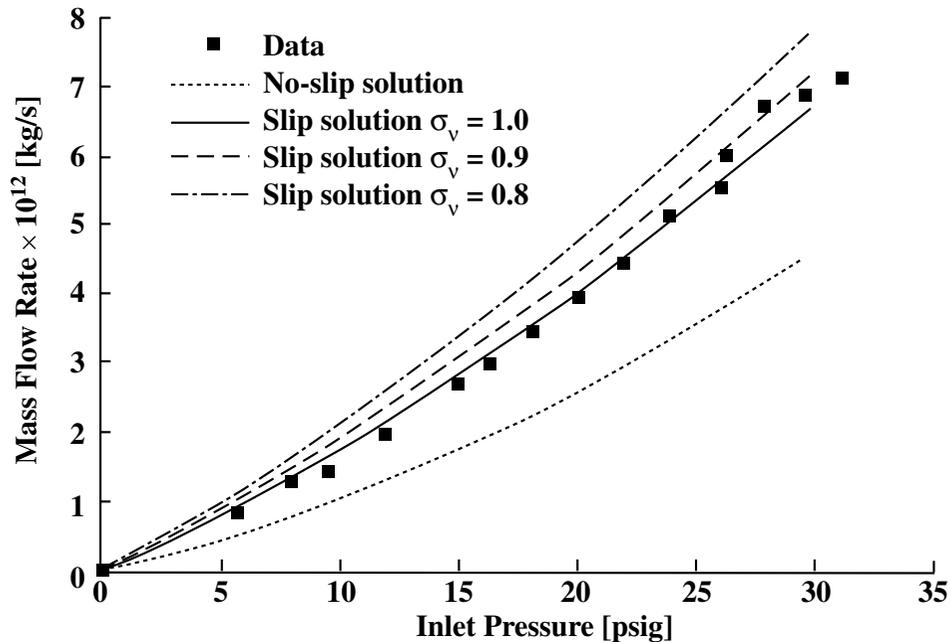

FIGURE 4.4 Mass flowrate vs. inlet pressure in a microchannel. (From Shih, J.C., et al. (1995) “Non-linear Pressure Distribution in Uniform Microchannels,” ASME AMD-MD-Vol. 238, American Society of Mechanical Engineers, New York. With permission.)

regimes are identified: (1) slip-flow regime,  $0 < Kn < 0.6$ ; (2) transition regime,  $0.6 < Kn < 17$ , where the mass flowrate is almost constant as the pressure changes; and (3) free-molecule flow,  $Kn > 17$ . Note that the demarcation between these three regimes is slightly different from that mentioned earlier. As stated, the different Knudsen number regimes are determined empirically and are therefore only approximate for a particular flow geometry.

Shih et al. (1995) conducted their experiments in a microchannel using helium as a fluid. The inlet pressure varied but the duct exit was atmospheric. Microsensors were fabricated *in situ* along their MEMS channel to measure the pressure. Figure 4.4 shows their measured mass flowrate vs. the inlet pressure. The data are compared to the no-slip solution and the slip solution using three different values of the tangential-momentum-accommodation coefficient: 0.8, 0.9 and 1.0. The agreement is reasonable with the case  $\sigma_v = 1$ , indicating perhaps that the channel used by Shih et al. was quite rough on the molecular scale. In a second experiment [Shih et al., 1996], nitrous oxide was used as the fluid. The square of the pressure distribution along the channel is plotted in Figure 4.5 for five different inlet pressures. The experimental data (symbols) compare well with the theoretical predictions (solid lines). Again, the non-linear pressure drop shown indicates that the gas flow is compressible.

Arkilic (1997) provided an elegant analysis of the compressible, rarefied flow in a microchannel. The results of his theory are compared to the experiments of Pong et al. (1994) in Figure 4.6. The dotted line is the incompressible flow solution, where the pressure is predicted to drop linearly with streamwise distance. The dashed line is the compressible flow solution that neglects rarefaction effects (assumes  $Kn = 0$ ). Finally, the solid line is the theoretical result that takes into account both compressibility and rarefaction via the slip-flow-boundary condition computed at the exit Knudsen number of  $Kn = 0.06$ . That theory compares most favorably with the experimental data. In the compressible flow through the constant-area duct, density decreases and thus velocity increases in the streamwise direction. As a result, the pressure distribution is nonlinear with negative curvature. A moderate Knudsen number (i.e., moderate slip) actually diminishes, albeit rather weakly, this curvature. Thus, compressibility and rarefaction effects lead to opposing trends, as pointed out by Beskok et al. (1996).

## 4.7 Molecular-Based Models

In the continuum models discussed thus far, the macroscopic fluid properties are the dependent variables, while the independent variables are the three spatial coordinates and time. The molecular models recognize the fluid as a myriad of discrete particles: molecules, atoms, ions and electrons. The goal here is to determine the position, velocity and state of all particles at all times. The molecular approach is either deterministic or probabilistic (refer to Figure 4.1). Provided that there is a sufficient number of microscopic particles within the smallest significant volume of a flow, the macroscopic properties at any location in the flow can then be computed from the discrete-particle information by a suitable averaging or weighted averaging process. This section discusses molecular-based models and their relation to the continuum models previously considered.

The most fundamental of the molecular models is a deterministic one. The motion of the molecules is governed by the laws of classical mechanics, although, at the expense of greatly complicating the problem, the laws of quantum mechanics can also be considered in special circumstances. The modern molecular dynamics (MD) computer simulations have been pioneered by Alder and Wainwright (1957; 1958; 1970) and reviewed by Ciccotti and Hoover (1986), Allen and Tildesley (1987), Haile (1993) and Koplik and Banavar (1995). The simulation begins with a set of  $N$  molecules in a region of space, each assigned a random velocity corresponding to a Boltzmann distribution at the temperature of interest. The interaction between the particles is prescribed typically in the form of a two-body potential energy, and the time evolution of the molecular positions is determined by integrating Newton's equations of motion. Because MD is based on the most basic set of equations, it is valid in principle for any flow extent and any range of parameters. The method is straightforward in principle but has two hurdles: choosing a proper and convenient potential for particular fluid and solid combinations and the colossal computer resources required to simulate a reasonable flowfield extent.

For purists, the former difficulty is a sticky one. There is no totally rational methodology by which a convenient potential can be chosen. Part of the art of MD is to pick an appropriate potential and validate the simulation results with experiments or other analytical/computational results. A commonly used potential between two molecules is the generalized Lennard–Jones 6–12 potential, to be used in the following section and further discussed in the section following that.

The second difficulty, and by far the most serious limitation of molecular dynamics simulations, is the number of molecules  $N$  that can realistically be modeled on a digital computer. Because the computation of an element of trajectory for any particular molecule requires consideration of *all* other molecules as potential collision partners, the amount of computation required by the MD method is proportional to  $N^2$ . Some saving in computer time can be achieved by cutting off the weak tail of the potential (see Figure 4.11) at, say,  $r_c = 2.5 \sigma$  and shifting the potential by a linear term in  $r$  so that the force goes smoothly to zero at the cutoff. As a result, only nearby molecules are treated as potential collision partners, and the computation time for  $N$  molecules no longer scales with  $N^2$ .

The state of the art of molecular dynamics simulations in the early 2000s is such that with a few hours of CPU time general-purpose supercomputers can handle around 100,000 molecules. At enormous expense, the fastest parallel machine available can simulate around 10 million particles. Because of the extreme diminution of molecular scales, the above translates into regions of liquid flow of about  $0.02 \mu\text{m}$  ( $200 \text{ \AA}$ ) in linear size, over time intervals of around  $0.001 \mu\text{s}$ , enough for continuum behavior to set in for simple molecules. To simulate 1 s of real time for complex molecular interactions (e.g., including vibration modes, reorientation of polymer molecules, collision of colloidal particles) requires unrealistic CPU time measured in hundreds of years.

Molecular dynamics simulations are highly inefficient for dilute gases where the molecular interactions are infrequent. The simulations are more suited for dense gases and liquids. Clearly, molecular dynamics simulations are reserved for situations where the continuum approach or the statistical methods are inadequate to compute from first principles important flow quantities. Slip-boundary conditions for liquid flows in extremely small devices are such a case, as will be discussed in the following section.

An alternative to the deterministic molecular dynamics is the statistical approach where the goal is to compute the probability of finding a molecule at a particular position and state. If the appropriate conservation equation can be solved for the probability distribution, important statistical properties such as the mean number, momentum or energy of the molecules within an element of volume can be computed from a simple weighted averaging. In a practical problem, it is such average quantities that concern us rather than the detail for every single molecule. Clearly, however, the accuracy of computing average quantities, via the statistical approach, improves as the number of molecules in the sampled volume increases. The kinetic theory of dilute gases is well advanced, but that for dense gases and liquids is much less so due to the extreme complexity of having to include multiple collisions and intermolecular forces in the theoretical formulation. The statistical approach is well covered in books such as those by Kennard (1938), Hirschfelder et al. (1954), Schaaf and Chambré (1961), Vincenti and Kruger (1965), Kogan (1969), Chapman and Cowling (1970), Cercignani (1988; 2000) and Bird (1994), and review articles such as those by Kogan (1973), Muntz (1989) and Oran et al. (1998).

In the statistical approach, the fraction of molecules in a given location and state is the sole dependent variable. The independent variables for monatomic molecules are time, the three spatial coordinates and the three components of molecular velocity. Those describe a six-dimensional phase space.<sup>4</sup> For diatomic or polyatomic molecules, the dimension of phase space is increased by the number of internal degrees of freedom. Orientation adds an extra dimension for molecules that are not spherically symmetric. Finally, for mixtures of gases, separate probability distribution functions are required for each species. Clearly, the complexity of the approach increases dramatically as the dimension of phase space increases. The simplest problems are, for example, those for steady, one-dimensional flow of a simple monatomic gas.

To simplify the problem we restrict the discussion here to monatomic gases having no internal degrees of freedom. Furthermore, the fluid is restricted to dilute gases, and molecular chaos is assumed. The former restriction requires the average distance between molecules,  $\delta$ , to be an order of magnitude larger than their diameter,  $\sigma$ . That will almost guarantee that all collisions between molecules are binary collisions, avoiding the complexity of modeling multiple encounters.<sup>5</sup> The molecular chaos restriction improves the accuracy of computing the macroscopic quantities from the microscopic information. In essence, the volume over which averages are computed has to have sufficient number of molecules to reduce statistical errors. It can be shown that computing macroscopic flow properties by averaging over a number of molecules will result in statistical fluctuations with a standard deviation of approximately 0.1% if one million molecules are used and around 3% if one thousand molecules are used. The molecular chaos limit requires the length scale  $L$  for the averaging process to be at least 100 times the average distance between molecules (i.e., typically averaging over at least one million molecules).

Figure 4.7, adapted from Bird (1994), shows the limits of validity of the dilute gas approximation ( $\delta/\sigma > 7$ ), the continuum approach ( $Kn < 0.1$ , as discussed previously) and the neglect of statistical fluctuations ( $L/\delta > 100$ ). Using a molecular diameter of  $\sigma = 4 \times 10^{-10}$  m as an example, the three limits are conveniently expressed as functions of the normalized gas density  $\rho/\rho_o$  or number density  $n/n_o$ , where the reference densities  $\rho_o$  and  $n_o$  are computed at standard conditions. All three limits are straight lines in the log-log plot of  $L$  vs.  $\rho/\rho_o$ , as depicted in Figure 4.7. Note the shaded triangular wedge inside which both the Boltzmann and Navier–Stokes equations are valid. Additionally, the lines describing the three limits very nearly intersect at a single point. As a consequence, the continuum breakdown limit always lies between the dilute gas limit and the limit for molecular chaos. As density or characteristic dimension is reduced in a dilute gas, the Navier–Stokes model breaks down before the level of statistical fluctuations becomes significant. In a dense gas, on the other hand, significant fluctuations may be present even when the Navier–Stokes model is still valid.

The starting point in statistical mechanics is the Liouville equation, which expresses the conservation of the  $N$ -particle distribution function in  $6N$ -dimensional phase space,<sup>6</sup> where  $N$  is the number of particles

<sup>4</sup>The evolution equation of the probability distribution is considered; hence, time is the seventh independent variable.

<sup>5</sup>Dissociation and ionization phenomena involve triple collisions and therefore require separate treatment.

<sup>6</sup>Three positions and three velocities for *each* molecule of a monatomic gas with no internal degrees of freedom.

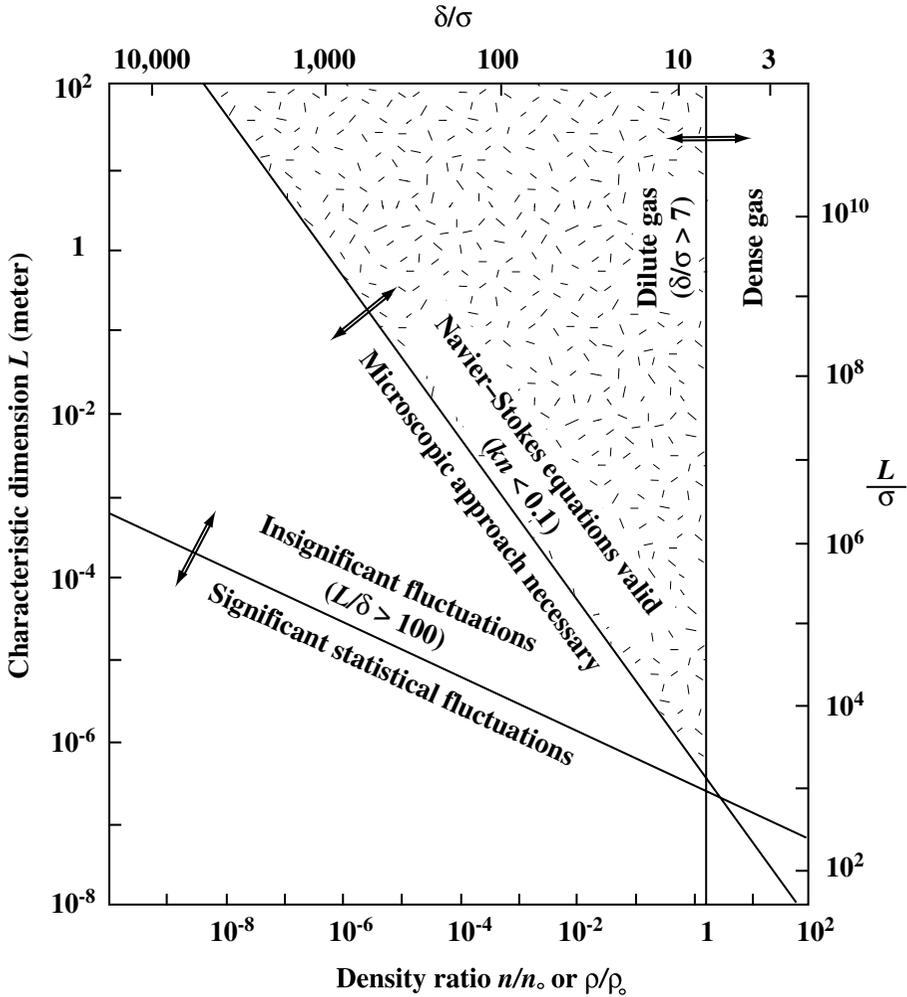

FIGURE 4.7 Effective limits of different flow models. (From Bird, G.A. (1994) *Molecular Gas Dynamics and the Direct Simulation of Gas Flows*, Clarendon Press, Oxford. With permission.)

under consideration. Considering only external forces that do not depend on the velocity of the molecules,<sup>7</sup> the Liouville equation for a system of  $N$  mass points reads:

$$\frac{\partial \mathcal{F}}{\partial t} + \sum_{k=1}^N \vec{\xi}_k \cdot \frac{\partial \mathcal{F}}{\partial \vec{x}_k} + \sum_{k=1}^N \vec{F}_k \cdot \frac{\partial \mathcal{F}}{\partial \vec{\xi}_k} = 0 \quad (4.51)$$

where  $\mathcal{F}$  is the probability of finding a molecule at a particular point in phase space,  $t$  is time,  $\vec{\xi}_k$  is the three-dimensional velocity vector for the  $k$ th molecule,  $\vec{x}_k$  is the three-dimensional position vector for the  $k$ th molecule and  $\vec{F}_k$  is the external force vector. Note that the dot product in the above equation is carried out over each of the three components of the vectors  $\vec{\xi}_k$ ,  $\vec{x}_k$  and  $\vec{F}_k$ , and that the summation is over all molecules. Obviously such an equation is not tractable for realistic number of particles.

A hierarchy of reduced distribution functions may be obtained by repeated integration of the Liouville equation above. The final equation in the hierarchy is for the single-particle distribution, which also

<sup>7</sup>This excludes Lorentz forces, for example.

involves the two-particle distribution function. Assuming molecular chaos, that final equation becomes a closed one (i.e., one equation in one unknown) and is known as the Boltzmann equation, the fundamental relation of the kinetic theory of gases. That final equation in the hierarchy is the only one that carries any hope of obtaining analytical solutions.

A simpler direct derivation of the Boltzmann equation is provided by Bird (1994). For monatomic gas molecules in binary collisions, the integro-differential Boltzmann equation reads:

$$\frac{\partial(nf)}{\partial t} + \xi_j \frac{\partial(nf)}{\partial x_j} + F_j \frac{\partial(nf)}{\partial \xi_j} = J(f, f^*), \quad j = 1, 2, 3 \quad (4.52)$$

where  $nf$  is the product of the number density and the normalized velocity distribution function ( $dn/n = f d\vec{\xi}$ );  $x_j$  and  $\xi_j$  are, respectively, the coordinates and speeds of a molecule;<sup>8</sup>  $F_j$  is a known external force;  $J(f, f^*)$  is the nonlinear collision integral that describes the net effect of populating and depopulating collisions on the distribution function. The collision integral is the source of difficulty in obtaining analytical solutions to the Boltzmann equation, and is given by:

$$J(f, f^*) = \int_{-\infty}^{\infty} \int_0^{4\pi} n^2 (f f_1^* - f_1 f^*) \xi_r \sigma d\Omega (d\vec{\xi})_1 \quad (4.53)$$

where the superscript \* indicates post-collision values,  $f$  and  $f_1$  represent two different molecules,  $\xi_r$  is the relative speed between two molecules,  $\sigma$  is the molecular cross-section,  $\Omega$  is the solid angle, and  $d\vec{\xi} = d\xi_1 d\xi_2 d\xi_3$ .

Once a solution for  $f$  is obtained, macroscopic quantities, such as density, velocity, temperature, etc., can be computed from the appropriate weighted integral of the distribution function. For example,

$$\rho = mn = m \int (nf) d\vec{\xi} \quad (4.54)$$

$$u_i = \int \xi_i f d\vec{\xi} \quad (4.55)$$

$$\frac{3}{2} kT = \int \frac{1}{2} m \xi_i \xi_i f d\vec{\xi} \quad (4.56)$$

If the Boltzmann equation is nondimensionalized with a characteristic length  $L$  and characteristic speed  $[2(k/m)T]^{1/2}$ , where  $k$  is the Boltzmann constant,  $m$  is the molecular mass, and  $T$  is temperature, the inverse Knudsen number appears explicitly in the right-hand side of the equation as follows:

$$\frac{\partial \hat{f}}{\partial \hat{t}} + \hat{\xi}_j \frac{\partial \hat{f}}{\partial \hat{x}_j} + \hat{F}_j \frac{\partial \hat{f}}{\partial \hat{\xi}_j} = \frac{1}{Kn} \hat{J}(\hat{f}, \hat{f}^*), \quad j = 1, 2, 3 \quad (4.57)$$

where the topping symbol  $\hat{\phantom{x}}$  represents a dimensionless variable, and  $\hat{f}$  is nondimensionalized using a reference number density  $n_0$ .

The five conservation equations for the transport of mass, momentum and energy can be derived by multiplying the Boltzmann equation above by, respectively, the molecular mass, momentum and energy, then integrating over all possible molecular velocities. Subject to the restrictions of dilute gas and molecular chaos stated earlier, the Boltzmann equation is valid for all ranges of Knudsen number from 0 to  $\infty$ . Analytical solutions to this equation for arbitrary geometries are difficult mostly because of the

<sup>8</sup> Constituting, together with time, the seven independent variables of the single-dependent-variable equation.

nonlinearity of the collision integral. Simple models of this integral have been proposed to facilitate analytical solutions; see, for example, Bhatnagar et al. (1954).

There are two important asymptotes to Eq. (4.57). First, as  $Kn \rightarrow \infty$ , molecular collisions become unimportant. This is the free-molecule-flow regime depicted in Figure 4.2 for  $Kn > 10$ , where the only important collision is that between a gas molecule and the solid surface of an obstacle or a conduit. Analytical solutions are then possible for simple geometries, and numerical simulations for complicated geometries are straightforward once the surface-reflection characteristics are accurately modeled. Second, as  $Kn \rightarrow 0$ , collisions become important and the flow approaches the continuum regime of conventional fluid dynamics. The Second Law specifies a tendency for thermodynamic systems to revert to equilibrium state, smoothing out any discontinuities in macroscopic flow quantities. The number of molecular collisions in the limit  $Kn \rightarrow 0$  is so large that the flow approaches the equilibrium state in a time short compared to the macroscopic time scale. For example, for air at standard conditions ( $T = 288 \text{ K}$ ;  $p = 1 \text{ atm}$ ), each molecule experiences, on the average, 10 collisions per nanosecond and travels  $1 \mu\text{m}$  in the same time period. Such a molecule has already *forgotten* its previous state after 1 ns. In a particular flowfield, if the macroscopic quantities vary little over a distance of  $1 \mu\text{m}$  or over a time interval of 1 ns, the flow of standard temperature and pressure (STP) air is near equilibrium.

At  $Kn = 0$ , the velocity distribution function is everywhere of the local equilibrium or Maxwellian form:

$$\widehat{f}^{(0)} = \frac{n}{n_o} \pi^{-3/2} \exp[-(\widehat{\xi} - \widehat{u})^2] \quad (4.58)$$

where  $\widehat{\xi}$  and  $\widehat{u}$  are, respectively, the dimensionless speeds of a molecule and the flow. In this Knudsen number limit, the velocity distribution of each element of the fluid instantaneously adjusts to the equilibrium thermodynamic state appropriate to the local macroscopic properties as this molecule moves through the flowfield. From the continuum viewpoint, the flow is isentropic and heat conduction and viscous diffusion and dissipation vanish from the continuum conservation relations.

The Chapman–Enskog theory attempts to solve the Boltzmann equation by considering a small perturbation of  $\widehat{f}$  from the equilibrium Maxwellian form. For small Knudsen numbers, the distribution function can be expanded in terms of  $Kn$  in the form of a power series:

$$\widehat{f} = \widehat{f}^{(0)} + Kn\widehat{f}^{(1)} + Kn^2\widehat{f}^{(2)} + \dots \quad (4.59)$$

By substituting the above series in the Boltzmann Eq. (4.57) and equating terms of equal order, the following recurrent set of integral equations result:

$$\begin{aligned} \widehat{J}(\widehat{f}^{(0)}, \widehat{f}^{(0)}) &= 0 \\ \widehat{J}(\widehat{f}^{(0)}, \widehat{f}^{(0)}) &= \frac{\partial \widehat{f}}{\partial \widehat{t}} + \widehat{\xi}_j \frac{\partial \widehat{f}^{(0)}}{\partial \widehat{x}_j} + \widehat{F}_j \frac{\partial \widehat{f}^{(0)}}{\partial \widehat{\xi}_j}, \dots \end{aligned} \quad (4.60)$$

The first integral is nonlinear and its solution is the local Maxwellian distribution, Eq. (4.58). The distribution functions  $\widehat{f}^{(1)}$ ,  $\widehat{f}^{(2)}$ , etc. each satisfies an inhomogeneous linear equation whose solution leads to the transport terms needed to close the continuum equations appropriate to the particular level of approximation. The continuum stress tensor and heat flux vector can be written in terms of the distribution function, which in turn can be specified in terms of the macroscopic velocity and temperature and their derivatives [Kogan, 1973]. The zeroth-order equation yields the Euler equations, the first-order equation results in the linear transport terms of the Navier–Stokes equations, the second-order equation gives the nonlinear transport terms of the Burnett equations, and so on. Keep in mind, however, that

the Boltzmann equation as developed in this section is for a monatomic gas. This excludes the all important air which is composed largely of diatomic nitrogen and oxygen.

As discussed earlier, the Navier–Stokes equations can and should be used up to a Knudsen number of 0.1. Beyond that, the transition flow regime commences ( $0.1 < Kn < 10$ ). In this flow regime, the molecular mean free path for a gas becomes significant relative to a characteristic distance for important flow-property changes to take place. The Burnett equations can be used to obtain analytical/numerical solutions for at least a portion of the transition regime for a monatomic gas, although their complexity has precluded much results for realistic geometries [Agarwal et al., 1999]. A certain degree of uncertainty also exists about the proper boundary conditions to use with the continuum Burnett equations, and experimental validation of the results has been very scarce. Additionally, as the gas flow further departs from equilibrium, the bulk viscosity ( $= \lambda + \frac{2}{3} \mu$ , where  $\lambda$  is the second coefficient of viscosity) is no longer zero, and Stokes' hypothesis no longer holds (see Gad-el-Hak, 1995, for an interesting summary of the issue of bulk viscosity).

In the transition regime, the molecularly based Boltzmann equation cannot easily be solved either, unless the nonlinear collision integral is simplified. So, clearly the transition regime is one in dire need of alternative methods of solution. MD simulations as mentioned earlier are not suited for dilute gases. The best approach for the transition regime right now is the direct simulation Monte Carlo (DSMC) method developed by Bird (1963; 1965; 1976; 1978; 1994) and briefly described below. Some recent reviews of DSMC include those by Muntz (1989), Cheng (1993), Cheng and Emmanuel (1995) and Oran et al. (1998). The mechanics as well as the history of the DSMC approach and its ancestors are well described in the book by Bird (1994).

Unlike molecular dynamics simulations, DSMC is a statistical computational approach to solving rarefied gas problems. Both approaches treat the gas as discrete particles. Subject to the dilute gas and molecular chaos assumptions, the direct simulation Monte Carlo method is valid for all ranges of Knudsen number, although it becomes quite expensive for  $Kn < 0.1$ . Fortunately, this is the continuum regime where the Navier–Stokes equations can be used analytically or computationally. DSMC is therefore ideal for the transition regime ( $0.1 < Kn < 10$ ), where the Boltzmann equation is difficult to solve. The Monte Carlo method is, like its namesake, a random number strategy based directly on the physics of the individual molecular interactions. The idea is to track a large number of randomly selected, statistically representative particles and to use their motions and interactions to modify their positions and states. The primary approximation of the direct simulation Monte Carlo method is to uncouple the molecular motions and the intermolecular collisions over small time intervals. A significant advantage of this approximation is that the amount of computation required is proportional to  $N$ , in contrast to  $N^2$  for molecular dynamics simulations. In essence, particle motions are modeled deterministically while collisions are treated probabilistically, each simulated molecule representing a large number of actual molecules. Typical computer runs of DSMC in the 1990s involve tens of millions of intermolecular collisions and fluid–solid interactions.

The DSMC computation is started from some initial condition and followed in small time steps that can be related to physical time. Colliding pairs of molecules in a small geometric cell in physical space are randomly selected after each computational time step. Complex physics such as radiation, chemical reactions and species concentrations can be included in the simulations without the necessity of non-equilibrium thermodynamic assumptions that commonly afflict nonequilibrium continuum-flow calculations. DSMC is more computationally intensive than classical continuum simulations and should therefore be used only when the continuum approach is not feasible.

The DSMC technique is explicit and time marching, and therefore always produces unsteady flow simulations. For macroscopically steady flows, Monte Carlo simulation proceeds until a steady flow is established, within a desired accuracy, at sufficiently large time. The macroscopic flow quantities are then the time average of all values calculated after reaching the steady state. For macroscopically unsteady flows, ensemble averaging of many independent Monte Carlo simulations is carried out to obtain the final results within a prescribed statistical accuracy.

## 4.8 Liquid Flows

From the continuum point of view, liquids and gases are both fluids obeying the same equations of motion. For incompressible flows, for example, the Reynolds number is the primary dimensionless parameter that determines the nature of the flowfield. True, water, for example, has density and viscosity that are, respectively, three and two orders of magnitude higher than those for air, but if the Reynolds number and geometry are matched, liquid and gas flows should be identical.<sup>9</sup> For MEMS applications, however, we anticipate the possibility of nonequilibrium flow conditions and the consequent invalidity of the Navier–Stokes equations and the no-slip-boundary conditions. Such circumstances can best be researched using the molecular approach. This was discussed for gases earlier, and the corresponding arguments for liquids will be given in the present section. The literature on non-Newtonian fluids in general and polymers in particular is vast (for example, the bibliographic survey by Nadolink and Haigh, 1995, cites over 4900 references on polymer drag reduction alone) and provides a rich source of information on the molecular approach for liquid flows.

Solids, liquids and gases are distinguished merely by the degree of proximity and the intensity of motions of their constituent molecules. In solids, the molecules are packed closely and confined, each hemmed in by its neighbors [Chapman and Cowling, 1970]. Only rarely would one solid molecule slip from its neighbors to join a new set. As the solid is heated, molecular motion becomes more violent and a slight thermal expansion takes place. At a certain temperature that depends on ambient pressure, sufficiently intense motion of the molecules enables them to pass freely from one set of neighbors to another. The molecules are no longer confined but are nevertheless still closely packed, and the substance is now considered a liquid. Further heating of the matter eventually releases the molecules altogether, allowing them to break the bonds of their mutual attractions. Unlike solids and liquids, the resulting gas expands to fill any volume available to it.

Unlike solids, both liquids and gases cannot resist finite shear force without continuous deformation—that is, the definition of a fluid medium. In contrast to the reversible, elastic, static deformation of a solid, the continuous deformation of a fluid resulting from the application of a shear stress results in an irreversible work that eventually becomes random thermal motion of the molecules—viscous dissipation. Around 25 million molecules of STP air are in a 1- $\mu\text{m}$  cube. The same cube would contain around 34 billion molecules of water. So, liquid flows are a continuum even in extremely small devices through which gas flows would not be. The average distance between molecules in the gas example is one order of magnitude higher than the diameter of its molecules, while that for the liquid phase approaches the molecular diameter. As a result, liquids are almost incompressible. Their isothermal compressibility coefficient  $\alpha$  and bulk expansion coefficient  $\beta$  are much smaller compared to those for gases. For water, for example, a hundredfold increase in pressure leads to less than 0.5% decrease in volume. Sound speeds through liquids are also high relative to those for gases, and as a result most liquid flows are incompressible,<sup>10</sup> the exception being propagation of ultra-high-frequency sound waves and cavitation phenomena.

The mechanism by which liquids transport mass, momentum and energy must be very different from that for gases. In dilute gases, intermolecular forces play no role, and the molecules spend most of their time in free flight between brief collisions at which instances the direction and speed of the molecules abruptly change. The random molecular motions are responsible for gaseous transport processes. In liquids, on the other hand, the molecules are closely packed though not fixed in one position. In essence, the liquid molecules are always in a collision state. Applying a shear force must create a velocity gradient so that the molecules move relative to one another, *ad infinitum* as long as the stress is applied. For liquids, momentum transport due to the random molecular motion is negligible compared to that due to the intermolecular forces. The straining between liquid molecules causes some to separate from their original neighbors, bringing them into the force field of new molecules. Across the plane of the shear stress, the

<sup>9</sup> Barring phenomena unique to liquids such as cavitation, free surface flows, etc.

<sup>10</sup> Note that we distinguish between a fluid and a flow as being compressible or incompressible. For example, the flow of the highly compressible air can be either compressible or incompressible.

sum of all intermolecular forces must, on the average, balance the imposed shear. Liquids at rest transmit only normal force, but when a velocity gradient occurs the net intermolecular force would have a tangential component.

The incompressible Navier–Stokes equations describe liquid flows under most circumstances. Liquids, however, do not have a well-advanced molecular-based theory as dilute gases do. The concept of mean free path is not very useful for liquids, and the conditions under which a liquid flow fails to be in quasi-equilibrium state are not well defined. There is no Knudsen number for liquid flows to guide us through the maze. We do not know, from first principles, the conditions under which the no-slip-boundary condition becomes inaccurate, or the point at which the stress–rate-of-strain relation or the heat-flux–temperature-gradient relation fails to be linear. Certain empirical observations indicate that those simple relations that we take for granted occasionally fail to accurately model liquid flows. For example, it has been shown in rheological studies [Loose and Hess, 1989] that non-Newtonian behavior commences when the strain rate approximately exceeds twice the molecular frequency scale:

$$\dot{\gamma} = \frac{\partial u}{\partial y} \geq 2\mathcal{T}^{-1} \quad (4.61)$$

where the molecular time-scale  $\mathcal{T}$  is given by:

$$\mathcal{T} = \left[ \frac{m\sigma^2}{\epsilon} \right]^{\frac{1}{2}} \quad (4.62)$$

where  $m$  is the molecular mass, and  $\sigma$  and  $\epsilon$  are, respectively, the characteristic length and energy scale for the molecules. For ordinary liquids such as water, this time scale is extremely small, and the threshold shear rate for the onset of non-Newtonian behavior is therefore extraordinarily high. For high-molecular-weight polymers, on the other hand,  $m$  and  $\sigma$  are both many orders of magnitude higher than their respective values for water, and the linear stress–strain relation breaks down at realistic values of the shear rate.

The moving contact line when a liquid spreads on a solid substrate is an example where slip flow must be allowed to avoid singular or unrealistic behavior in the Navier–Stokes solutions [Dussan and Davis, 1974; Dussan, 1976; 1979; Thompson and Robbins, 1989]. Other examples where slip flow must be admitted include corner flows [Moffatt, 1964; Koplik and Banavar, 1995] and extrusion of polymer melts from capillary tubes [Pearson and Petrie, 1968; Richardson, 1973; Den, 1990].

Existing experimental results of liquid flow in microdevices are contradictory. This is not surprising given the difficulty of such experiments and the lack of a guiding rational theory. Pfahler et al. (1990; 1991), Pfahler (1992) and Bau (1994) summarize the relevant literature. For small-length-scale flows, a phenomenological approach for analyzing the data is to define an *apparent* viscosity  $\mu_a$  calculated so that if it were used in the traditional no-slip Navier–Stokes equations instead of the fluid viscosity  $\mu$ , the results would be in agreement with experimental observations. Israelachvili (1986) and Gee et al. (1990) found that  $\mu_a = \mu$  for thin-film flows as long as the film thickness exceeds 10 molecular layers ( $\approx 5$  nm). For thinner films,  $\mu_a$  depends on the number of molecular layers and can be as much as  $10^5$  times larger than  $\mu$ . Chan and Horn's (1985) results are somewhat different: The apparent viscosity deviates from the fluid viscosity for films thinner than 50 nm.

In polar-liquid flows through capillaries, Migun and Prokhorenko (1987) report that  $\mu_a$  increases for tubes smaller than 1  $\mu\text{m}$  in diameter. In contrast, Debye and Cleland (1959) report  $\mu_a$  smaller than  $\mu$  for paraffin flow in porous glass with average pore size several times larger than the molecular length scale. Experimenting with microchannels ranging in depths from 0.5 to 50  $\mu\text{m}$ , Pfahler et al. (1991) found that  $\mu_a$  is consistently smaller than  $\mu$  for both liquid (isopropyl alcohol, silicone oil) and gas (nitrogen, helium) flows in microchannels. For liquids, the apparent viscosity decreases with decreasing channel depth. Other researchers using small capillaries report that  $\mu_a$  is about the same as  $\mu$  [Anderson

and Quinn, 1972; Tuckermann and Pease, 1981; 1982; Tuckermann, 1984; Guvenc, 1985; Nakagawa et al., 1990].

Very recently, Sharp (2001) and Sharp et al. (2001) asserted that, despite the significant inconsistencies in the literature regarding liquid flows in microchannels, such flows are well predicted by macroscale continuum theory. A case can be made to the contrary, however, as will be seen at the end of this section, and the final verdict on this controversy is yet to come.

The above contradictory results point to the need for replacing phenomenological models by first-principles ones. The lack of a molecular-based theory of liquids—despite extensive research by the rheology and polymer communities—leaves molecular dynamics simulations as the best weapon in the first-principles arsenal. MD simulations offer a unique approach to checking the validity of the traditional continuum assumptions. However, as was pointed out earlier, such simulations are limited to exceedingly minute flow extent.

Thompson and Troian (1997) provide molecular dynamics simulations to quantify the dependence of the slip-flow-boundary condition on shear rate. Recall the linear Navier boundary condition introduced earlier:

$$\Delta u|_w = u_{\text{fluid}} - u_{\text{wall}} = L_s \left. \frac{\partial u}{\partial y} \right|_w \quad (4.63)$$

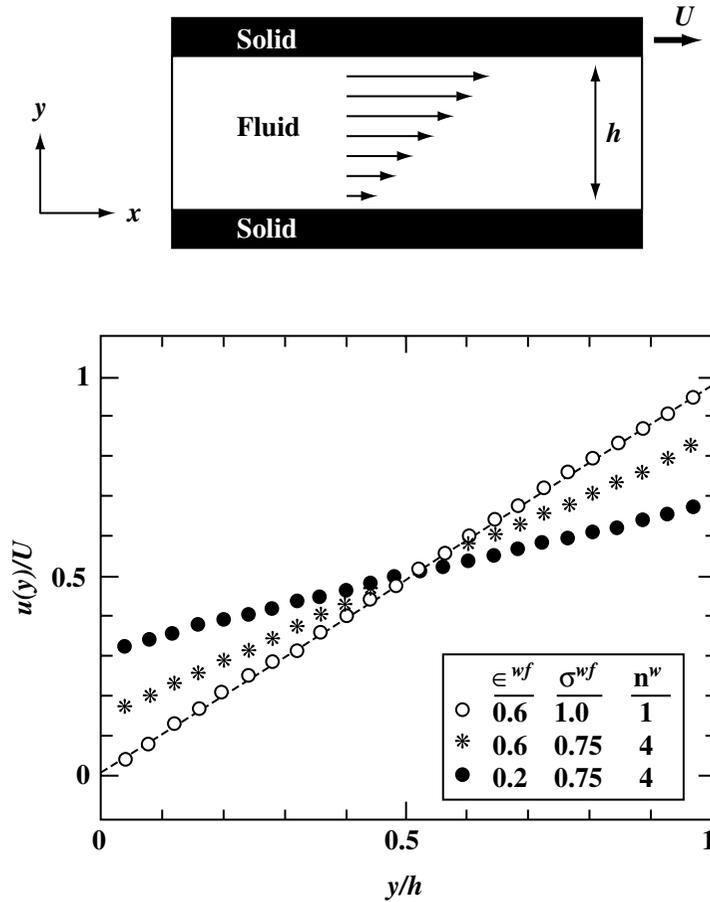

where  $L_s$  is the constant slip length, and  $\left. \frac{\partial u}{\partial y} \right|_w$  is the strain rate computed at the wall. The goal of Thompson and Troian's simulations was to determine the degree of slip at a solid–liquid interface as the interfacial parameters and the shear rate change. In their simulations, a simple liquid underwent planar shear in a Couette cell, as shown in Figure 4.8. The typical cell measured  $12.51 \times 7.22 \times h$ , in units of molecular length scale  $\sigma$ , where the channel depth  $h$  varied in the range of  $16.71 \sigma$  to  $24.57 \sigma$ , and the corresponding number of molecules simulated ranged from 1152 to 1728. The liquid is treated as an isothermal ensemble of spherical molecules. A shifted Lennard–Jones 6–12 potential is used to model intermolecular interactions, with energy and length scales  $\epsilon$  and  $\sigma$  and cut-off distance  $r_c = 2.2\sigma$ :

$$V(r) = 4\epsilon \left[ \left( \frac{r}{\sigma} \right)^{-12} - \left( \frac{r}{\sigma} \right)^{-6} - \left( \frac{r_c}{\sigma} \right)^{-12} + \left( \frac{r_c}{\sigma} \right)^{-6} \right] \quad (4.64)$$

The truncated potential is set to zero for  $r > r_c$ .

The fluid–solid interaction is also modeled with a truncated Lennard–Jones potential, with energy and length scales  $\epsilon^{wf}$  and  $\sigma^{wf}$  and cut-off distance  $r_c$ . The equilibrium state of the fluid is a well-defined liquid phase characterized by number density  $n = 0.81\sigma^{-3}$  and temperature  $T = 1.1\epsilon/k$ , where  $k$  is the Boltzmann constant.

The steady-state velocity profiles resulting from Thompson and Troian's (1997) MD simulations are depicted in Figure 4.8 for different values of the interfacial parameters  $\epsilon^{wf}$ ,  $\sigma^{wf}$  and  $n^w$ . Those parameters, shown in units of the corresponding fluid parameters  $\epsilon$ ,  $\sigma$  and  $n$ , characterize, respectively, the strength of the liquid–solid coupling, the thermal roughness of the interface and the commensurability of wall and liquid densities. The macroscopic velocity profiles recover the expected flow behavior from continuum hydrodynamics with boundary conditions involving varying degrees of slip. Note that when slip exists, the shear rate  $\dot{\gamma}$  no longer equals  $U/h$ . The degree of slip increases (i.e., the amount of momentum transfer at the wall–fluid interface decreases) as the relative wall density  $n^w$  increases or the strength of the wall–fluid coupling  $\sigma^{wf}$  decreases—in other words, when the relative surface energy corrugation of the wall decreases. Conversely, the corrugation is maximized when the wall and fluid densities are commensurate and the strength of the wall–fluid coupling is large. In this case, the liquid *feels* the corrugations in the surface energy of the solid owing to the atomic close packing. Consequently,

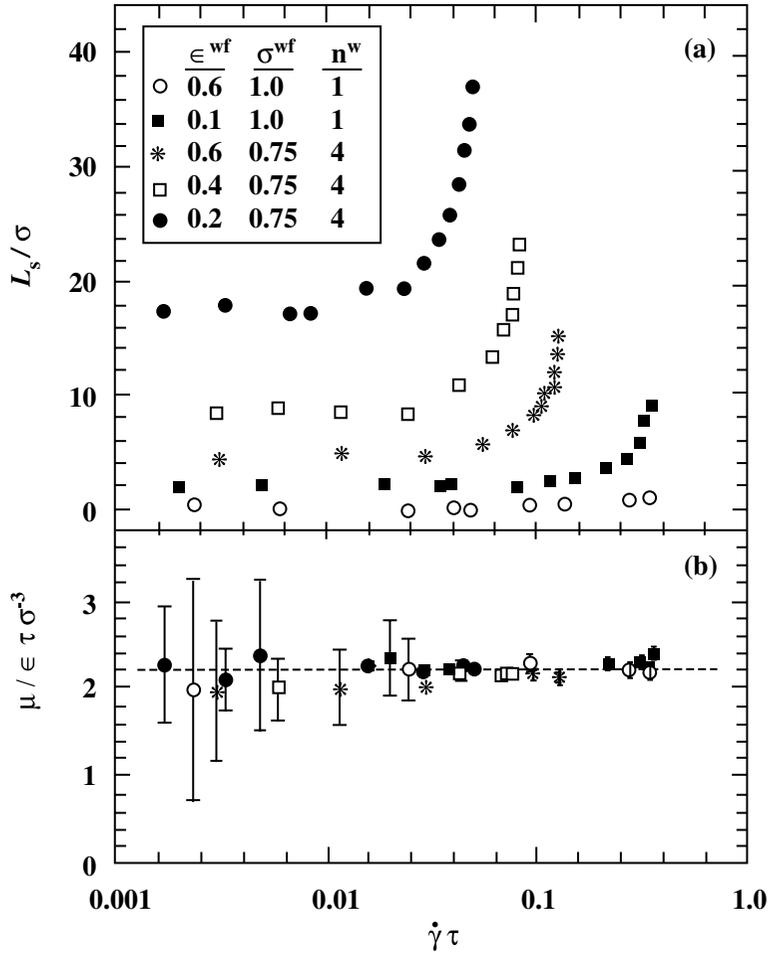

**FIGURE 4.8** Velocity profiles in a Couette flow geometry at different interfacial parameters. All three profiles are for  $U = \sigma \mathcal{T}^{-1}$ , and  $h = 24.57\sigma$ . The dashed line is the no-slip Couette-flow solution. (From Thompson, P.A., and Troian, S.M. (1997) *Phys. Rev. Lett.* **63**, pp. 766–769. With permission.)

there is efficient momentum transfer and the no-slip condition applies, or in extreme cases, a “stick” boundary condition takes hold.

Variations of the slip length  $L_s$  and viscosity  $\mu$  as functions of shear rate  $\dot{\gamma}$  are shown in parts (a) and (b) of [Figure 4.9](#), for five different sets of interfacial parameters. For Couette flow, the slip length is computed from its definition,  $\Delta u|_w / \dot{\gamma} = (U/\dot{\gamma} - h)/2$ . The slip length, viscosity and shear rate are normalized in the figure using the respective molecular scales for length  $\sigma$ , viscosity  $\epsilon \mathcal{T} \sigma^{-3}$  and inverse time  $\mathcal{T}^{-1}$ . The viscosity of the fluid is constant over the entire range of shear rates ([Figure 4.9b](#)), indicating Newtonian behavior. As indicated earlier, non-Newtonian behavior is expected for  $\dot{\gamma} \geq 2\mathcal{T}^{-1}$ , well above the shear rates used in Thompson and Troian’s simulations.

At low shear rates, the slip length behavior is consistent with the Navier model (i.e., is independent of the shear rate). Its limiting value  $L_s^0$  ranges from 0 to  $\sim 17\sigma$  for the range of interfacial parameters chosen ([Figure 4.9a](#)). In general, the amount of slip increases with decreasing surface-energy corrugation. Most interestingly, at high shear rates, the Navier condition breaks down as the slip length increases rapidly with  $\dot{\gamma}$ . The critical shear-rate value for the slip length to diverge,  $\dot{\gamma}_c$ , decreases as the surface energy corrugation decreases. Surprisingly, the boundary condition is nonlinear even though the liquid is still Newtonian. In dilute gases, the linear slip condition and the Navier–Stokes equations, with their linear stress–strain relation, are both valid to the same order of approximation in Knudsen number. In other

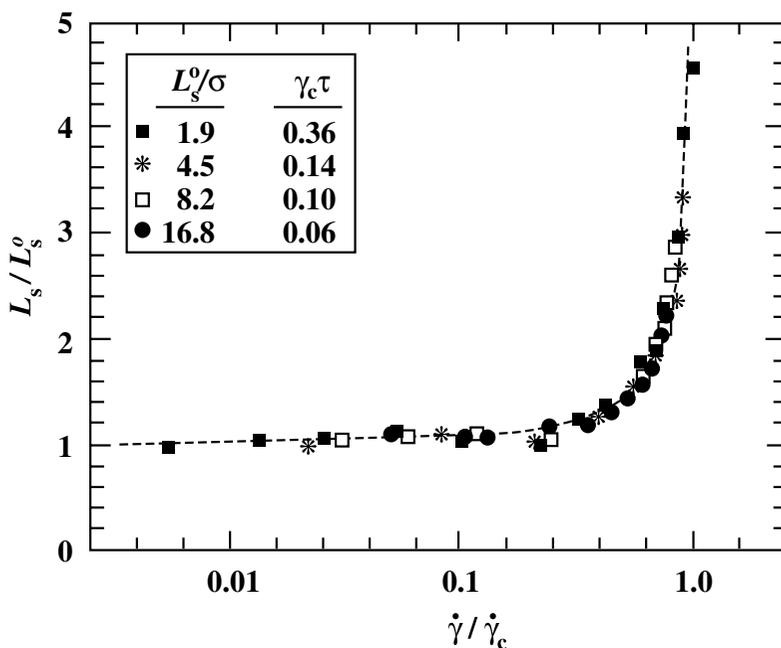

**FIGURE 4.9** Variation of slip length and viscosity as functions of shear rate. (From Thompson, P.A., and Troian, S.M. (1997) *Phys. Rev. Lett.* **63**, pp. 766–769. With permission.)

words, deviation from linearity is expected to take place at the same value of  $Kn = 0.1$ . In liquids, in contrast, the slip length appears to become nonlinear and to diverge at a critical value of shear rate well below the shear rate at which the linear stress–strain relation fails. Moreover, the boundary condition deviation from linearity is not gradual but is rather catastrophic. The critical value of shear rate  $\dot{\gamma}_c$  signals the point at which the solid can no longer impart momentum to the liquid. This means that the same liquid molecules sheared against different substrates will experience varying amounts of slip and vice versa.

Based on the above results, Thompson and Troian (1997) suggest a universal boundary condition at a solid–liquid interface. Scaling the slip length  $L_s$  by its asymptotic limiting value  $L_s^o$  and the shear rate  $\dot{\gamma}$  by its critical value  $\dot{\gamma}_c$  collapses the data in the single curve shown in Figure 4.10. The data points are well described by the relation:

$$L_s = L_s^o \left[ 1 - \frac{\dot{\gamma}}{\dot{\gamma}_c} \right]^{-\frac{1}{2}} \quad (4.65)$$

The nonlinear behavior close to a critical shear rate suggests that the boundary condition can significantly affect flow behavior at macroscopic distances from the wall. Experiments with polymers confirm this

**FIGURE 4.10** Universal relation of slip length as a function of shear rate. (From Thompson, P.A., and Troian, S.M. (1997) *Phys. Rev. Lett.* **63**, pp. 766–769. With permission.)

observation [Atwood and Schowalter, 1989]. The rapid change in the slip length suggests that, for flows in the vicinity of  $\dot{\gamma}_c$ , small changes in surface properties can lead to large fluctuations in the apparent boundary condition. Thompson and Troian (1997) conclude that the Navier slip condition is but the low-shear-rate limit of a more generalized universal relationship which is nonlinear and divergent. Their relation provides a mechanism for relieving the stress singularity in spreading contact lines and corner flows, as it naturally allows for varying degrees of slip on approach to regions of higher rate of strain.

To place the above results in physical terms, consider water<sup>11</sup> at a temperature of  $T = 288$  K. The energy scale in the Lennard–Jones potential is then  $\epsilon = 3.62 \times 10^{-21}$  J. For water,  $m = 2.99 \times 10^{-26}$  kg,  $\sigma = 2.99 \times 10^{-10}$  m, and at standard temperature  $n = 3.35 \times 10^{28}$  molecules/m<sup>3</sup>. The molecular time scale can thus be computed as  $\mathcal{T} = [m\sigma^2/\epsilon]^{1/2} = 8.31 \times 10^{-13}$  s. For the third case depicted in Figure 4.10 (the open squares),  $\dot{\gamma}_c \mathcal{T} = 0.1$ , and the critical shear rate at which the slip condition diverges is thus  $\dot{\gamma}_c = 1.2 \times 10^{11}$  s<sup>-1</sup>. Such an enormous rate of strain<sup>12</sup> may be found in extremely small devices having extremely high speeds. On the other hand, the conditions to achieve a measurable slip of  $17\sigma$  (the solid circles in Figure 4.9) are not difficult to encounter in microdevices: a density of the solid four times that of the liquid and an energy scale for the wall–fluid interaction that is one fifth the energy scale for the liquid.

The limiting value of slip length is independent of the shear rate and can be computed for water as  $L_s^o = 17\sigma = 4.91 \times 10^{-9}$  m. Consider a water microbearing having a shaft diameter of 100  $\mu\text{m}$ , rotation rate of 20,000 rpm and minimum gap of  $h = 1$   $\mu\text{m}$ . In this case,  $U = 0.1$  m/s and the no-slip shear rate is  $U/h = 10^5$  s<sup>-1</sup>. When slip occurs at the limiting value just computed, the shear rate and the wall slip

<sup>11</sup>Water molecules are complex ones, forming directional, short-range covalent bonds, thus requiring a more complex potential than the Lennard–Jones (L–J) to describe the intermolecular interactions. For the purpose of the qualitative example described here, however, we use the computational results of Thompson and Troian (1997) who employed the L–J potential.

<sup>12</sup>Note, however, that  $\dot{\gamma}_c$  for high-molecular-weight polymers would be many orders of magnitude smaller than the value developed here for water.

velocity are computed as follows:

$$\dot{\gamma} = \frac{U}{h + 2L_s^o} = 9.90 \times 10^4 \text{ s}^{-1} \quad (4.66)$$

$$\Delta u|_w = \dot{\gamma}L_s = 4.87 \times 10^{-4} \text{ m/s} \quad (4.67)$$

As a result of the Navier slip, the shear rate is reduced by 1% from its no-slip value, and the slip velocity at the wall is about 0.5% of  $U$ , small but not insignificant.

## 4.9 Surface Phenomena

The surface-to-volume ratio for a machine with a characteristic length of 1 m is  $1 \text{ m}^{-1}$ , while that for a MEMS device having a size of  $1 \mu\text{m}$  is  $10^6 \text{ m}^{-1}$ . The million-fold increase in surface area relative to the mass of the minute device substantially affects the transport of mass, momentum and energy through the surface. Obviously surface effects dominate in small devices. The surface boundary conditions in MEMS flows have already been discussed earlier. In microdevices, it has been shown that it is possible to have measurable slip-velocity and temperature jump at a solid–fluid interface. In this section, we illustrate other ramifications of the large surface-to-volume ratio unique to MEMS, and provide a molecular viewpoint to surface forces.

In microdevices, both radiative and convective heat loss/gain are enhanced by the huge surface-to-volume ratio. Consider a device having a characteristic length  $L_s$ . Use of the lumped capacitance method to compute the rate of convective heat transfer, for example, is justified if the Biot number ( $\equiv hL_s/\kappa_s$ , where  $h$  is the convective heat transfer coefficient of the fluid and  $\kappa_s$  is the thermal conductivity of the solid) is less than 0.1. Small  $L_s$  implies small Biot number and a nearly uniform temperature within the solid. Within this approximation, the rate at which heat is lost to the surrounding fluid is given by:

$$\rho_s L_s^3 c_s \frac{dT}{dt} = -hL_s^2 (T_s - T_\infty) \quad (4.68)$$

where  $\rho_s$  and  $c_s$  are, respectively, the density and specific heat of the solid;  $T_s$  is its (uniform) temperature;  $T_\infty$  is the ambient fluid temperature. Solution of the above equation is trivial, and the temperature of a hot surface drops exponentially with time from an initial temperature  $T_i$ ,

$$\frac{T_s(t) - T_\infty}{T_i - T_\infty} = \exp\left[-\frac{t}{\mathcal{T}}\right] \quad (4.69)$$

where the time constant  $\mathcal{T}$  is given by:

$$\mathcal{T} = \frac{\rho_s L_s^3 c_s}{hL_s^2} \quad (4.70)$$

For small devices, the time it takes the solid to cool down is proportionally small. Clearly, the million-fold increase in surface-to-volume ratio implies a proportional increase in the rate at which heat escapes. Identical scaling arguments can be made regarding mass transfer.

Another effect of the diminished scale is the increased importance of surface forces and the waning importance of body forces. Based on biological studies, Went (1968) concludes that the demarcation length scale is around 1 mm. Below that, surface forces dominate over gravitational forces. A 10-mm piece of paper will fall down when gently placed on a smooth, vertical wall, while a 0.1-mm piece will stick. Try it! *Stiction* is a major problem in MEMS applications. Certain structures such as long, thin

polysilicon beams and large, thin comb drives have a propensity to stick to their substrates and thus fail to perform as designed [Mastrangelo and Hsu, 1992; Tang et al., 1989].

Conventional dry friction between two solids in relative motion is proportional to the normal force, which is usually a component of the moving device weight. The friction is independent of the contact-surface area because the van der Waals cohesive forces are negligible relative to the weight of the macroscopic device. In MEMS applications, the cohesive intermolecular forces between two surfaces are significant and the stiction is independent of the device mass but is proportional to its surface area. The first micromotor did not move—despite large electric current through it—until the contact area between the 100- $\mu\text{m}$  rotor and the substrate was reduced significantly by placing dimples on the rotor's surface [Fan et al., 1988; 1989; Tai and Muller, 1989].

One last example of surface effects that, to my knowledge, has not been investigated for microflows is the adsorbed layer in gaseous wall-bounded flows. It is well known [Brunauer, 1944; Lighthill, 1963] that when a gas flows in a duct, the gas molecules are attracted to the solid surface by the van der Waals and other forces of cohesion. The potential energy of the gas molecules drops on reaching the surface. The adsorbed layer partakes the thermal vibrations of the solid, and the gas molecules can only escape when their energy exceeds the potential energy minimum. In equilibrium, at least part of the solid would be covered by a monomolecular layer of adsorbed gas molecules. Molecular species with significant partial pressure—relative to their vapor pressure—may locally form layers two or more molecules thick. Consider, for example, the flow of a mixture of dry air and water vapor at STP. The energy of adsorption of water is much larger than that for nitrogen and oxygen, making it more difficult for water molecules to escape the potential energy trap. It follows that the lifetime of water molecules in the adsorbed layer significantly exceeds that for the air molecules (by 60,000-fold, in fact) and, as a result, the thin surface layer would be mostly water. For example, if the proportion of water vapor in the ambient air is 1:1,000 (i.e., very low humidity level), the ratio of water to air in the adsorbed layer would be 60:1. Microscopic roughness of the solid surface causes partial condensation of the water along portions having sufficiently strong concave curvature. So, surfaces exposed to non-dry-air flows are mainly liquid water surfaces. In most applications, this thin adsorbed layer has little effect on the flow dynamics, despite the fact that the density and viscosity of liquid water are far greater than those for air. In MEMS applications, however, the layer thickness may not be an insignificant portion of the characteristic flow dimension and the water layer may have a measurable effect on the gas flow. A hybrid approach of molecular dynamics and continuum flow simulations or MD–Monte Carlo simulations may be used to investigate this issue.

It should be noted that recently Majumdar and Mezic (1998; 1999) have studied the stability and rupture into droplets of thin liquid films on solid surfaces. They point out that the free energy of a liquid film consists of a surface tension component as well as highly nonlinear volumetric intermolecular forces resulting from van der Waals, electrostatic, hydration and elastic strain interactions. For water films on hydrophilic surfaces such as silica and mica, Majumdar and Mezic (1998) estimate the equilibrium film thickness to be about 0.5 nm (2 monolayers) for a wide range of ambient-air relative humidities. The equilibrium thickness grows very sharply, however, as the relative humidity approaches 100%.

Majumdar and Mezic's (1998; 1999) results open many questions. What are the stability characteristics of their water film in the presence of air flow above it? Would this water film affect the accommodation coefficient for microduct air flow? In a modern Winchester-type hard disk, the drive mechanism has a read/write head that floats 50 nm above the surface of the spinning platter. The head and platter together with the air layer in between form a slider bearing. Would the computer performance be affected adversely by the high relative humidity on a particular day when the adsorbed water film is no longer "thin"? If a microduct hauls liquid water, would the water film adsorbed by the solid walls influence the effective viscosity of the water flow? Electrostatic forces can extend to almost 1  $\mu\text{m}$  (the Debye length), and that length is known to be highly pH dependent. Would the water flow be influenced by the surface and liquid chemistry? Would this explain the contradictory experimental results of liquid flows in microducts discussed earlier?

The few examples above illustrate the importance of surface effects in small devices. From the continuum viewpoint, forces at a solid–fluid interface are the limit of pressure and viscous forces acting on

a parallel elementary area displaced into the fluid, when the displacement distance is allowed to tend to zero. From the molecular point of view, all macroscopic surface forces are ultimately traced to intermolecular forces, a subject extensively covered in the book by Israelachvili (1991) and references therein. Here we provide a very brief introduction to the molecular viewpoint. The four forces in nature are (1) the strong and (2) weak forces describing the interactions among neutrons, protons, electrons, etc.; (3) the electromagnetic forces between atoms and molecules; and (4) gravitational forces between masses. The range of action of the first two forces is around  $10^{-5}$  nm; hence, neither concerns us overly in MEMS applications. The electromagnetic forces are effective over a much larger though still small distance on the order of the interatomic separations (0.1 to 0.2 nm). Effects over longer range—several orders of magnitude longer—can and do rise from the short-range intermolecular forces. For example, the rise of liquid column in capillaries and the action of detergent molecules in removing oily dirt from fabric are the result of intermolecular interactions. Gravitational forces decay with the distance to second power, while intermolecular forces decay much quicker, typically with the seventh power. Cohesive forces are therefore negligible once the distance between molecules exceeds a few molecular diameters, while massive bodies such as stars and planets are still strongly interacting, via gravity, over astronomical distances.

Electromagnetic forces are the source of all intermolecular interactions and the cohesive forces holding atoms and molecules together in solids and liquids. They can be classified into (1) purely electrostatic arising from the Coulomb force between charges, interactions between charges, permanent dipoles, quadrupoles, etc.; (2) polarization forces arising from the dipole moments induced in atoms and molecules by the electric field of nearby charges and permanent dipoles; and (3) quantum mechanical forces that give rise to covalent or chemical bonding and to repulsive steric or exchange interactions that balance the attractive forces at very short distances. The Hellman–Feynman theorem of quantum mechanics states that once the spatial distribution of the electron clouds has been determined by solving the appropriate Schrödinger equation, intermolecular forces may be calculated on the basis of classical electrostatics, in effect reducing all intermolecular forces to Coulombic forces. Note, however, that intermolecular forces exist even when the molecules are totally neutral. Solutions of the Schrödinger equation for general atoms and molecules are not easy, of course, and alternative modeling are sought to represent intermolecular forces. The van der Waals attractive forces are usually represented with a potential that varies as the inverse sixth power of distance, while the repulsive forces are represented with either a power or an exponential potential.

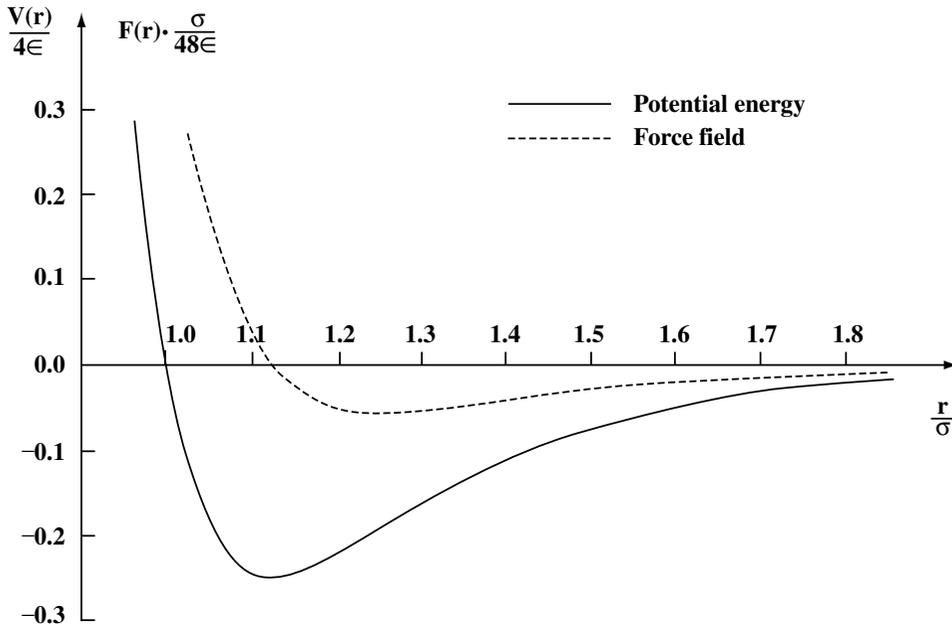

A commonly used potential between two molecules is the generalized Lennard–Jones (L–J 6–12) pair potential given by:

$$V_{ij}(r) = 4\epsilon \left[ c_{ij} \left( \frac{r}{\sigma} \right)^{-12} - d_{ij} \left( \frac{r}{\sigma} \right)^{-6} \right] \quad (4.71)$$

where  $V_{ij}$  is the potential energy between two particles  $i$  and  $j$ ;  $r$  is the distance between the two molecules;  $\epsilon$  and  $\sigma$  are, respectively, characteristic energy and length scales; and  $c_{ij}$  and  $d_{ij}$  are parameters to be chosen for the particular fluid and solid combinations under consideration. The first term in the right-hand side is the strong repulsive force that is felt when two molecules are at extremely close range comparable to the molecular length scale. That short-range repulsion prevents overlap of the molecules in physical space. The second term is the weaker, van der Waals attractive force that commences when the molecules are sufficiently close (several times  $\sigma$ ). That negative part of the potential represents the attractive polarization interaction of neutral, spherically symmetric particles. The power of 6 associated with this term is derivable from quantum mechanics considerations, while the power of the repulsive part of the potential is found empirically. The Lennard–Jones potential is zero at very large distances, has a weak negative peak at  $r$  slightly larger than  $\sigma$ , is zero at  $r = \sigma$  and is infinite as  $r \rightarrow 0$ .

The force field resulting from this potential is given by:

$$F_{ij}(r) = -\frac{\partial V_{ij}}{\partial r} = \frac{48\epsilon}{\sigma} \left[ c_{ij} \left( \frac{r}{\sigma} \right)^{-13} - \frac{d_{ij}}{2} \left( \frac{r}{\sigma} \right)^{-7} \right] \quad (4.72)$$

**FIGURE 4.11** Typical Lennard–Jones 6–12 potential and the intermolecular force field resulting from it. Only a small portion of the potential function is shown for clarity. (From Gad-el-Hak, M. (1999) *J. Fluids Eng.* **121**, pp. 5–33, ASME, New York. With permission.)

A typical L–J 6–12 potential and force field are shown in [Figure 4.11](#), for  $c = d = 1$ . The minimum potential  $V_{\min} = -\epsilon$  corresponds to the equilibrium position (zero force) and occurs at  $r = 1.12\sigma$ . The attractive van der Waals contribution to the minimum potential is  $-2\epsilon$ , while the repulsive energy contribution is  $+\epsilon$ . Thus, the inverse 12th-power repulsive force term decreases the strength of the binding energy at equilibrium by 50%.

The L–J potential is commonly used in molecular dynamics simulations to model intermolecular interactions between dense gas or liquid molecules and between fluid and solid molecules. As mentioned earlier, such potential is not accurate for complex substances such as water whose molecules form directional covalent bonds. As a result, MD simulations for water are much more involved.

## 4.10 Parting Remarks

The 40-year-old vision of Richard Feynman of building minute machines is now a reality. Microelectromechanical systems have witnessed explosive growth during the last decade and are finding increased applications in a variety of industrial and medical fields. The physics of fluid flows in microdevices has been explored in this chapter. While we now know considerably more than we did just few years ago, much physics remains to be explored so that rational tools can be developed for the design, fabrication and operation of MEMS devices.

The traditional Navier–Stokes model of fluid flows with no-slip-boundary conditions works only for a certain range of the governing parameters. This model basically demands two conditions: (1) The fluid is a continuum, which is almost always satisfied as there are usually more than 1 million molecules in the smallest volume in which appreciable macroscopic changes take place; this is the molecular chaos restriction. (2) The flow is not too far from thermodynamic equilibrium, which is satisfied if there is a sufficient number of molecular encounters during a time period that is small compared to the smallest time scale for flow changes. During this time period the average molecule would have moved a distance small compared to the smallest flow length scale.

For gases, the Knudsen number determines the degree of rarefaction and the applicability of traditional flow models. As  $Kn \rightarrow 0$ , the time and length scales of molecular encounters are vanishingly small compared to those for the flow, and the velocity distribution of each element of the fluid instantaneously adjusts to the equilibrium thermodynamic state appropriate to the local macroscopic properties as this molecule moves through the flowfield. From the continuum viewpoint, the flow is isentropic and heat conduction and viscous diffusion and dissipation vanish from the continuum conservation relations, leading to the Euler equations of motion. At small but finite  $Kn$ , the Navier–Stokes equations describe near-equilibrium, continuum flows.

Slip flow must be taken into account for  $Kn > 0.001$ . The slip-boundary condition is at first linear in Knudsen number, then nonlinear effects take over beyond a Knudsen number of 0.1. At the same transition regime ( $0.1 < Kn < 10$ ), the linear-stress–rate-of-strain and heat-flux–temperature-gradient relations—needed to close the Navier–Stokes equations—also break down, and alternative continuum equations (e.g., Burnett or higher order equations) or molecular-based models must be invoked. In the transition regime, provided that the dilute gas and molecular chaos assumptions hold, solutions to the difficult Boltzmann equation are sought, but physical simulations such as Monte Carlo methods are more readily executed in this range of Knudsen number. In the free-molecule-flow regime ( $Kn > 10$ ), the nonlinear collision integral is negligible and the Boltzmann equation is drastically simplified. Analytical solutions are possible in this case for simple geometries, and numerical integration of the Boltzmann equation is straightforward for arbitrary geometries, provided that the surface-reflection characteristics are accurately modeled.

Gaseous flows are often compressible in microdevices even at low Mach numbers. Viscous effects can cause sufficient pressure drop and density changes for the flow to be treated as compressible. In a long, constant-area microduct, all Knudsen number regimes may be encountered, and the degree of rarefaction increases along the tube. The pressure drop is nonlinear and the Mach number increases downstream, limited only by choked-flow condition.

Similar deviation and breakdown of the traditional Navier–Stokes equations occur for liquids as well, but there the situation is more murky. Existing experiments are contradictory. There is no kinetic theory of liquids, and first-principles prediction methods are scarce. Molecular dynamics simulations can be used, but they are limited to extremely small flow extents. Nevertheless, measurable slip is predicted from MD simulations at realistic shear rates in microdevices.

Much nontraditional physics is still to be learned and many exciting applications of microdevices are yet to be discovered. The future is bright for this emerging field of science and technology. Richard Feynman was right about the possibility of building mite-size machines but was somewhat cautious in forecasting that such machines, while they “would be fun to make,” may or may not be useful.

### 5.1 Abstract

---

Full-system simulation of microelectromechanical systems (MEMS) involves coupling of many diverse processes with disparate spatial and temporal scales. In its simplest form, all elements in a MEMS device are represented as equivalent analog circuits so that robust simulators such as SPICE can solve for the entire system. However, devices, and especially fluidic devices, do not usually have such equivalent analogs and may require full simulation of individual components. This is particularly true for new designs, which often involve unfamiliar physics; such lumped models and continuum approximations are inappropriate in this case. In this chapter, we address such issues for an integrated simulation approach for MEMS with

the ultimate objective of deriving low-dimensional models that can be used for MEMS design in full-system simulations. In particular, we present an integrated circuit and microfluidic simulator, the SPICE–NekTar simulator, which allows coupled simulation of flow, structure, thermal and electrical domains. The overall architecture and various algorithms, including the coupling of the circuit and microfluidic simulators, are described. An application of the simulator is demonstrated for a controlled microliquid dosing system using detailed numerical models for the fluid field, a low-dimensional model for the flow sensor and circuit elements for the electronic control. Unlike other simulators, which employ mostly lumped models for the various components, we formulate here a methodology for distributed systems.

## 5.2 Introduction

---

### 5.2.1 Full-System Simulation

Microelectromechanical systems (MEMS) involve complex functions governed by diverse transient physical and electrical processes for each of their many components. The design complexity and functionality complexity of MEMS exceed by far the complexity of VLSI systems. Today, however, very large-scale integration (VLSI) systems are simulated routinely thanks to the many advances in CAD and simulation tools achieved over the last two decades. It is clear that similar and even greater advances are required in the MEMS field in order to make full-system simulation of MEMS a reality in the near future. This will enable the MEMS community to explore new pathways of discovery and expand the role and influence of MEMS at a rapid rate.

To develop a systems-level simulation framework that is sufficiently accurate and robust, all processes involved must be simulated at a comparable degree of accuracy and integrated seamlessly. That is, circuits, semiconductors, springs and masses, beams and membranes as well as the flow field should be simulated in a consistent and compatible way and in reasonable computational time! This coupling of diverse domains has already been addressed by the electrical engineering community, primarily for mixed circuit-device simulation.

The combination of circuits and devices necessitates the use of different levels of description. At a first level for analog circuits represented by lumped continuum models, the use of ordinary differential equations (ODEs) and algebraic equations (AEs) is sufficient. However, some other devices and circuits can be described as digital automata, and Boolean equations of mathematical logic should be employed in the description; they correspond to digital circuit simulation on the digital level. Finally, some semiconductor devices of the kind encountered in MEMS have to be described as linear and nonlinear partial differential equations (PDEs), and they are usually employed on the device simulation level. Mixed-level simulation is implemented for digital–analog (or analog–mixed) circuit simulation and for analog circuit-device simulation. In the following, we briefly review the common practice in simulating circuits with some nonfluidic devices.

The code SPICE (Simulation Program with Integrated Circuit Emphasis) was developed in the 1970s at the University of California, Berkeley [Nagel and Pederson, 1973] and since then has become the unofficial industrial standard for integrated circuit (IC) designers. SPICE is a general-purpose simulation program for circuits that may contain resistors, capacitors, inductors, switches, transmission lines, etc., as well as the five most common semiconductor devices: diodes, bipolar junction transistors (BJTs), junction field effect transistors (JFETs), metal semiconductor field effect transistors (MESFETs) and metal oxide semiconductor field effect transistors (MOSFETs). SPICE has built-in models for the semiconductor devices, and the user specifies only the pertinent model parameter values. However, these devices are typically simple and can be described by lumped models—combinations of ordinary differential equations and algebraic equations (ODEs/AEs). In some cases, such as in submicron devices, even for usual semiconductor devices (i.e., MOSFET), simple modeling is not straightforward and it is more art than science to transfer from basic PDEs to approximated ODEs and algebraic equations. Mechanical systems can be recast into electrical systems, which can be handled by SPICE. This can be understood more clearly by considering the analogy of a mass–spring–damper system driven by an external force with a parallel-connected RLC (resistance, inductance, capacitance) circuit with a current source, taking mass to correspond to capacitance, dampers to resistors, springs to inductive elements, and forces to currents.

However, there are other devices that cannot be represented by lumped models and such an analogy may not be valid. While SPICE is essentially an ODE solver (i.e., an analog circuit simulator only), another

successful code, CODECS (Coupled Device and Circuit Simulator), provides a truly mixed level description of both circuits and devices. This code, too, was developed at the University of California, Berkeley [Mayaram and Pederson, 1992] and employs combinations of both ODEs and PDEs with algebraic equations. CODECS incorporates SPICE3, the latest version of SPICE written in C [Quarles, 1989], for the circuit simulation capability. The multirate dynamics introduced by combinations of devices and circuits is handled efficiently by a multilevel Newton method or a full-Newton method for transient analysis, unlike the standard Newton method employed in SPICE. CODECS is appropriate for one- and two-dimensional devices, but recent developments have produced efficient algorithms for three-dimensional devices as well [Mayaram et al., 1993].

The aforementioned simulation tools for IC design can be used for MEMS simulations, and, in fact, SPICE has been used to model electrostatic lateral resonators [Lo et al., 1996]. The assumption here is that all device components can be recast as equivalent analog circuit elements that SPICE recognizes. Clearly, this approach can be used in some well-studied structures, such as membranes or simple microbeams, but very rarely for microflows. However, in the last decade there has been an intense effort to produce such models and corresponding software, such as MEMCAD [Senturia et al., 1992], which has become a commercial package [Gilbert et al., 1993] for electrostatic and mechanical analysis of microstructures. Other such packages are the SOLIDIS and IntelliCAD (IntelliSense and ISE). In these simulation approaches, the flowfield is not simulated but its effect is typically expressed by the equivalent of a drag coefficient that provides damping. In some cases, as in the squeezed gas film in silicon accelerometers, an equivalent RLC circuit can also be obtained [Veijola et al., 1995]; however, this is the exception rather than the rule. Even the structural components are often modeled analytically, and significant effort has been devoted to constructing reduced-order macromodels [Hung et al., 1997; Gabbay, 1998]. These are typically nonlinear, low-dimensional models obtained from projections of full three-dimensional simulations to a few representative modal shapes. Nonlinear function fitting is then employed so that analytical forms can be written and these structural models are then imported to SPICE as analog circuit equivalent elements.

This reduced-order macromodeling approach has been used with success in a variety of applications, including, for example, the electrostatic actuation of a suspended beam and elastically suspended plates [Gabbay, 1998]. Their great advantage is computational speed, but they are limited to small displacements and small deformations (i.e., mostly in the linear regime) and are appropriate for familiar designs only. Unfortunately, most of the MEMS devices are operating in nonlinear regimes, including electrostatic actuators, flow fields and structures. More importantly, the real impact of MEMS and anticipated benefits will come from new designs, yet unknown, which may be pre-tested using full simulations and all processes are simulated accurately without sacrificing important details of the physics. MEMS simulation based on full-physics models may then be more appropriate for exploring new concepts, whereas macromodeling may be employed efficiently for familiar designs and in known operating regimes.

In the following, we address some of the specific issues encountered in each of the coupled domains, (i.e., fluid, electric, structure, thermal), analyze their corresponding computational complexity and propose algorithms for their integration.

## 5.2.2 Computational Complexity of MEMS Flows

Liquid and gas flows in microdevices are characterized by a low Reynolds number, typically of order one or less in channels with heights in the submillimeter range [Ho and Tai, 1998; Gad-el-Hak, 1999]. They are unsteady due to external excitation from a moving boundary or an electric field, often driven by high-frequency oscillators—for example, 50 KHz for the MIT electrostatic comb-drive [Freeman et al., 1998]. The domain of microflows is three dimensional and geometrically complex, consisting of large-aspect-ratio components, abrupt expansions and rough boundaries. In addition, microdevices interact with larger devices, resulting in fluid flow going through disparate regimes.

Accurate and efficient simulation of microflows should take into account the above factors. For example, the significant geometric complexity of MEMS flows suggests that finite elements and boundary elements are more suitable than finite differences for efficient discretization [Ye et al., 1999]. However, because of the nonlinear effects, either through the convection or boundary conditions, boundary element methods

are also limited in their application range despite their efficiency for linear flows [Aluru and White, 1996]. A particularly promising approach developed recently for MEMS flows makes use of meshless and mesh-free approaches [Aluru, 1999], where particles are “sprinkled” almost randomly into the flow and boundary. This approach handles the geometric complexity of MEMS flows effectively but the issues of accuracy and efficiency have not been fully resolved yet. In regard to nonlinearities, one may argue that at such a low Reynolds number the convection effects should be neglected, but in complex geometries with abrupt turns the convective acceleration terms may be substantial, thus they need to be taken into account.

The computational difficulties for liquid and gas flows are of different types. Gas microflows are compressible and can experience large density variations. In addition, for channels below 10  $\mu\text{m}$  or at subatmospheric conditions, serious *rarefaction effects* may be present; that is, the walls “move” (see Beskok et al., 1996; Beskok, this volume). In this case, either modified Navier–Stokes equations with appropriate *slip-boundary conditions* or higher order approximations are necessary to describe the governing flow dynamics. To this end, a nondimensional number, the *Knudsen number*, defined as the ratio of the mean free path to the characteristic domain size, defines which model (and correspondingly which numerical method) is appropriate for simulating gas microflows [Bird, 1994]. For submicron devices, atomistic or molecular simulations are necessary as the familiar concept of continuum description breaks down. The direct simulation Monte Carlo (DSMC) method (described elsewhere in this volume) is one efficient method of simulating highly rarefied flows.

On the other hand, liquid flows in microscales are “granular;” that is, they form a layering structure very close to the wall over a distance of a few molecule diameters [Koplik and Banavar, 1995]. This is accompanied by large-density fluctuations very close to the wall that lead to anomalous heat and momentum transport. Liquid flows, in particular, are very sensitive to the wall type and, although such an issue may not be important for averaged heat and momentum transport rates in flow domains of 100  $\mu\text{m}$  or greater, it is extremely important in smaller domains. This distinction suggests two possible approaches in simulating liquid flows in microscales: a phenomenological one, using the Navier–Stokes equation and similar to macrodomain flows, and a molecular approach based on the molecular dynamics (MD) approach [Allen and Tildesley, 1994; Koplik and Banavar, 1995]. The MD approach is deterministic, following the trajectories of all molecules involved, unlike the DSMC approach, which is stochastic and represents collisions as a random process. The drawback of the Navier–Stokes approach is that events at the molecular level are modeled via continuum-like parameters. For example, consider the problem of routing microdroplets on a silicon surface, effectively altering dynamically the contact line of the microdrop. This is a molecular-level process, but in the continuum approach it is determined via a macrodomain-type formulation (e.g., via gradients), which may lead to erroneous results. Accurate MD modeling of the contact line will be truly predictive, as it will take into account the wall–fluid interaction at the molecular level. The wall type and the specific fluid type are taken into account by different potentials that describe intermolecular structure and force. However, such a detailed simulation requires an enormous amount of molecules (e.g., hundreds of millions of molecules) and is limited to a very small region, probably around the contact line region only. It is thus important to develop new hybrid approaches that combine the best features of both methods [Hadjiconstantinou, 1999].

In summary, geometry and surface effects, compressibility and rarefaction, unsteadiness and unfamiliar physics make simulation of microflows a challenging task. The true challenge, however, comes from the interaction of the fluidic system with other system components (e.g., the structure, the electric field and the thermal field). In the following sections, we discuss this interaction.

### 5.2.3 Coupled-Domain Problems

In coupled-domain problems, such as flow–structure or structure–electric, or a combination of both, there are significant disparities in temporal and spatial scales. These disparities, in turn, imply that multiple grids and heterogeneous time-stepping algorithms may be needed for discretization, leading to very complicated and consequently computational prohibitive simulation algorithms. Simplifications are typically made, with one of the fields represented at a reduced resolution level or by low-dimensional

systems or even by equivalent lumped dynamical models. For example, consider the electric activation of a cantilever microbeam made of piezoelectric material. The emphasis may be on modeling the electronic circuit and the motion; thus, a simple model for the motion-induced hydrodynamic damping may be constructed avoiding full simulation of the flow around the beam.

Possible construction of low-order dynamical models could be achieved by projecting the results of detailed numerical simulations onto spaces spanned by a very small number of degrees of freedom—the so-called *nonlinear macromodeling* approach (see Gabbay [1998] and Senturia et al. [1997]). To clarify the concept of a macromodel we give a specific example (taken from Senturia et al. [1997]) for a suspended membrane of thickness  $t$  and deflected at its center by an amplitude  $d$  under the action of uniform pressure force  $P$ . Let  $2a$  be the length of the membrane;  $E$ , the Young’s module;  $\nu$ , the Poisson ratio; and  $\sigma$ , the residual stress. One can use analytical methods to obtain the resulting form of the pressure-deflection relation (e.g., power series, assuming a circular thin membrane). This can be extended to more general shapes and nonlinear responses, for example:

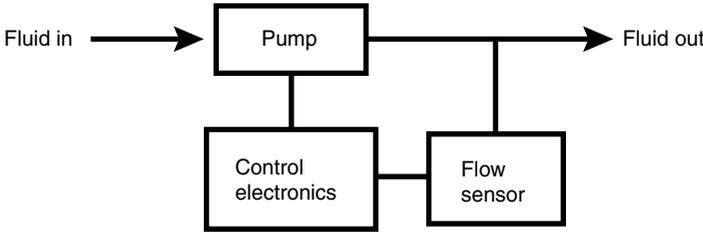

$$P = \frac{C_1 t}{a^2} + \frac{C_2 f(\nu)}{a^4} \frac{E}{1 - \nu} d^3 \tag{5.1}$$

where  $C_1$  and  $C_2$  are dimensionless constants that depend on the shape of the membrane, and  $f(\nu)$  is a slowly varying function of the Poisson ratio. This function is determined from detailed finite element simulations over a range of length  $a$ , thickness  $t$ , and material properties  $\nu$  and  $E$ . Such “best-fits” are tabulated and are used in the simulation according to the specific structure considered, without the need for solving the partial differential equations governing the dynamics of the structure. They can also be built automatically as has been demonstrated by Gabbay (1998). Another type of a macromodel based on neural networks training will be presented later for a flow sensor.

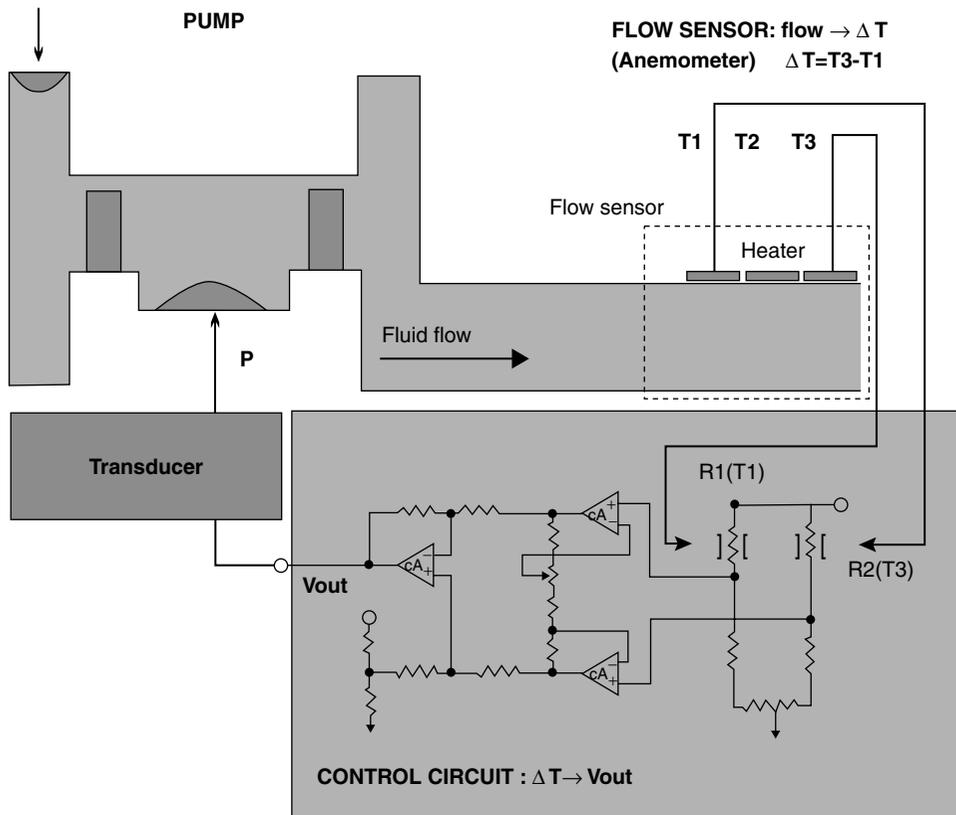

Unfortunately, construction of such macromodels is not always possible, and this lack of simplified models for the many and diverse components of microsystems makes system-level simulation a challenging task. On the other hand, model development for electronic components (transistors, resistors, capacitors, etc.) has reached a state of maturity. Therefore, considerable attention should be focused on models for nonelectronic components. This is necessary for the design and verification of complete microsystems. In this chapter, we describe an integrated approach for simulation of microsystems with the emphasis being on microfluidic systems. To this end, we resort to full simulation of the fluidic system, which involves interactions with moving structures. To illustrate the formulation more clearly, we next present a target simulation problem that represents the aforementioned challenges.

### 5.2.4 A Prototype Problem

An example of a microfluidic system is a microliquid dosing system shown schematically in Figure 5.1. This system is made up of a micropump, a microflow sensor and an electronic control circuit. The electronic circuit adjusts the pump flow rate so that a constant flow is maintained in the microchannel. A realization of this system is shown in Figure 5.2 along with the details of the control circuit. Simulation of the complete system requires models for the micropump, the microflow sensor and the electronic components shown in Figure 5.2. When models, low-order or full-physics, are available for all components,

**FIGURE 5.1** Block diagram of a generic microfluidic system. The flow sensor senses the flow rate, which is controlled by the electronic circuit controlling the pump.

**FIGURE 5.2** Realization of the microfluidic system showing the electronic control circuit. The fluid flow determines the temperature  $\Delta T$  of the flow sensor. This temperature is transformed by the control electronics into the voltage  $V_{out}$ , which in turn controls the pump pressure  $P$  by a transformation of the voltage to a proportional pressure.

including the fluid flow, the complete system can be simulated using a standard circuit simulator such as SPICE [Nagel, 1975; Quarles, 1989].

In the absence of macromodels for the micropump and the microflow sensor, the typical approach for microsystem simulation makes use of lumped-element equivalent circuit descriptions for these devices [Tilmans, 1996]. However, such an approach has two main limitations:

1. It is suitable only for open-loop systems, where there is no feedback from the output to the input.
2. It is applicable only for small-signal conditions.

These two limitations arise in the model development process where several assumptions are made in order to construct the lumped-element equivalent circuits; therefore, this approach would not be suitable when the large-signal behavior of a closed-loop system is of interest.

To address the above problem, we present a coupled circuit/microfluidic device simulator that efficiently couples the discretized Navier–Stokes equations describing a microfluidic device (numerical model) to the solution of circuit equations. Such a capability is unique in that it allows direct and efficient simulation of microfluidic systems without the need for mapping finite element descriptions into equivalent networks [Tilmans, 1996] or analog hardware description languages (AHDLS) [Bielefeld et al., 1997].

The remainder of this chapter is organized as follows: An overview of coupled circuit and device simulation is given in Section 5.3, followed by a description of the circuit and fluidic simulators in Section 5.4. The details of the coupled circuit/fluidic simulator are presented in Section 5.5, and an illustrative example is described in Section 5.6. Conclusions are provided in Section 5.7.

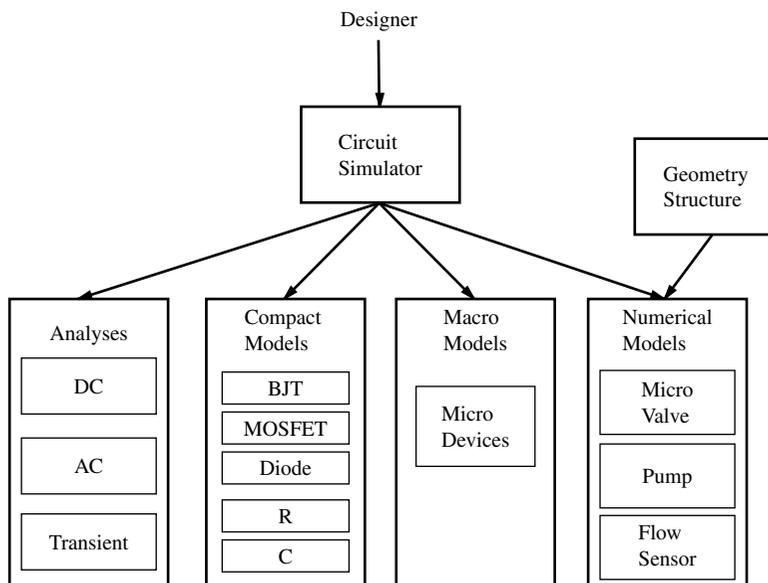

### 5.3 Coupled Circuit-Device Simulation

Coupled simulation techniques have been used for simulation of a sensor system [Schroth et al., 1995]. In this approach, the finite element program ANSYS [Moaveni, 1999] is coupled to an electrical simulator PSPICE [Keown, 1997]. Although such an approach has been demonstrated to work for system simulations, the coupling is not efficient. Special coupling algorithms and time-stepping schemes are required to enable fast simulation of microsystems; therefore, a tight coupling between the circuit and device simulators is necessary for simulation efficiency [Mayaram and Pederson, 1992; Mayaram et al., 1993].

The coupled circuit-device simulator allows verification of microfluidic systems. It provides accurate large- and small-signal simulation of systems even in the absence of proper macromodels for the microfluidic devices. On the other hand, the coupled simulator is important for constructing and validating macromodels. As important effects (such as highly nonlinear or distributed behavior, compressibility or slip flow) are identified, they can be implemented in the macromodels and verified for system simulation using the coupled simulator. Furthermore, critical devices can be simulated using the full physics-based numerical models when there are stringent accuracy requirements on the simulated results.

The concept of a coupled circuit and device simulator has proved to be extremely beneficial in the domain of integrated circuits. Since the first of such simulators, MEDUSA [Engl et al., 1982], became available in the early 1980s, significant work has addressed coupled simulation. These activities have focused on improved algorithms and faster execution speeds and applications. Commercial TCAD vendors also support a mixed circuit-device simulation capability [Silvaco International, 1995; Technology Modeling Associates, 1997]. Because the computational costs of these simulators are high, they are not used on a routine basis. However, there are several critical applications in which these simulators are extremely valuable. These include simulation of radio frequency (RF) circuits [Rotella et al., 1997], single-event-upset simulation of memories [Woodruff and Rudeck, 1993], simulation of power devices [Ravanelli and Hu, 1991], and validation of nonquasistatic MOSFET models [Park et al., 1991].

The coupled circuit-device simulator for microfluidic applications is illustrated in Figure 5.3. This simulator supports compact models for the electronic components and available macromodels for microfluidic devices. In addition, numerical models are available for the microfluidic components which can be utilized when detailed and accurate modeling is required. As an example, specific components such as

**FIGURE 5.3** The coupled circuit/fluidic device simulator. Microfluidic systems, including the control electronics, can be simulated using accurate numerical models for all components.

microvalves, pumps and flow sensors are shown in Figure 5.3. The coupling of the circuit and microfluidic components is handled by imposing suitable boundary conditions on the fluid solver. This simulator allows the simulation of a complete microfluidic system including the associated control electronics. The details of the various simulators and coupling methods are described in the sections below.

One of the biggest disadvantages of such an approach is the high computational cost involved. The major cost comes from solving the three-dimensional, time-dependent Navier–Stokes equations in complex geometric domains. Thus, efficient flow solvers are critical to the success of a coupled circuit–microfluidic device simulator. Any performance improvements in the solution of the Navier–Stokes equations directly translate into a significant performance gain for the coupled simulator.

## 5.4 Overview of Simulators

The circuit simulator employed here is based on the circuit simulator SPICE3f5 [Quarles, 1989] and the microfluidic simulator on the code *NexTor* [Karniadakis and Sherwin, 1999; Kirby et al., 1999]. A brief description of the algorithms and software structure of each of these simulators is provided in this section.

### 5.4.1 The Circuit Simulator: SPICE3

Electrical circuits consist of many components (resistors, capacitors, inductors, transistors, diodes and independent sources) which are described by algebraic and/or differential relations between the component’s currents and voltages. These relationships are called the *branch constitutive relations* [Sangiovanni-Vincentelli, 1981]. The circuits also satisfy conservation laws known as the Kirchhoff’s laws; these laws result in algebraic equations. Therefore, a circuit is described by a set of coupled, nonlinear, differential algebraic equations, which are both highly nonlinear and stiff, which imposes certain limitations on the solution methods. One of the most commonly used analyses is the *time-domain transient analysis*. We briefly describe below the solution approach used for this analysis.

#### 5.4.1.1 Time Discretization

At each time step of the transient analysis, the time derivatives are replaced by an algebraic equation using an integration method. Typically, an implicit linear multistep method of the backward-differentiation type suitable for stiff ODEs is used [Sangiovanni-Vincentelli, 1981]:

$$\mathbf{v} \approx \alpha_0 \mathbf{v}_{t_n} + \sum_{k=1}^n \alpha_k \mathbf{v}_{t_{n-k}} \quad (5.2)$$

#### 5.4.1.2 Linearization

Time discretization yields a system of nonlinear algebraic equations, which are typically solved by a Newton–Raphson method. The nonlinear components are replaced by linear equivalent models for each iteration of the Newton’s method:

$$f(\mathbf{v}_{t_n}^{j+1}) \approx f(\mathbf{v}_{t_n}^j) + \partial f(\mathbf{v}) / \partial \mathbf{v} |_{\mathbf{v}_{t_n}^j} \cdot (\mathbf{v}_{t_n}^{j+1} - \mathbf{v}_{t_n}^j) \quad (5.3)$$

#### 5.4.1.3 Equation Solution

After time discretization and application of Newton’s method a linear system of equations is obtained at each iteration of the Newton method. These equations are described by:

$$\mathbf{A} \mathbf{v}^{j+1} = \mathbf{b} \quad (5.4)$$

where  $\mathbf{A} \in \mathfrak{R}^{n \times n}$ ,  $\mathbf{v}^{j+1} \in \mathfrak{R}^n$  and  $\mathbf{b} \in \mathfrak{R}^n$ . They can be solved by sparse matrix techniques [Kundert, 1987].

The time-domain simulation algorithm can be summarized in the following steps [Sangiovanni-Vincentelli, 1981]:

1. Read circuit description and initialize data structures.
2. Increment time,  $t_n = t_{n-1} + h$ .
3. Update values of independent sources at  $t_n$ .
4. Predict values of unknown variables at  $t_n$ .
5. Apply integration Eq. (1) to capacitors and inductors.
6. Apply linearization Eq. (2) to nonlinear circuit elements.
7. Assemble linear circuit equations.
8. Solve linear circuit equations.
9. Check convergence; if not converged, go to step 6.
10. Estimate local truncation error.
11. Select new time step  $h$ ; rollback time if truncation error is unacceptable.
12. If  $t_n < t_{stop}$ , go to step 3.

### 5.4.2 The Fluid Simulator: *NekTar*

The flow solver corresponds to a particular version of the code *NekTar*, which is a general-purpose computational fluid dynamics (CFD) code for simulating incompressible, compressible and plasma flows in unsteady three-dimensional geometries. The major algorithmic developments are described in Sherwin (1995) and Warburton (1999), and the capabilities are summarized in Figure 5.4. The code uses meshes similar to those for standard finite element and finite volume and consist of structured or unstructured grids, or a combination of both. The formulation is also similar to those methods, corresponding to Galerkin and discontinuous Galerkin projections for the incompressible and compressible Navier–Stokes

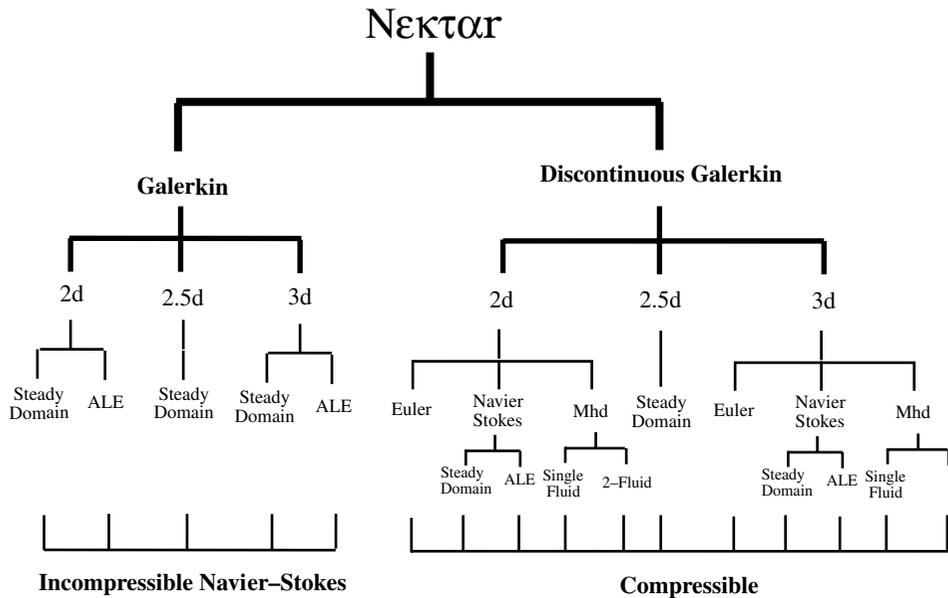

FIGURE 5.4 Hierarchy of the *NekTar* code. Note that “2.5d” refers to a three-dimensional capability with one of the directions being homogeneous in the geometry. Also, ALE refers to moving computational domains required in dynamic flow–structure interactions. Gaseous microflows can be simulated by either the compressible or incompressible version, depending on the pressure/density variations.

equations, respectively. Field variables, data and geometry are represented in terms of hierarchical (Jacobi) polynomial expansions [Karniadakis and Sherwin, 1999]; both iso-parametric and super-parametric representations are employed. These expansions are ordered in vertex, edge, face and interior (or bubble) modes. For the Galerkin formulation, the required  $C^0$  continuity across elements is imposed by choosing the appropriate edge (and face, in three-dimensional) modes; at low order expansions, this formulation reduces to the standard finite element formulation. The discontinuous Galerkin is a flux-based formulation, and all field variables have  $L^2$  continuity; at low order, this formulation reduces to the standard finite-volume formulation.

This new generation of Galerkin and discontinuous Galerkin spectral/h-p element methods implemented in the code *NekTar* does not replace but rather extends the classical finite element and finite volumes with which the CFD practitioners are familiar [Karniadakis and Sherwin, 1999]. The additional advantages are that convergence of the discretization and thus solution verification can be obtained without remeshing (h-refinement) and that the quality of the solution does not depend on the quality of the original discretization. In [Figure 5.4](#) we summarize the major current capabilities of the general code *NekTar* for incompressible, compressible and even plasma flows. In particular for microflows, both the compressible and incompressible versions are used. For gas microflows we account for rarefaction by using velocity-slip and temperature-jump boundary conditions [Beskok et al., 1996; Beskok and Karniadakis, 1999; Beskok, this volume]. An extension of the classical Maxwell's boundary condition is employed in the code in the form:

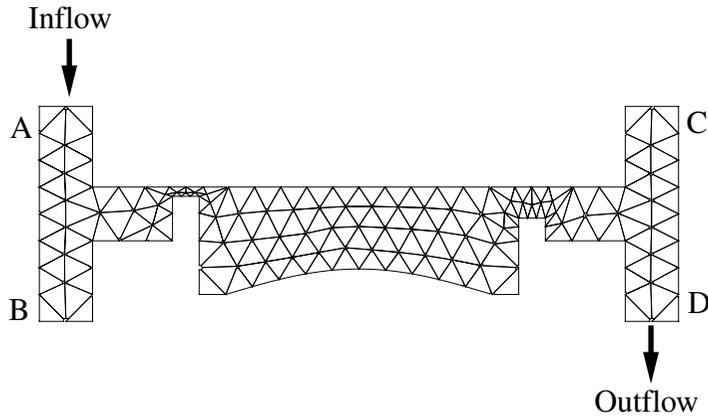

$$U_g - U_w = \frac{Kn}{1 - bKn} (\nabla U)_w \cdot \hat{n} \quad (5.5)$$

Here we define the Knudsen number as  $Kn = \lambda/L$ , with  $\lambda$  the mean free path of the gas molecules and  $L$  the characteristic length scale in the flow. Also,  $U_g$  is the velocity (tangential component) of the gas at the wall,  $U_w$  is the wall velocity, and  $\hat{n}$  is the unit normal vector. The constant  $b$  is adjusted to reflect the physics of the problem as we go from the slightly rarefied regime (slip flow) to the transition regime ( $Kn \approx 1$ ) or free molecular regime ( $Kn > 5$  to 10). For  $b = 0$ , we recover the classical linear relationship between velocity slip and shear stress, first proposed by Maxwell. However, for  $b = -1$ , we obtain a second-order accuracy [Beskok and Karniadakis, 1999], and in general for  $b \neq 0$ , Eq. (5.5) leads to finite slip at the wall, unlike the linear boundary condition (for  $b = 0$ ) used in most codes. The boundary condition in Eq. (5.5) has been used with success in the entire Knudsen number regime,  $Kn \approx 0$  to 200 (see several examples in Beskok and Karniadakis, 1999).

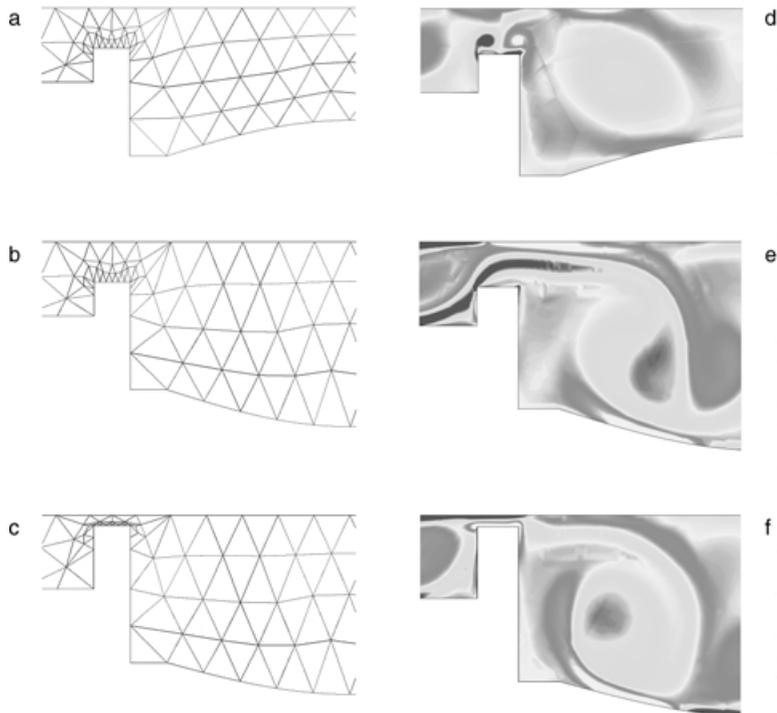

One of the key points in obtaining *efficiency* in simulations of moving domains is the type of discretization employed in the flow solver. In *NekTar* we employ the so-called h-p version of the finite element method with spectral Jacobi polynomials as basic functions. Convergence is obtained via a dual path in this approach, either by increasing the number of elements (h-refinement) or by increasing the order of the spectral polynomial (p-refinement). In the latter case, a faster convergence is obtained without the need for remeshing. Instead, the number of degrees of freedom is increased in the *modal space* by increasing the polynomial order ( $p$ ) while keeping the mesh unchanged. It is, of course, the cost of reconstructing the mesh that is orders of magnitude higher in time-dependent simulations both in terms of computer and human time.

Regarding the type of elements (subdomains), *NekTar* uses hybrid meshes (both structured and unstructured). For example, in three-dimensional simulations, a hybrid grid may consist of tetrahedra, hexahedra, triangular prisms, and even pyramids. In [Figure 5.5](#) we plot the mesh used in the simulation of the pump, and in [Figure 5.6](#) we plot the flow field at three different time instances.

In the following, we briefly describe how we formulate the algorithm for a compatible and efficient flow-structure coupling.

**FIGURE 5.5** Mesh of the pump used in the flow simulator *Nektar*. This device was first introduced by Beskok and Warburton (1998) as a mixing device between two microchannels. Here, B and C are blocked so the device is operating as a pump from A to D.

**FIGURE 5.6** (Color figure follows p. 12-26.) Close up of the vorticity contours for  $Re = 30$  simulation at the left valve (meshes shown on right side). Top:  $\tau\omega = 0.28$ , corresponding to the beginning of the suction stage; start-up vortices due to the motion of the inlet valve can be identified. Middle:  $\tau\omega = 0.72$ , corresponding to the end of the suction stage; a vortex jet pair is visible in the pump cavity. Bottom:  $\tau\omega = 84$ , corresponding to early ejection stage; further evolution of the vortex jet and the start-up vortex of the exit valve can be identified. (Courtesy of A. Beskok.)

### 5.4.3 Formulation for Flow-Structure Interactions

We consider the incompressible Navier–Stokes equations in a time-dependent domain,  $\Omega(t)$ :

$$u_{i,t} + u_j u_{i,j} = -(p\delta_{ij})_j + \nu u_{i,jj} + f_i \text{ in } \Omega(t) \quad (5.6)$$

$$u_{j,j} = 0 \text{ in } \Omega(t) \quad (5.7)$$

where  $\nu$  is the viscosity and  $f_i$  is a body force. We assume for clarity homogeneous boundary conditions; velocity-slip-boundary conditions can be included relatively easily in the Galerkin framework as mixed (Robin) boundary conditions. Multiplying Eq. (5.6) by test functions and integrating by parts, we obtain:

$$\int_{\Omega(t)} v_i (u_{i,t} + u_j u_{i,j}) dx = \int_{\Omega(t)} v_{i,j} (p\delta_{ij} - \nu u_{i,j} + v_i f_i) dx \quad (5.8)$$

The next step is to define the reference system on which time differentiation takes place. This was accomplished by Ho (1989) by use of the Reynold’s transport theorem and by using the fact that the test function  $v_i$  is following the material points; therefore, its time derivative in that reference frame is zero:

$$\frac{dv_i}{dt} \Big|_{x_p} = v_{i,t} + w_j v_{i,j} = 0$$

where  $w_j$  is a velocity that describes the motion of the time-dependent domain  $\Omega(t)$ ;  $x_p$  denotes the material point. The final variational statement then becomes:

$$\frac{d}{dt} \int_{\Omega(t)} v_i u_i dx + \int_{\Omega(t)} [v_i (u_j - w_j) u_{i,j} - v_i u_i w_{j,j}] dx = \int_{\Omega(t)} [v_{i,j} p \delta_{ij} - \nu v_{i,j} u_{i,j} + v_i f_i] dx \quad (5.9)$$

This is the ALE formulation of the momentum equation. It reduces to the familiar Eulerian and Lagrangian forms by setting  $w_j = 0$  and  $w_j = u_p$ , respectively. However,  $w_j$  can be chosen arbitrarily to minimize the mesh deformation. We discuss this algorithm next.

### 5.4.4 Grid Velocity Algorithm

The grid velocity is arbitrary in the ALE formulation; therefore, great latitude exists in the choice of technique for updating it. Mesh constraints such as smoothness, consistency, and lack of edge crossover, combined with computational constraints such as memory use and efficiency, dictate the update algorithm used. In the current work, we address the problem of solving for the mesh velocity in terms of its graph theory equivalent problem. Mesh positions are obtained using methods based on a graph theory analogy to the spring problem. Vertices are treated as *nodes*, while edges are treated as *springs* of varying length and tension. At each time step, the mesh coordinate positions are updated by equilibration of the spring network. Once the new vertex positions are calculated, the mesh velocity is obtained through differences between the original and equilibrated mesh vertex positions.

Specifically, we incorporate the idea of variable diffusivity while maintaining computational efficiency by avoiding solving full Laplacian equations. The method we use for updating the mesh velocity is a variation of the barycenter method [Battista et al., 1998] and relies on graph theory. Given the graph  $G = (V, E)$  of element vertices  $V$  and connecting edges  $E$ , we define a partition  $V = V_0 \cup V_1 \cup V_2$  of  $V$  such that  $V_0$  contains all vertices affixed to the moving boundary,  $V_1$  contains all vertices on the outer boundary of the computational domain, and  $V_2$  contains all remaining interior vertices. To create the effect of variable diffusivity, we use the concept of layers. As discussed in Lohner and Yang (1996), it is desirable for the

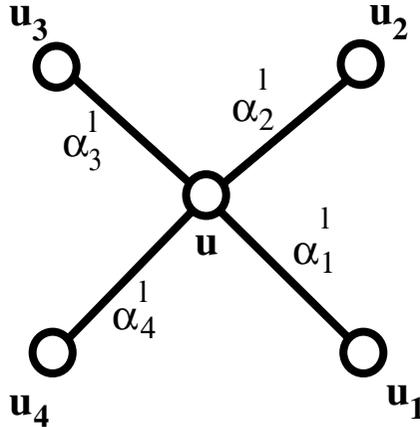

FIGURE 5.7 Graph showing vertices with associated velocities and edges with associated weights.

vertices very close to the moving boundary to have a grid velocity almost equivalent to that of the boundary. Hence, locally the mesh appears to move with solid movement, whereas far away from the moving boundary the velocity must gradually go to zero. To accomplish this in our formulation, we use the concept of local tension within layers to allow us to prescribe the rigidity of our system. Each vertex is assigned to a layer value which heuristically denotes its distance from the moving boundary. Weights are chosen such that vertices closer to the moving boundary have a higher influence on the updated velocity value. To find the updated grid velocity  $u^g$  at a vertex  $v \in V_2$ , we use a force-directed method. Given a configuration as shown in Figure 5.7, the grid velocity at the center vertex is given by:

$$u^g = \sum_{i=1}^{\deg(v)} \alpha_i u_i^l, \quad \sum_{i=1}^{\deg(v)} \alpha_i^l = 1$$

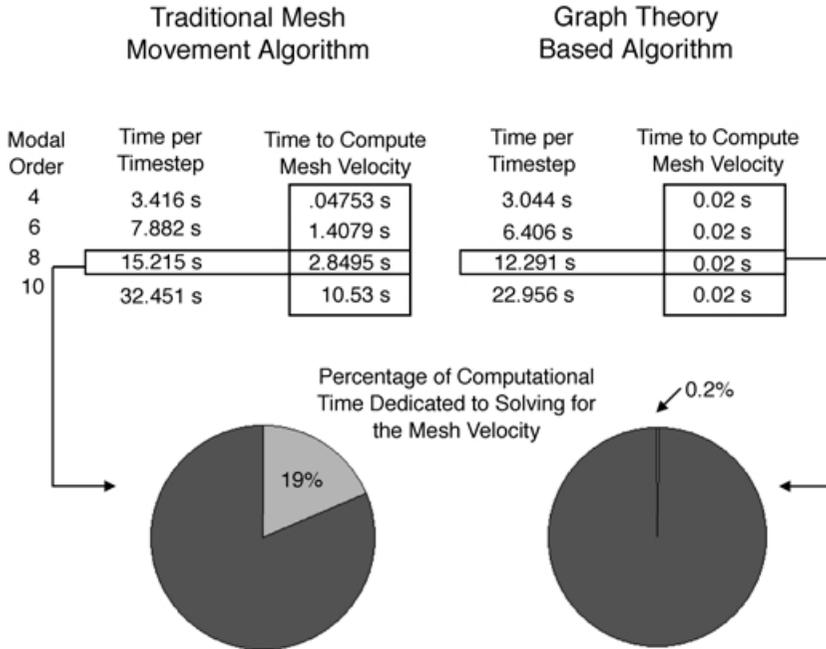

where  $\deg(v)$  is the number of edges meeting at the vertex  $v$  and  $\alpha_i^l$  is the  $l$ th layer weight associated with the  $i$ th edge. This is subjected to the following constraints:  $u^g = 0 (\forall v \in V_1)$ , and  $u^g (\forall v \in V_0)$  is prescribed to be the wall velocity. This procedure is repeated for a few cycles following an incomplete iteration algorithm, over all  $v \in V_2$ . (Here, by “incomplete” we mean that only a few sweeps are performed and full convergence is not sought.) Once the grid velocity is known at every vertex, the updated vertex positions are determined using explicit time integration of the newly found grid velocities.

An example of the improved computational speed gained by following the graph-theory approach vs. the classical approach of employing Poisson solvers to update the grid velocity is shown in Figure 5.8. We have computed the portion of CPU time devoted exclusively to the solver as a function of the spectral order employed in the discretization. The problem we considered involved the motion of a piezoelectric membrane induced by vortex shedding caused by a bluff body in front of the membrane. We see that a two- to three-orders of magnitude speed-up can be obtained using the graph-based algorithm.

### 5.4.5 The Structural Simulator

The membrane of the micropump is modeled using the linear string-beam equation:

$$\frac{d^2 y}{dt^2} + \frac{R}{m} \frac{dy}{dt} + \frac{EI}{m} \frac{d^4 y}{dx^4} - \frac{T}{m} \frac{d^2 y}{dx^2} = \frac{F}{m} \quad (5.10)$$

**FIGURE 5.8** Comparison of CPU time for the grid velocity algorithm between the classical approach (Poisson solver) and the new approach (graph algorithm). On the left-most column is the order of spectral polynomial approximation.

where

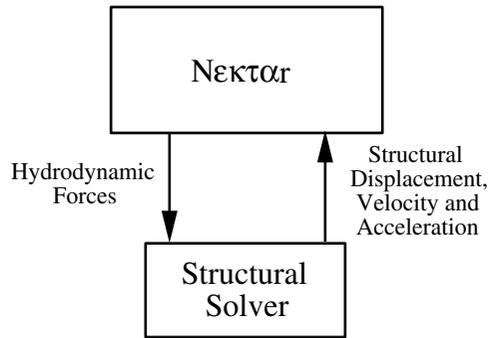

- $E$  is the Young's modulus of elasticity.
- $I$  is the second moment of inertia.
- $T$  is the axial tension.
- $F$  is the hydrodynamic forcing.
- $R$  is the coefficient of structural damping.
- $m$  is the structural mass per unit length.

In this model, the coefficients are given by the physical parameters of the membrane used within the pump, and the hydrodynamic forcing on the membrane is provided by  $N\kappa T\alpha r$ .

Assume that the membrane lies in the interval  $[0, L]$ . For the micropump configuration, we have chosen the boundary conditions  $y(0) = y(L) = 0, y''(0) = y''(L) = 0$  which correspond to a fixed-hinged membrane. Equation (5.10) combined with these boundary conditions lends itself to the use of eigenfunction decomposition for the efficient solution of the membrane motion. We begin by transforming the problem to lie on the interval  $[0, 1]$  using the linear mapping  $x = L\xi, \xi \in [0, 1]$ . The eigenfunctions of this system are given by  $\phi_n = \frac{1}{2} \sin \sqrt{\lambda_n} \xi; \sqrt{\lambda_n} = (n-1)\pi, n = 1, 2, \dots, \infty$ . If we assume a solution of the form  $y(\xi, t) = \sum_{n=1}^N A_n(t) \phi_n(\xi)$ , then by employing the Galerkin method we obtain the following evolution equation for the coefficients  $A_n(t)$ :

$$\frac{d^2 A_n}{dt^2} + \frac{R}{m} \frac{dA_n}{dt} + \left( \frac{EI}{mL^4} \lambda_n - \frac{T}{m^2} \right) \lambda_n A_n = \frac{1}{m} \int_0^1 F d\xi \quad (5.11)$$

We then solve this evolution equation using the Newmark scheme [Hughes, 1987], which returns the coefficients for the displacement, velocity and acceleration of the membrane. This information is then returned to  $N\kappa T\alpha r$  as demonstrated in Figure 5.9.

**FIGURE 5.9** Coupling between *NekTar* and the structural solver. *NekTar* provides the hydrodynamic force information on the membrane. With this information the structural solver calculates the membrane’s response. Structural displacement, velocity and acceleration are then returned to *NekTar* for determining the influence of the structure’s motion on the fluid.

### 5.4.6 Differences between Circuit Fluid and Solid Simulators

The above descriptions suggest some differences between the various simulators. The key distinguishing features are

- The fluid simulator is computationally more expensive than the structure and circuit simulators.
- SPICE3 has a reliable error estimation for time discretization; therefore, a rollback in time can be done if the truncation error is unacceptable. As a result, SPICE3 automatically controls the simulation time step to ensure an acceptable user-specified error. *NekTar* is a much more complex code and does not have an automatic time-step control scheme for coupled fluid–structure simulation.
- SPICE3 uses implicit numerical integration methods for time-domain simulation. These methods are efficient for circuit simulation, because the circuit equations are stiff. For the fluid solver, however, explicit methods are simpler to implement and reasonably efficient. For this reason, *NekTar* uses semi-implicit methods for the time-domain integration (explicit for the advection terms and implicit for the diffusion terms of the Navier–Stokes equations), which suffer from the standard CFL (Courant–Friedrichs–Levy condition for the time step) restrictions. However, the flow time step is much higher than the electronics time step due to the relevant physical time scales. Also, the Newmark scheme for the structure is unconditionally stable.

## 5.5 Circuit-Microfluidic Device Simulation

For coupled circuit/microfluidic device simulation, four different physical domains (electrical, structure mechanical, fluid mechanical and thermal) must be considered, as shown in [Figure 5.10](#). These domains are coupled to one another as described below.

In [Figure 5.2](#) four types of coupling can be identified:

1. Electromechanical coupling for a piezoelectric actuation of the pump membrane
2. Fluid–structure coupling due to volume displacement of the pump membrane
3. Fluid–thermal coupling because of the thermoresistor cooling in the fluid when an anemometer type of microflow sensor is used
4. Electrothermal thermoresistor heating due to current flow in the microflow sensor

The overall system can be simulated using different approaches. One could use detailed physical simulation for each coupled domain. Another way is the use of lumped-element equivalent circuits,

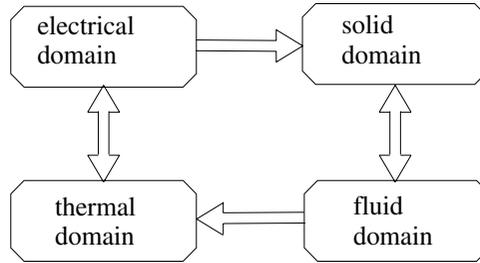

FIGURE 5.10 Coupling between the various physical domains.

compact or macromodels and/or analog hardware description languages. A third possibility is to use a combination of coupled solvers, compact models and lumped elements. In this work, we will demonstrate this third approach.

### 5.5.1 Software Integration

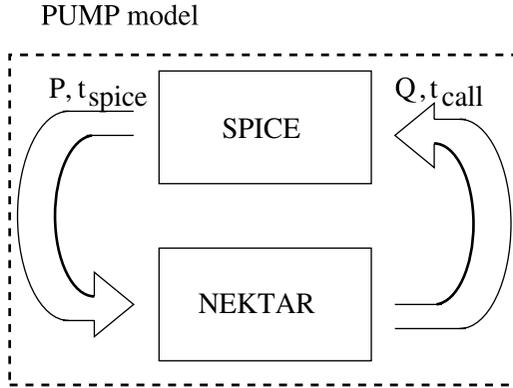

The interaction of the full system is based on different abstraction levels, using lumped circuit elements, compact/macromodels and a direct interconnection of solvers for various domains. The circuit simulator SPICE3 is chosen as the controlling solver for the following reasons:

- SPICE3 has advanced time-step control.
- Models for different abstraction levels can be easily implemented in SPICE3.
- Lumped-element equivalent circuits can be readily simulated.

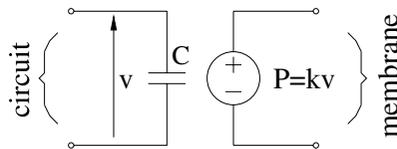

Relatively simple elements are implemented as lumped elements or compact models. These elements are electromechanical transducers (piezoelectric actuator) and thermoresistors. Flow sensors are much more complicated but often the fluid flow around sensors is relatively simple. For example, if the fluid flow in a channel is fully developed then it has a parabolic profile for the velocity, thus this profile can be used (compact model) for the flow sensors as well. It is important to note that these compact models are parameterized and can be highly nonlinear. These models are obtained by insight gained from detailed physical-level simulations, such as Navier–Stokes simulations, DSMC, and linearized solutions of the Boltzmann equation [Beskok and Karniadakis, 1999]. The pump can also be described as a lumped element [Klein et al., 1998]. However, these lumped-element descriptions are applicable only for small variations in the fluid flow. Usually pumps operate in a nonlinear and non-smooth mode of fluid flow with a strong fluid–structure interaction; therefore, a detailed physical-level simulation of the pump is required. A simplification can be made by employing a macromodel of the form described in Eq. (1) but here we employ full Navier–Stokes simulations with full dynamics. For this reason, the following options are used:

- Electromechanical actuators, thermoresistors and flow sensors are described as lumped elements and/or compact models.
- The pump is modeled at the detailed physical level.
- All lumped elements and models are implemented in SPICE3.
- The pump is implemented as a direct SPICE3–*NekTar* interconnection (Figure 5.11). SPICE3 transfers the time  $t_{\text{spice}}$  and pressure  $P$  for the membrane activation to *NekTar* and receives the flowrate  $Q$  and the time  $t_{\text{call}}$  for the next call to *NekTar*.

A detailed description of this coupling is provided later.

**FIGURE 5.11** The SPICE3–*NeκTαr* interaction for the pump microsystem of [Figure 5.2](#). SPICE3 provides the time  $t_{\text{spice}}$  and pressure  $P$  for the membrane actuation to *NeκTαr*. *NeκTαr* transfers the flowrate  $Q$  at time  $t_{\text{call}}$  for the next call of *NeκTαr* by SPICE3.

**FIGURE 5.12** Lumped model for piezoelectric actuation. The voltage  $V$  is transformed into a pressure  $P$  that is used to activate the membrane of the pump.

## 5.5.1 Lumped Element and Compact Models for Devices

### 5.5.1.1 Model for Piezoelectric Transducers

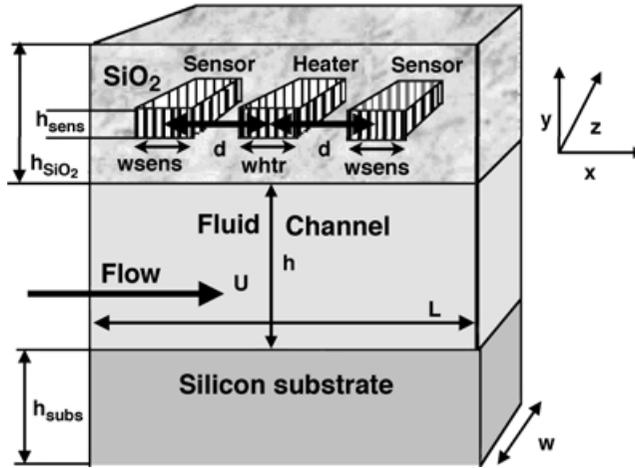

The model for electromechanical coupling with a piezoelectric actuation of the membrane is shown in [Figure 5.12](#). This model forms the interface between the electrical and mechanical networks. The electrical characteristics of the piezoelectric actuator are described by the capacitor  $C$ . The input voltage  $V$  translates into an output pressure  $P$  by virtue of the piezoelectric effect with coefficient  $k$ . This pressure is an input argument to *NeκTαr*. The mechanical characteristics of the piezoelectric actuator are coupled with the mechanical characteristics of the substrate [Timoshenko and Woinowsky-Krieger, 1970; Klein, 1997].

### 5.5.1.2 Compact Model for Flow Sensor

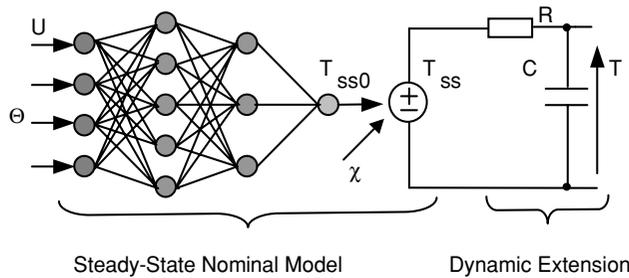

For the anemometer type of flow sensor [Rasmussen and Zaghoul, 1999] shown in [Figure 5.13](#), a macromodel has been developed by Mikulchenko et al. (2000). This macromodel ([Figure 5.14](#)) is based on neural networks trained using data from detailed physical simulations.

The inputs to the neural network are the flow velocity  $U$  and the vector of geometrical and physical parameters  $\Theta$ . The results from this model are in good agreement with the simulated data for a large range of parameters [Mikulchenko et al., 2000].

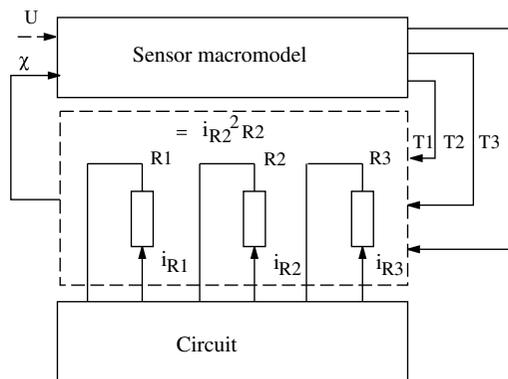

The dynamic macromodel is incorporated in SPICE3 by coupling it with a sensor circuit and a model for thermoresistors for the heater and sensors as shown in [Figure 5.15](#). Based on the fluid flow rate, the thermoresistor temperatures ( $T_1$ ,  $T_2$  and  $T_3$ ) change, which in turn alter the resistance values and the sensing circuit currents and voltages.

**FIGURE 5.13** Structure of an anemometer-type flow sensor (thermocouple). This sensor is made up of a heating element and two sensing elements. The temperature difference between the sensors is used to measure the flow.

**FIGURE 5.14** Dynamic macromodel for the flow sensor. The steady-state solution  $T_{ss0}$  corresponds to a nominal power for the heat source  $\chi$ . The neural network output  $T_{ss0}$  is a multivariate function of the flow velocity  $U$  and the vector of geometrical and physical parameters  $\Theta$ .  $T_{ss}$  is a linear function of the heat source  $\chi$  and  $T_{ss0}$ .

**FIGURE 5.15** Macromodel implementation in SPICE3. Based on the fluid flow rate the thermoresistor temperatures ( $T_1$ ,  $T_2$  and  $T_3$ ) change, which in turn alter the resistance values and the sensing circuit currents and voltages.

### 5.5.1.3 Effective Time-Stepping Algorithms

In general, the flow solver *NEκTar* can be implemented as one big model in SPICE3. This is accomplished by calling *NEκTar* from SPICE3 for each Newton iteration. However, such a coupling is extremely inefficient, because a call to *NEκTar* is computationally very expensive. Furthermore, the time scales and nonlinearities are extremely different for the circuit and fluidic devices. If one considers only the circuit element, then a SPICE3 simulation results in nonuniform time steps and several Newton iterations for each time step. Typical time constants for circuits are of the order of  $10^{-12}$  to  $10^{-6}$  seconds. On the other hand, fluidic devices have a typical time constant of the order  $10^{-4}$  to  $10^{-1}$  seconds.

This property can be exploited to improve simulation performance by calling *NEκTar* only at some of the circuit time points following a subcycling type of algorithm. Between these time points, the *NEκTar* outputs can be modeled as constant values. Further improvement in performance is possible by taking into account the usage of semi-explicit methods for fluid simulation. In this case, the flowrate  $Q_n$  for time point  $t_n$  is calculated by the explicit scheme:  $Q_n = F(\mathbf{P}_{n-1}, \mathbf{V}_{n-1}, t_n)$ , where  $\mathbf{P}$  is the vector of the pressure at mesh points, and  $\mathbf{V}$  is the vector of velocities at mesh points. For the SPICE3–*NEκTar* interaction described earlier, the important quantities are the distributed pressure  $P$  for the pump membrane and the flowrate  $Q_n$ . This functional relationship can be expressed as follows:  $Q_n = f(P_{n-1}, Q_{n-1}, t_n)$ .

Based on this observation an efficient time-stepping scheme is obtained as shown in Figure 5.16. Here, time is plotted on the horizontal axis and the SPICE3 iterations are plotted on the vertical axis;  $t_{S,k}$  and  $t_{N,k}$  are the SPICE3 and *NEκTar* time points, respectively. *NEκTar* selects a time step  $h_{N,i} = t_{N,i} - t_{N,i-1}$  independent of SPICE3, based on the Courant number (CFL) constraint for convection. The *NEκTar* time points  $t_{N,i}$  are used as synchronization time points with SPICE3, whereby  $t_{N,i} = t_{S,k}$ . The flowrate  $Q$  has a constant value between these synchronization time points. The membrane pressure  $p_{j,k}$  is calculated

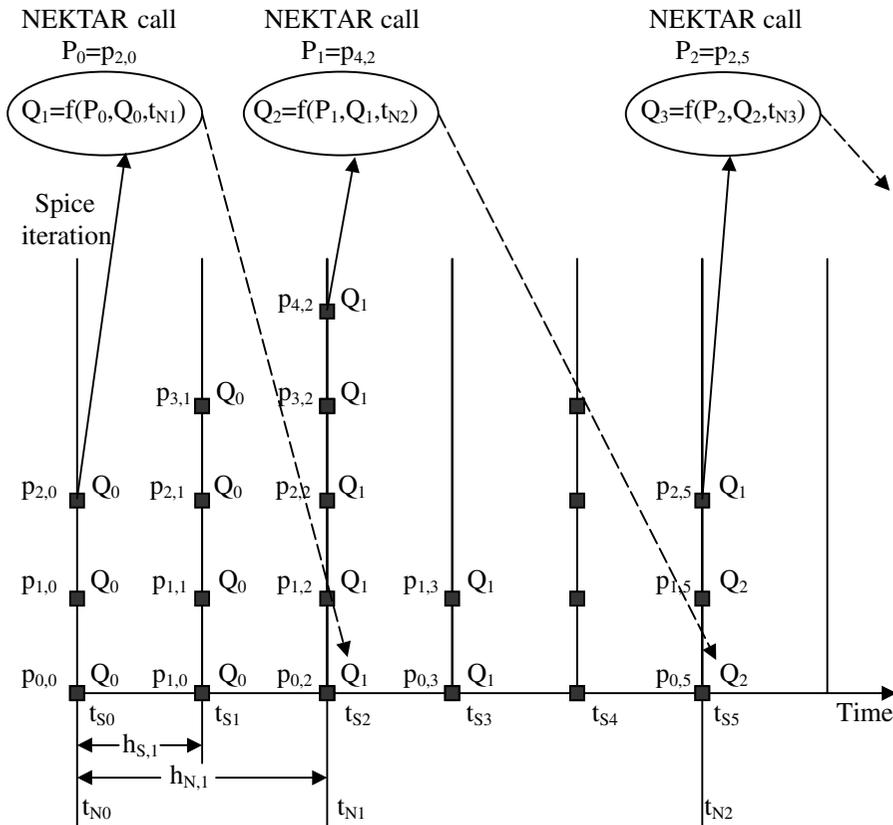

FIGURE 5.16 Time-stepping scheme for SPICE3–*NEκTar* coupling.

as a function of the circuit behavior for each SPICE3 call at time  $t_{s,k}$  and iteration  $j$ . The pressure  $p_i = p_{M,k}$  at the final SPICE3 iteration  $M$ , for a synchronization time point  $t_{s,k} = t_{N,j}$  is an input. A  $N\kappa T\alpha r$  call is made at  $t_{N,i}$  and a new value of  $Q$  is computed using the relation  $Q_{i+1} = f(P_i, Q_i, t_{N,i+1})$ . This value is then used for the next  $N\kappa T\alpha r$  time point,  $t_{N,i+1}$ .

The main features of this time-stepping scheme can be summarized as follows:

- $N\kappa T\alpha r$  is called from SPICE3.
- The time step for SPICE3 is much smaller than the time step for  $N\kappa T\alpha r$ .
- $N\kappa T\alpha r$  specifies the next synchronization time point.

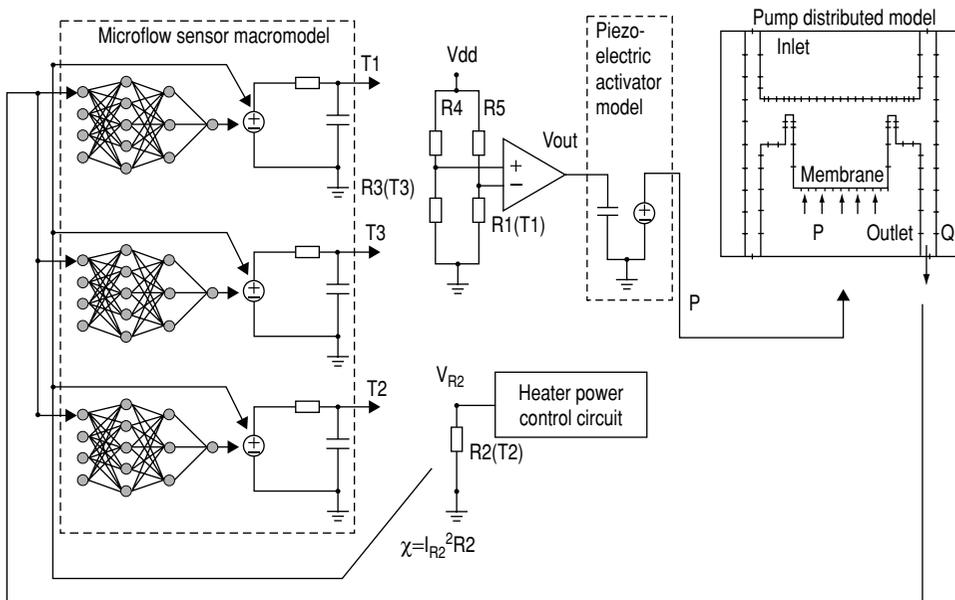

From this, it can be concluded that the number of  $N\kappa T\alpha r$  calls are the same as that of stand-alone  $N\kappa T\alpha r$ . This is the best possible situation in terms of efficiency for the coupled SPICE3– $N\kappa T\alpha r$  simulation.

## 5.6 Demonstrations of the Integrated Simulation Approach

### 5.6.1 Microfluidic System Description

A microliquid dosing system is used as an illustrative example. This system is made up of a micropump, a flow sensor and an electronic control circuit. The electronic circuit adjusts the pump flow rate. A simplified simulation circuit is shown in Figure 5.17.

In this system, the flow rate  $Q$  determines the flow sensor velocity  $U$  for a given set of geometry parameters ( $h, d, w_{sens}$ ). Based on the fluid flow rate, the thermoresistor temperatures ( $T_1, T_2$  and  $T_3$ ) change, which in turn alter the resistance values  $R_1(T_1), R_2(T_2)$  and  $R_3(T_3)$ . The resistances  $R_1(T_1)$  and  $R_3(T_3)$

**FIGURE 5.17** Description of the complete system for simulation. The pump flow rate  $Q$  determines the flow sensor velocity  $U$ . This yields the temperatures for the sensor thermoresistors. The difference between the resistance values  $R_1(T_1)$  and  $R_3(T_3)$  is transformed into the voltage  $V_{out}$  by the control electronics, which is used to control the pressure  $P$  for the pump membrane. This, in turn, determines the flow rate  $Q$ .

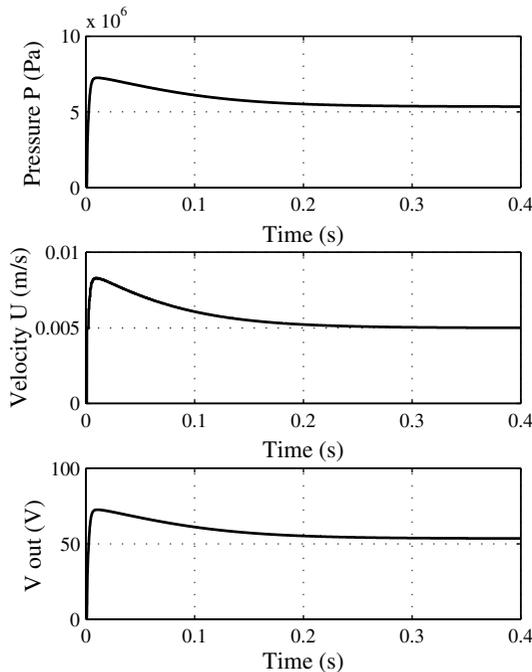

are included in a Wheatstone-bridge arrangement with two fixed resistors  $R_4$  and  $R_5$ . The voltage difference  $V_{R_3(T_3)} - V_{R_1(T_1)}$  is directly proportional to the temperature difference  $T_3 - T_1$ . This voltage difference is linearly transformed to the output voltage  $V_{out}$  by an operational amplifier with a controlled gain. This output voltage determines the pressure  $P$ , which activates the pump membrane and changes the flow rate  $Q$ . The thermoresistor of the heater ( $R_2$ ) is activated by the control electronics that maintain a constant heater temperature.

### 5.6.2 SPICE3– $N\kappa T\alpha r$ Integration

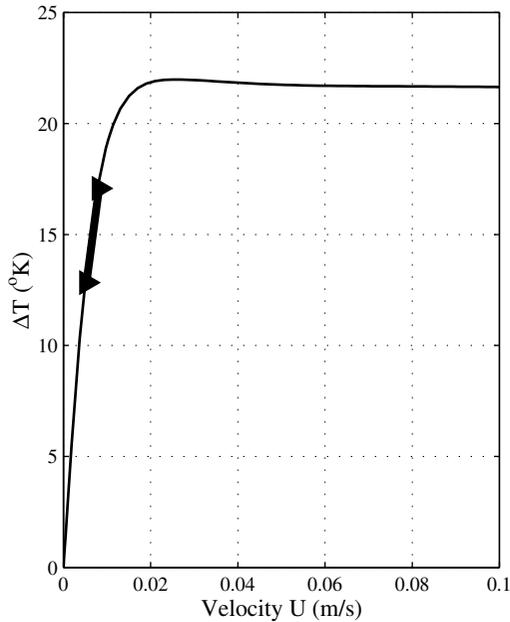

As mentioned earlier,  $N\kappa T\alpha r$  is embedded as a subroutine in SPICE3. The interaction with SPICE3 is by means of the model code and the simulation engine. Synchronization time points are determined by  $N\kappa T\alpha r$  and used by the SPICE3 transient analysis engine. The pump is modeled as a SPICE3 element with  $N\kappa T\alpha r$  being the underlying simulation engine. The other elements in the circuit are described by lumped element descriptions and/or compact models.

### 5.6.3 Simulation Results

The simulation results from the coupled simulator are presented in Figure 5.18. In this simulation, one can determine the pressure on the pump membrane, the flow velocity and the output control voltage as a function of time for various component parameters. As an example, consider the microflow sensor, the characteristics for which are shown in Figure 5.19. It is seen that for the given range of flow velocity the temperature difference between the upstream and downstream sensor temperatures is in the range 12 to 7 K. This simulation required approximately 5 minutes of CPU time on a 300-MHz Pentium II processor. Thus, the coupled simulator is reasonably efficient and provides valuable information to the system or device developers.

**FIGURE 5.18** External pressure for the pump membrane, inlet velocity for the microflow sensor, and amplifier output voltage for the simulation of the microfluidic system as a function of time.

**FIGURE 5.19** Flow-sensor characteristics and region of operation. A small change in velocity results in a large change in  $\Delta T$ , the difference of the upstream and downstream sensor temperatures.

## 5.7 Summary and Discussion

Coupled-domain simulation is necessary in MEMS applications, as many different physical phenomena are present and different processes are taking place simultaneously. Depending on the specific application (e.g., a microsensor vs. a microactuator or a more complex system), some aspects of the device must be simulated in detail at high resolution while others must be accounted for by a low-dimensional description. Nonlinear macromodels are a possibility, but this is inadequate for the microfluidic system, which is typically highly unsteady and nonlinear. In addition, in the microdomain certain nonstandard flow features have to be modeled accurately such as velocity slip or temperature jump in gas flows, viscous electrokinetic effects in liquid flows and particle trajectories in particulate flows. To this end, we have developed a code that can simulate flows in the micro- and macrodomains both for liquids and gases. In addition, it includes a library of linear and nonlinear structures, such as beams, membranes, cables, etc.

For the coupled-domain simulation, the main driver program is SPICE3, a popular code for circuit simulation. In this chapter, a coupled circuit and microfluidic device simulator was presented. The simulator allows simulation of a complete microfluidic system in which thermal, flow, structural and electrical domains are integrated. The coupling of these simulators was described and demonstrated for a microliquid dosing system. The integrated simulator can be utilized for parametric studies and optimal design of microfluidic systems.

The integration of different simulators required for complete MEMS simulations is a difficult problem with challenges well beyond software integration. It involves disparate temporal and spatial scales leading to great stiffness and inefficiencies, new physical assumptions and approximations for some of the components, issues of numerical stability, staggered time-marching procedures, new fast solvers for coupled problems and optimization and control algorithms. Most of the mature algorithms are inefficient in this context so new methods are required in order to produce a new generation of simulation algorithms for MEMS devices. In this chapter, we have demonstrated that this is possible by coupling two accurate codes and resolving, at least at some level, some of these coupling issues. However, significant

improvements can be made for specific devices. For example, for the membrane-driven micropump presented here, convergence of the coupling algorithm could be accelerated by inspecting the time-dependent, mass-conservation equation for every SPICE time step and obtaining a new estimate of flow from:

$$Q_{\text{new}} = Q_{\text{old}} + \frac{\Delta V}{\Delta t}$$

where  $\Delta V$  is the change in volume due to the change in the membrane position, and  $\Delta t$  is the time between two consecutive SPICE calls. This requires solving for the structure only but not necessarily for the entire flow field, which is the most computationally intensive part. The structure solver is very fast and can be called as often as necessary without a serious computational overhead.

### 6.1 Introduction

---

Nominally, microchannels can be defined as channels whose dimensions are less than 1 mm and greater than 1  $\mu\text{m}$ . Above 1 mm the flow exhibits behavior that is the same as most macroscopic flows. Below 1  $\mu\text{m}$  the flow is better characterized as nanoscopic. Currently, most microchannels fall into the range of 30 to 300  $\mu\text{m}$ . Microchannels can be fabricated in many materials—glass, polymers, silicon, metals—using various processes including surface micromachining, bulk micromachining, molding, embossing and conventional machining with microcutters. These methods and the characteristics of the resulting flow channels are discussed elsewhere in this handbook.

Microchannels offer advantages due to their high surface-to-volume ratio and their small volumes. The large surface-to-volume ratio leads to a high rate of heat and mass transfer, making microdevices excellent tools for compact heat exchangers. For example, the device in [Figure 6.1](#) is a cross-flow heat exchanger constructed from a stack of 50 14-mm  $\times$  14-mm foils, each containing 34 200- $\mu\text{m}$ -wide  $\times$  100- $\mu\text{m}$ -deep channels machined into the 200- $\mu\text{m}$ -thick stainless steel foils by the process of direct, high-precision mechanical micromachining [Brandner et al., 2000; Schaller et al., 1999]. The direction of flow in adjacent foils is alternated 90°, and the foils are attached by means of diffusion bonding to create a stack of cross-flow heat exchangers capable of transferring 10 kW at a temperature difference of

**FIGURE 6.1** (Color figure follows p. 12-26.) Micro heat exchanger constructed from rectangular channels machined in metal. (Courtesy of K. Schubert and D. Cacuci, Forschungszentrum, Karlsruhe.)

80 K using water flowing at 750 kg/hr. The impressively large rate of heat transfer is accomplished mainly by the large surface area covered by the interior of the microchannel: approximately  $3600 \text{ mm}^2$  packed into a 14-mm cube.

A second example of the application of microchannels is in the area of microelectromechanical systems (MEMS) devices for biological and chemical analyses. The primary advantages of microscale devices in these applications are the good match with the scale of biological structures and the potential for placing multiple functions for chemical analysis on a small area—the concept of a “chemistry laboratory on a chip.”

Microchannels are used to transport biological materials such as (in order of size) proteins, DNA, cells and embryos or to transport chemical samples and analytes. Typical of such devices is the i-STAT blood sample analysis cartridge shown in Figure 6.2. The sample is taken on board the chip through a port and moved through the microchannels by pressure to various sites where it is mixed with analyte and moved to a different site where the output is read. Flows in biological devices and chemical analysis microdevices are usually much slower than those in heat transfer and chemical reactor microdevices.

### 6.1.1 Unique Aspects of Liquids in Microchannels

Flows in microscale devices differ from their macroscopic counterparts for two reasons: the small scale makes molecular effects such as wall slip more important, and it amplifies the magnitudes of certain ordinary continuum effects to extreme levels. Consider, for example, strain rate and shear rate which

**FIGURE 6.2** Blood sample cartridge using microfluidic channels. (Courtesy of i-Stat, East Windsor, NJ.)

scale in proportion to the velocity scale,  $U_s$ , and inverse proportion to the length scale,  $L_s$ . Thus, 100-mm/s flow in a 10- $\mu\text{m}$  channel experiences a shear rate of the order of  $10^4 \text{ s}^{-1}$ . Acceleration scales as  $U_s^2/L_s$  and is similarly enhanced. The effect is even more dramatic if one tries to maintain the same volume flux while scaling down. The flux scales as  $Q \sim U_s L_s^2$ , so at constant flux  $U_s \sim L_s^{-2}$  and both shear and acceleration go as  $L_s^{-3}$ . Fluids that are Newtonian at ordinary rates of shear and extension can become non-Newtonian at very high rates. The pressure gradient becomes especially large in small cross-section channels. For fixed volume flux, the pressure gradient increases as  $L_s^{-4}$ .

Electrokinetic effects occur at the interface between liquids and solids such as glass due to chemical interaction. The result is an electrically charged double layer that induces a charge distribution in a very thin layer of fluid close to the wall. Application of an electric field to this layer creates a body force capable of moving the fluid as if it were slipping over the wall. The electro-osmotic effect and the electrophoretic effect (charges around particles) will be discussed in detail in a later section. Neither occurs in gases.

The effects of molecular structure are quite different in gases and liquids. If the Knudsen number (defined as  $Kn = \lambda/L_s$ , where  $\lambda$  is the mean free path in a gas and  $L_s$  is the characteristic channel dimension) is greater than  $10^{-3}$  [Gad-el-Hak, 1999; Janson et al., 1999], nonequilibrium effects may start to occur. Modified slip boundary conditions can be used in continuum models for Knudsen numbers between  $10^{-1}$  and  $10^{-3}$  [Gad-el-Hak, 1999]. As the Knudsen number continues to increase, continuum assumptions and fluid theory are no longer applicable. Analysis of such flow requires consideration of different physical phenomena [see Chapter 8 in this book on Analytical and Computational Models for Microscale Flows; Arkilic et al., 1997; Gad-el-Hak, 1999; Harley et al., 1995; Janson et al., 1999].

Because the density of liquids is about 1000 times the density of gases, the spacing between molecules in liquids is approximately ten times less than the spacing in gases. Liquid molecules do not have a mean free path, but following Bridgman (1923), the lattice spacing,  $\delta$ , may be used as a similar measure. The lattice spacing,  $\delta$ , is defined as [Probstein, 1994]:

$$\delta \sim \left( \frac{\bar{V}_1}{N_A} \right)^{1/3} \quad (6.1)$$

where  $\bar{V}_1$  is the molar volume and  $N_A$  is Avogadro's number. For water, this spacing is 0.3 nm. In a 1- $\mu\text{m}$  gap and a 50- $\mu\text{m}$ -diameter channel, the equivalent Knudsen numbers are  $3 \times 10^{-4}$  and  $6 \times 10^{-6}$ , respectively, well within the range of obeying continuum flow. In gases, effects such as slip at the wall occur when the mean free path length of the molecules is more than about one tenth of the flow dimension (i.e., flow

dimensions of order less than 650 nm in air at STP). (Note that the mean free path length of a gas is longer than the mean spacing between its molecules; see Chapter 4 for a detailed discussion.) In liquids, this condition will not occur unless the channels are smaller than approximately 3 nm, and continuum hydrodynamics may provide a useful description at scales even smaller than this because the forces of interaction between molecules in liquids are long range. For example, Stokes' classical result for drag on a sphere is routinely applied to particles whose diameters are well below 100 nm. Thus, liquid flow in microdevices should be described adequately by continuum hydrodynamics well below dimensions of 1  $\mu\text{m}$ .

Molecular effects in liquids are difficult to predict because the transport theory is less well developed than the kinetic theory of gases. For this reason, studies of liquid microflows in which molecular effects may play a role are much more convincing if done experimentally.

Liquids are essentially incompressible. Consequently, the density of a liquid in microchannel flow remains very nearly constant as a function of distance along the channel, despite the very large pressure gradients that characterize microscale flow. This behavior greatly simplifies the analysis of liquid flows relative to gas flows wherein the large pressure drop in a channel leads to large expansion and large changes of thermal heat capacity.

The large heat capacity of liquids relative to gases implies that the effects of internal heating due to viscous dissipation are much less significant in liquid flows. The pressure drop in microchannel flow can be very large, and because all of the work of the pressure difference against the mean flow ultimately goes into viscous dissipation, effects due to internal heating by viscous dissipation may be significant. However, they will be substantially less in liquids than in gases, and they can often be ignored, allowing one to approximate the liquid as a constant density, constant property fluid.

The dynamic viscosity,  $\mu$ , of a liquid is larger than that of a gas by a factor of about 100 (see Table 6.1). This implies much higher resistance to flow through the channels. The kinematic viscosity of a liquid is typically much less than the kinematic viscosity of a gas, owing to the much higher density of liquids (Table 6.1). This implies much more rapid diffusion of momentum in gases. Similar statements pertain qualitatively to the thermal conductivity and the thermal diffusivity.

Liquids in contact with solids or gases have surface tension in the interface. At the microscale, the surface tension force becomes one of the most important forces, far exceeding body forces such as gravity and electrostatic fields.

Bubbles can occur in liquids, for good or ill. Unwanted bubbles can block channels, or substantially alter the flow. But, bubbles can also be used to apply pressure and to perform pumping by heating and cooling the gases inside the bubble.

Particulates and droplets suspended in liquids have densities that match liquid more closely. Settling is much less rapid in liquids, and suspensions have the ability to follow the accelerations of the flow. This effect can also keep suspended impurities in suspension for much longer, thereby increasing the probability that an impurity will introduce unwanted behavior.

Liquids can interact with solids to form an electric double layer at the interface. This is the basis for the phenomena of electro-osmosis and electrophoresis, both of which can be used to move fluid and particles in channels. These topics will be discussed in detail in a later section. Liquids can be non-Newtonian, especially at the high shear rates encountered in microchannels.

**TABLE 6.1** Dynamic and Kinematic Viscosities of Typical Liquids Compared to Air at 1 atm

## 6.1.2 Continuum Hydrodynamics of Pressure Driven Flow in Channels

The general continuum description of the flow of an incompressible, Newtonian fluid flow with variable properties and no body forces other than gravity (i.e., no electrical forces) consists of the incompressible continuity equation:

$$\frac{\partial u_j}{\partial x_j} = 0 \quad (6.2)$$

and the momentum equation:

$$\rho \left( \frac{\partial u_i}{\partial t} + u_j \frac{\partial u_i}{\partial x_j} \right) = \frac{\partial \tau_{ij}}{\partial x_j} + \rho b_i \quad (6.3)$$

where the fluid stress is given by Stokes' law of viscosity:

$$\tau_{ij} = -p\delta_{ij} + \mu \left( \frac{\partial u_i}{\partial x_j} + \frac{\partial u_j}{\partial x_i} \right) \quad (6.4)$$

Here,  $u_i$  is the  $i$ th component of the velocity vector  $\mathbf{u}(\mathbf{x}, t)$ ,  $\rho$  is the mass density ( $\text{kg/m}^3$ ),  $b_i$  is the body force per unit mass ( $\text{m/s}^2$ ) (often,  $b_i = g_i$ , the gravitational acceleration), and  $\tau_{ij}$  is the stress tensor ( $\text{N/m}^2$ ). The corresponding enthalpy equation is

$$\rho c_p \left( \frac{\partial T}{\partial t} + u_j \frac{\partial T}{\partial x_j} \right) = -\frac{\partial q_j}{\partial x_j} + \Phi \quad (6.5)$$

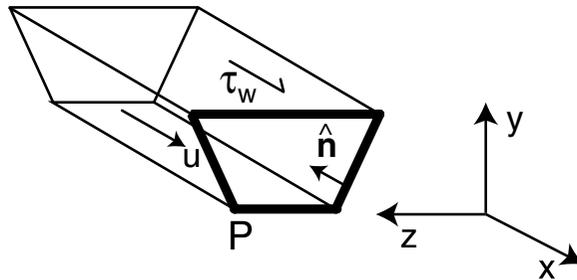

where  $T$  is the temperature, and  $q$  is the heat flux ( $\text{J/s m}^2$ ) given by Fourier's law of heat conduction by molecular diffusion  $k$ ,

$$q_i = -k \frac{\partial T}{\partial x_i} \quad (6.6)$$

The rate of conversion of mechanical energy into heat due to internal viscous heating is

$$\Phi = \mu \left( \frac{\partial u_i}{\partial x_j} + \frac{\partial u_j}{\partial x_i} \right) \frac{\partial u_i}{\partial x_j} \quad (6.7)$$

Consider a long parallel duct or channel with the  $x$ -direction along the axis of the channel and the coordinates  $y$  and  $z$  in the plane perpendicular to the axis of the channel (Figure 6.3). The entering flow

**FIGURE 6.3** Flow in a duct of arbitrary cross section A.  $P$  is the perimeter and  $\tau_w$  is the wall shear stress.

undergoes a transient response in which the velocity and temperature profiles change in the streamwise direction. This process continues until the flow properties become independent of the streamwise position. In this state of fully developed velocity profile, the velocity field is unidirectional,  $\mathbf{u}(x) = (u(y, z), 0, 0)$ , and there is no acceleration of the fluid. Thus, for fully developed flow with gravitational body force  $\mathbf{g}$  the equations become, very simply:

$$\rho \frac{\partial u}{\partial t} = -\frac{dp}{dx} + \rho g_x + \frac{\partial}{\partial y} \left( \mu \frac{\partial u}{\partial y} \right) + \frac{\partial}{\partial z} \left( \mu \frac{\partial u}{\partial z} \right) \quad (6.8)$$

$$\rho c_p \frac{\partial T}{\partial t} = \frac{\partial}{\partial y} \left( k \frac{\partial T}{\partial y} \right) + \frac{\partial}{\partial z} \left( k \frac{\partial T}{\partial z} \right) + \Phi \quad (6.9)$$

Finally, if the flow is steady and the temperature and properties are constant, then the equation for streamwise velocity profiles becomes a simple Poisson equation:

$$\frac{\partial^2 u}{\partial y^2} + \frac{\partial^2 u}{\partial z^2} = \frac{1}{\mu} \frac{d}{dx} (p - \rho g_x x) \quad (6.10)$$

In the absence of electrokinetic effects and for shear rates less than about  $10^{12} \text{ s}^{-1}$ , the appropriate boundary condition is the no-slip condition:

$$u = 0 \quad \text{on the boundary } P \quad (6.11)$$

### 6.1.3 Hydraulic Diameter

Control volume analysis of fully developed flow leads naturally to the concept of the *hydraulic diameter*. Figure 6.3 shows flow in a duct of arbitrary cross section. Because the flow is fully developed and unidirectional (assuming a straight duct), the acceleration is zero and control volume analysis of the momentum reduces to a simple force balance in the streamwise direction,

$$-\frac{dp}{dx} A = \bar{\tau}_w P \quad (6.12)$$

where

$$\bar{\tau}_w = \frac{1}{P} \oint_p \tau_w dl \quad (6.13)$$

is the wall shear stress averaged around the perimeter, and the local wall shear stress is given by:

$$\tau_w = \mu \left. \frac{\partial u}{\partial n} \right|_{n=0} \quad (6.14)$$

Equation (6.12) displays the relevance of the ratio of the area  $A$  to the perimeter  $P$ . In practice, the hydraulic diameter is defined to be

$$D_h = \frac{4A}{P} \quad (6.15)$$

so that when the cross section is a circle,  $D_h$  equals the diameter of the circle. The hydraulic diameter provides a convenient way to characterize a duct with a single length scale and a basis for comparison between ducts of different shapes. A common approximation is to also estimate the flow resistance in a duct or channel as the resistance of a round duct whose diameter is equal to the hydraulic diameter. This approximation is useful but subject to errors of order 10 to 20%. Because solution of Poisson's equation to obtain the exact wall shear stress is accomplished readily by numerical means, it is not necessary.

### 6.1.4 Flow in Round Capillaries

Flow in a round tube is the archetype for all duct and channel flows. While microfabrication characteristically yields channels of noncircular cross section, the round cross section is a useful and familiar point of reference, and microcapillaries are not uncommon. Extensive macroscale research on pipe flows dates back to Hagen's (1839), Poiseuille's (1841) and Reynolds' (1883) original studies in the 19th century. Independently, both Hagen (1839) and Poiseuille (1841) observed the relation between pressure head and velocity and its inverse proportionality to the fourth power of tube diameter.

In a round capillary of radius  $a = D/2$  and radial coordinate  $r$ , it is well known that the velocity profile across a diameter is parabolic:

$$u = u_{\max} \left( 1 - \frac{r^2}{a^2} \right) \quad (6.16)$$

where the maximum velocity is given by:

$$u_{\max} = \frac{a^2}{4\mu} \left( -\frac{dp}{dx} \right) \quad (6.17)$$

The volume flow rate,  $Q$ , is given by:

$$Q = \bar{U}A \quad (6.18)$$

where the average velocity,  $\bar{U}$ , defined by:

$$\bar{U} = \frac{1}{\pi a^2} \int_0^a u(r) 2\pi r dr \quad (6.19)$$

is numerically equal to

$$\bar{U} = \frac{1}{2} u_{\max} \quad (6.20)$$

Using these relations it is easily shown that the pressure drop in a length  $L$ ,  $\Delta p = (-dp/dx)L$ , is given by:

$$\Delta p = \frac{8\mu L Q}{\pi a^4} \quad (6.21)$$

The Darcy friction factor,  $f$ , is defined so that:

$$\Delta p = f \frac{L}{D} \rho \frac{\bar{U}^2}{2} \quad (6.22)$$

(the Fanning friction factor is one fourth the Darcy friction factor). The Reynolds number is defined, in

terms of a characteristic length scale,<sup>1</sup>  $L_s$ , by:

$$Re = \frac{\rho \bar{U} L_s}{\mu} \quad (6.23)$$

For a round pipe, the characteristic length scale is the diameter of the pipe,  $D$ . The friction factor for laminar flow in a round capillary is given by:

$$f = \frac{64}{Re} \quad (6.24)$$

The Poiseuille number is sometimes used to describe flow resistance in ducts of arbitrary cross section. It is defined by:

$$\begin{aligned} Po &= f Re/4 \\ &= -\frac{1}{\mu} \frac{dp}{dx} \frac{D_h^2}{2\bar{U}} \end{aligned} \quad (6.25)$$

where  $L_s$  used in the calculation of  $Re$  is  $D_h$ . The Poiseuille number has a value of 16 for a round capillary.

The inverse relationship between friction factor and Reynolds number has been well documented on the macroscale. It means that the pressure drop is linearly proportional to the flow rate,  $Q$ . In the laminar region there is no dependence on surface roughness.

As the Reynolds number increases above 2000 in a circular duct, the flow begins to transition to turbulence. At this point, the friction factor increases dramatically, and the flow resistance ultimately becomes proportional to  $Q^2$  rather than  $Q$ .

### 6.1.5 Entrance Length Development

Before the flow reaches the state of a fully developed velocity profile, it must transition from the profile of the velocity at the entrance to the microduct, whatever that is, to the fully developed limit. This transition occurs in the *entrance length* of the duct. In this region, the flow looks like a boundary layer that grows as it progresses downstream. Ultimately, the viscously retarded layers meet in the center of the duct at the end of the entrance length.

The pressure drop from the beginning of the duct to a location  $x$  is given by:

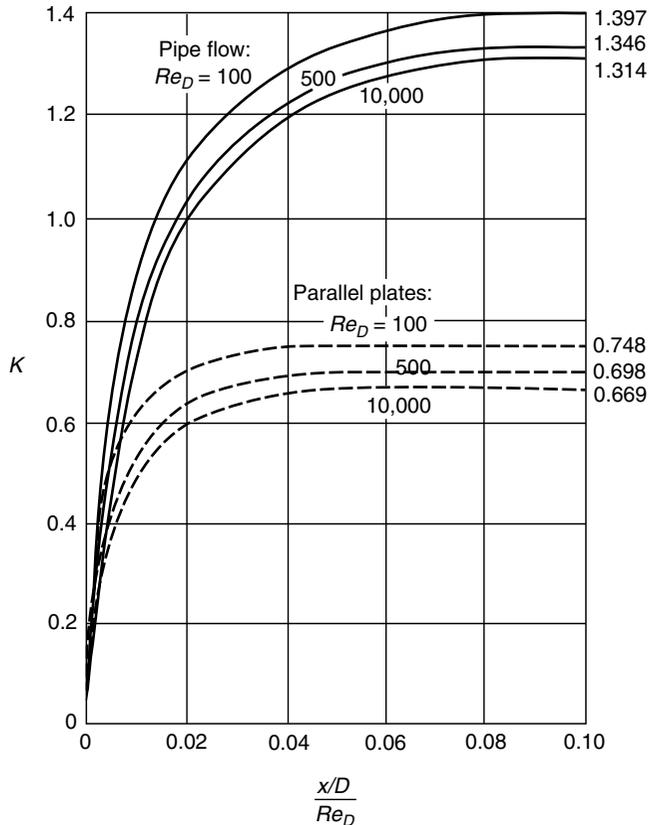

$$p_0 - p(x) = \left( f \frac{x}{D_h} + K(x) \right) \frac{\rho \bar{U}^2}{2} \quad (6.26)$$

where  $K(x)$  is the pressure drop parameter given in [Figure 6.4](#) for a circular duct and for parallel plates [White, 1991]. One sees that the flow development is largely completed by  $x/D = 0.065 Re$ .

### 6.1.6 Transition to Turbulent Flow

In 1883, Reynolds found a critical value of velocity,  $u_{crit}$ , above which the form of the flow resistance changes. The corresponding dimensionless parameter is the critical Reynolds number,  $Re_{crit}$ , below which disturbances in the flow are not maintained. Such disturbances may be caused by inlet conditions such as a sharp edge or unsteadiness in the flow source. Depending on the Reynolds number, disturbances may also be introduced by natural transition to turbulent flow.

<sup>1</sup>In the remainder of this chapter, the characteristic length scale used in calculating  $Re$  is to be inferred from context, e.g., generally  $D_h$  for a rectangular channel and  $D$  for a circular tube.

**FIGURE 6.4** Entrance length parameter  $K$  for laminar flow in the inlet of a duct. (From White, F.M. (1991) *Viscous Flow*, second edition, McGraw-Hill, New York, p. 292. With permission.)

Reynolds found  $Re_{crit}$  to be approximately 2000, and this value has been generally accepted. Once the flow is fully turbulent, the empirical relationship often used to correlate friction factor and the Reynolds number for smooth pipes and initially proposed by Blasius is

$$f \approx 0.3164 Re^{-0.25} \tag{6.27}$$

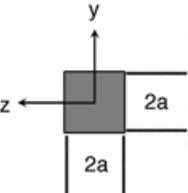

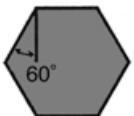

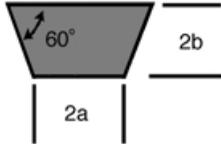

For rough pipes, the friction factor departs from the Blasius relation in the turbulent region. This departure occurs at different values of  $Re$  depending on the magnitude of the surface roughness. The Moody chart summarizes the traditional friction factor curves and is readily available in any basic fluids textbook (e.g., White, 1994, p. 318).

### 6.1.7 Noncircular Channels

Fully developed flow in noncircular ducts is found by solving the Poisson equation (Eq. 6.10). Frequently, analytical solutions can also be found, but the numerical approach is so reliable that there is little need for exact solutions. Developing flow in the entrance region is more difficult, but here again numerical approaches are relatively straightforward. Table 6.2 summarizes the flow resistance for various laminar flows. One sees that the effect of the shape of the channel is relatively weak.

As mentioned earlier, a common approximation made in analyzing flow in ducts of noncircular cross section is to use the results for circular ducts, but with the hydraulic diameter of the noncircular duct replacing that of the round duct. For example, this can be done to estimate the flow resistance of fully developed flow and the resistance in the entrance region.

## 6.2 Experimental Studies of Flow Through Microchannels

Despite the fundamental simplicity of laminar flow in straight ducts, experimental studies of microscale flow have often failed to reveal the expected relationship between the friction factor and Reynolds number. Further, flow discrepancies are neither consistently higher nor lower than macroscale predictions. A summary of the experiments that have been conducted to investigate the behavior of fluid flow in microchannels, over a large range of Reynolds numbers, geometries and experimental conditions, is presented in Table 6.3. In reviewing these results, they will be grouped according to the results of friction factor measurements (follow macroscale predictions, higher than predictions, and lower than predictions).

The first experimental investigations of flow through microchannels in the early 1980s were motivated by the interest in high-performance heat sinking. The large surface-to-volume ratios of microchannels make them excellent candidates for efficient heat transfer devices, as discussed in the introduction to this chapter. Tuckerman and Pease (1981) studied flow through an array of microchannels with approximately rectangular cross sections (height range 50 to 56  $\mu\text{m}$ , width range 287 to 320  $\mu\text{m}$ ). Although this study was focused primarily on heat transfer characteristics, they “confirmed that the flow rate obeyed

**TABLE 6.3** Experimental Conditions for Flow Resistance Experiments

Study	Working Fluid	Channel Description	Reynolds Numbers
Choi et al. (1991)	Nitrogen gas	Circular: diameter 3–81 $\mu\text{m}$	$\sim 30$ –20,000
Flockhart and Dhariwal (1998)	Water	Trapezoidal: depth 27–63 $\mu\text{m}$ , width 100–1000 $\mu\text{m}$ , length 12–36 mm	<600
Jiang et al. (1995)	Water	Circular: diameter 8–42 $\mu\text{m}$ ; rectangular, trapezoidal and triangular: depth 13.4–46 $\mu\text{m}$ , width 35–110 $\mu\text{m}$ , length 2.5–10 mm	Circular: < $\sim 1.2$ ; unclear for other geometries
Mala and Li (1999)	Water	Circular: diameter 50–254 $\mu\text{m}$	Up to 2500
Papautsky et al. (1999a)	Water	Array of rectangular channels, each: depth 30 $\mu\text{m}$ , width 600 $\mu\text{m}$ , length 3 mm	1–18
Papautsky et al. (1999b)	Water	Rectangular array of channels: height 22.71–26.35 $\mu\text{m}$ , width 150–600 $\mu\text{m}$ , length 7.75 mm	0.001–10
Peng et al. (1994)	Water	Rectangular: height 100–300 $\mu\text{m}$ , width 200–400 $\mu\text{m}$ , length 50 mm	50–4,000
Pfahler et al. (1991)	<i>n</i> -Propanol, silicone oil, nitrogen gas, helium gas	Rectangular and trapezoidal, depending on channel: depth 0.48–38.7 $\mu\text{m}$ , width 55–115 $\mu\text{m}$ , length 10.2–10.9 mm	Liquids: $\ll 1$ to approx. 80
Qu et al. (2000)	Water	Trapezoidal: depth 28–114 $\mu\text{m}$ , width 148–523 $\mu\text{m}$ , length 28 mm	$\sim 10$ –1,450
Sharp et al. (2000)	Water	Circular: diameter 75–242 $\mu\text{m}$	50–2500
Tuckerman and Pease (1981)	Water	Array of etched rectangular/ trapezoidal, each: depth 50–56 $\mu\text{m}$ , width 287–320 $\mu\text{m}$ , length 1 cm	$\sim 200$ –600
Wilding et al. (1994)	Water, biological fluids	Trapezoidal: depth 20–40 $\mu\text{m}$ , width 40–150 $\mu\text{m}$ , length 11.7 mm	Water: 17–126
Wu and Little (1983)	Nitrogen, helium and argon	Trapezoidal or U-shaped: depth 28–65 $\mu\text{m}$ , width 133–200 $\mu\text{m}$ , length 7.6–40.3 mm	$\sim 200$ –15,000
Yu et al. (1995)	Nitrogen gas, water	Circular: diameter 19–102 $\mu\text{m}$	250–20,000

*Note:* When a range of values for channel dimension is given, it indicates that several channels were used, with different individual dimensions.

Poiseuille's equation." Shortly thereafter, a study of microchannels for use in small Joule–Thomson refrigerators was performed [Wu and Little, 1983]. Significant roughnesses were present in some of these etched silicon or glass channels, but friction factors measured in the smoothest channel showed reasonable agreement with theoretical macroscale predictions. Several other experiments have also shown general agreement with macroscale theoretical predictions for friction factor, in at least certain parameter ranges [Flockhart and Dhariwal, 1998; Jiang et al., 1995; Sharp et al., 2000; Wilding et al., 1994].

Geometrical differences were emphasized in Jiang et al.'s (1995) experiments, which employed circular glass microchannels and silicon microchannels with rectangular, trapezoidal and triangular cross sections. Although linear relationships between flow rate and pressure drop were observed in all the microchannels, a direct analysis of the friction factor was not performed except in the case of the circular microchannels ( $D = 8$ –42  $\mu\text{m}$ ,  $Re < 1.2$ ). In the circular case, the friction factor matched theoretical predictions to within 10 to 20%.

Focusing primarily on biological fluids, but also using water and saline as working fluids, Wilding et al. (1994) found that results for water flowing in silicon micromachined channels (Reynolds numbers  $\sim 17$  to 126) agreed well with theory for at least the lower Reynolds numbers tested. The disagreement at higher Reynolds numbers was noted to be a result of "entrance effects and inertial losses" not included in the theory.

Saline was also used as the working fluid without much change in the results, suggesting that surface charge effects are minimal. Biological fluids, as expected, exhibited shear thinning and non-Newtonian behavior.

Comparison of numerical calculations for flow in trapezoidal channels finds good agreement between numerics and experiment for  $Re < 600$ , although some entrance effects were observed in the shortest channels [Flockhart and Dhariwal, 1998]. The numerical calculations were motivated by the fact that this particular trapezoidal geometry is very common in microfluidic applications as a result of anisotropic etching techniques employed in fabrication, particularly in  $\langle 100 \rangle$  silicon.

Microscale measurements of the friction factor by Sharp et al. (2000) generally agree with the macroscale laminar theory to within  $\pm 2\%$  experimental error over all Reynolds numbers up to transition ( $-50 < Re < 2000$ ), for water flowing through circular fused silica microchannels with  $D \sim 75$  to  $242 \mu\text{m}$ . Similar agreement is also obtained using a 20% solution of glycerol and 1-propanol. Occasional discrepancies that fall outside of the error bars tend to occur in the Reynolds number range  $1200 < Re < 2000$ , but in no case is the discrepancy greater than +4%.

Studies finding an increase in friction factor on the microscale under certain conditions include Wu and Little (1983), Peng et al. (1994), Mala and Li (1999), Qu et al. (2000) and Papautsky et al. (1999a; 1999b). In some cases, the departure from agreement with theoretical predictions is reasonably linked with a change in roughness or geometrical parameter. For example, Wu and Little's (1983) friction factor measurements appear to correlate with surface roughness, as the results agreed well with theory for smooth channels, but the agreement decreased as the roughness increased. In the rougher channels (absolute roughness up to  $40 \mu\text{m}$ ), the measured friction factors were higher than theoretical predictions. A linear relationship between  $f$  and  $Re$  was maintained in the laminar region, and the authors suggested that a transition to turbulence appeared at  $Re$  lower than expected (namely, 400) for the roughest glass channel.

In an effort to understand the influence of geometrical parameters (specifically, hydraulic diameter and aspect ratio) on flow resistance, Peng et al. (1994) considered water flows in rectangular machined steel grooves enclosed with a fiberglass cover. A large range of  $Re$  were obtained (50 to 4000), and a geometrical dependence was observed. For the most part,  $f$  increased with increasing  $H/W$  and also with increasing  $D_h$  (holding  $H/W$  constant).

The friction factor was observed to be higher than macroscale predictions for five of seven geometrical cases, all except  $H/W = 0.5$ . Because the relationship between  $f$  and  $Re$  no longer appeared inversely proportional, new power laws were suggested for this correlation in the laminar and turbulent regions, namely,  $f \propto Re^{-1.98}$  and  $f \propto Re^{-1.72}$ , respectively.

In addition to proposing new correlations in the laminar and fully turbulent regions, Peng et al. (1994) suggested that the regions themselves must be redefined depending upon the geometry of the microchannel. As in macroscale flows (*cf.* standard Moody chart, White, 1994, p. 318), two distinct relationships between  $f$  and  $Re$  were observed, one in the lower  $Re$  region and one in the higher  $Re$  region. The area between the two trends represents the transition region. The critical Reynolds number,  $Re_{\text{crit}}$  (the  $Re$  above which the low  $Re$  linear trend is no longer appropriate), exhibits a dependence on the hydraulic diameter.  $Re_{\text{crit}}$  was estimated at 200 for  $D_h < 220 \mu\text{m}$ , 400 for  $D_h = 240 \mu\text{m}$  and 700 for  $260 < D_h < 360 \mu\text{m}$ , implying, according to Peng et al. (1994), the occurrence of "early transition to turbulence" in these microchannels.

A second study of the dependence on geometrical parameters, but for much smaller  $Re$  ( $\sim 0.001$  to 10), measured friction factors generally higher than macroscale theory [Papautsky et al., 1999b], more so for the smallest  $Re$  ( $< 0.01$ ). As the Reynolds number increased to 10, the measured friction factor neared the theoretical macroscale predictions, though it still remained up to 20% high, even considering experimental error. A possible dependence of friction characteristics due to size was observed at a small aspect ratios ( $< 0.2$ ), although the authors were not able to attribute this independently to either the small dimension required for small aspect ratio ( $O, 20$  to  $40 \mu\text{m}$ ) or very low Reynolds number.

Nonlinear trends between pressure drop and flowrate were observed for  $Re$  as low as 300 by Mala and Li (1999), specifically for water flowing through a  $130\text{-}\mu\text{m}$ -diameter stainless steel microtube. At small Reynolds numbers ( $Re < 100$ ) the measured friction factors were in "rough agreement" with conventional theory, but for all other  $Re$  (up to 2500), the friction factors were consistently higher in stainless steel and fused silica microtubes (circular cross section). Measured flow friction for trapezoidal

channels was 8 to 38% higher than macroscale predictions for the range of parameters studied by Qu et al. (2000), and a dependence on  $D_h$  and  $Re$  was also observed.

Another group of studies found the flow resistance to be less than theoretical macroscale predictions for certain conditions [Choi et al., 1991; Peng et al., 1994; Pfahler et al., 1990a; 1990b; 1991; Yu et al., 1995]. In the study of geometrical effects by Peng et al. (1994), the friction factor was found to be lower than the macroscale theoretical prediction for two out of seven cases, namely, when  $H/W = 0.5$ . A clear trend between  $Re_{crit}$  and aspect ratio was observable. Although previously described, the trends between friction factor behavior and aspect ratio or hydraulic diameter were less consistent.

Comparing the friction factors for flow through channels with several fluids (2-propanol, *n*-propanol and silicone oil), Pfahler et al. (1990a; 1990b; 1991) found the measured friction factors to be lower than theoretical values for all but two cases: a small depth and very low  $Re$  (0.8  $\mu\text{m}$ ,  $Re \ll 1$ ) case and the case with largest depth ( $\sim 40 \mu\text{m}$ ). The authors acknowledged that their results depend heavily on channel size measurement, which was extremely difficult to measure accurately for the shallowest channels (depth  $< 1 \mu\text{m}$ ). The Reynolds numbers in their liquid flow experiments varied from much less than 1 to approximately 80 [Pfahler et al., 1991]. A possible size effect was noted for the silicone oil experiments; namely, for a channel with 3.0- $\mu\text{m}$  depth,  $f Re$  did not remain constant as  $Re$  varied from 0.01 to 0.3.

In addition to measuring friction factors, Choi et al. (1991) measured surface roughness and heat transfer coefficients for nitrogen gas flowing through microtubes with diameters in the range of 3 to 81  $\mu\text{m}$  and  $L/D$  ratios of 640 to 8100. The measured friction factors in both the laminar and turbulent region were lower than predicted by macroscale theory. The measured absolute root mean square (rms) roughness was in the range of 10 to 80 nm, such that the normalized rms roughness,  $\epsilon/D$ , was less than 0.006 for all but one case. No variations were observed that appeared to depend on roughness.

A similar study of flows through microtubes with diameters of 19 to 102  $\mu\text{m}$  obtained extremely high Reynolds numbers for microscale conditions, up to 20,000 [Yu et al., 1995]. The normalized roughness of the tubes,  $\epsilon/D$ , was estimated at 0.0003. For both water and gas, the measured friction factors were lower than macroscale predictions, by approximately 19% in laminar flow and 5% in the turbulent flow regime.

To aid in comparing the results of these studies, a normalized friction factor,  $C^*$ , is defined as:

$$C^* = \frac{(f Re)_{\text{experimental}}}{(f Re)_{\text{theoretical}}} \quad (6.28)$$

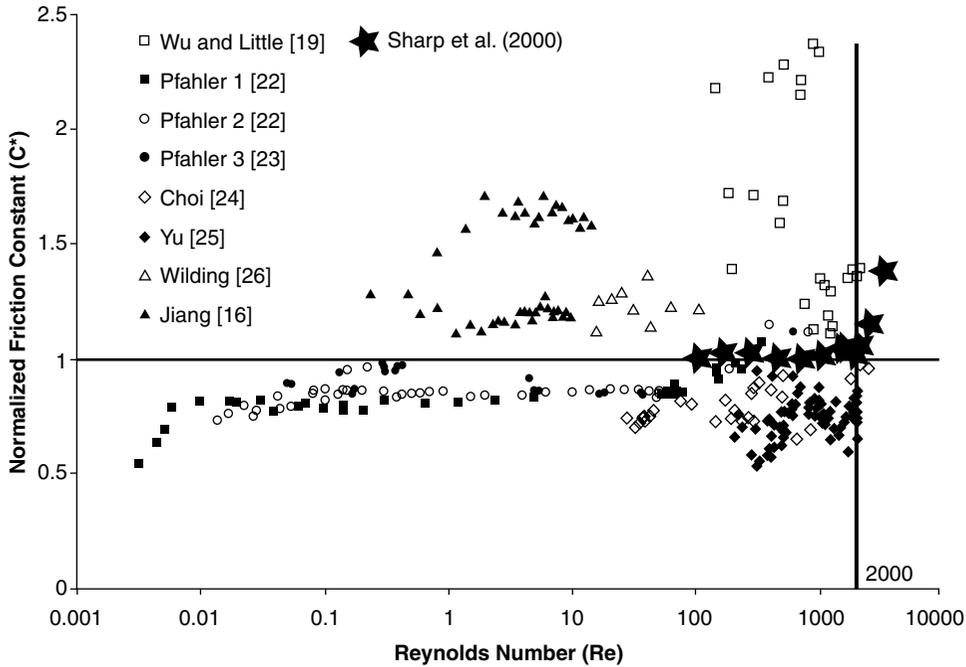

The wide variability of results is illustrated in [Figure 6.5](#). There is also wide variability in experimental conditions, microchannel geometries and methodology. However, the inconsistencies demonstrate the need for detailed velocity measurements in order to elucidate potential microscale effects and mechanisms in these channels.

## 6.2.1 Proposed Explanations for Measured Behavior

Thus far, the explanations offered in the literature for anomalous behavior of friction factor and flow resistance in microchannels include surface/roughness effects and electrical charge, variations in viscosity, microrotational effects of individual fluid molecules, “early” transition to turbulence, entrance effects and inaccuracies in measuring channel dimensions.

In macroscale theory, small to moderate surface roughness does not affect the flow resistance relationship in the laminar region [White, 1994]. Microscale results are inconclusive regarding the effects of surface roughness on resistance in the laminar region. Resistance results have shown both a strong increase due to roughness [Wu and Little, 1983] and no effect due to roughness [Choi et al., 1991].

In terms of surface effects on viscosity, a roughness viscosity model (RVM) has been introduced by Mala (1999), based on work by Merkle et al. (1974). Assuming that surface roughness increases the momentum transfer near the wall, Mala (1999) proposed that the roughness viscosity,  $\mu_r$ , as a function of  $r$ , is higher near the wall and proportional to the Reynolds number. Implementing this roughness-viscosity model for water flowing through trapezoidal channels, Qu et al. (2000) found reasonable agreement with model prediction and experimental results in most cases. However, the model did not

**FIGURE 6.5** Comparison of  $C^*$  vs. Reynolds number for several previous studies. Data from Papautsky et al. (1999a), with additional data from Sharp et al. (2000). References are [19] Wu and Little (1983), [22] Pfahler et al. (1990a), [23] Pfahler et al. (1991), [24] Choi et al. (1991), [25] Yu et al. (1995), [26] Wilding et al. (1994) and [16] Jiang et al. (1995).

accurately depict the increased slope in the relationship between pressure drop and Reynolds number observed in the same experiments for  $Re \geq 500$ .

It is possible that unexpected electrokinetic effects occur at the interface between the channel and the fluid due to chemical interactions. These effects have not been adequately addressed to date in the flow resistance studies.

Direct measurement of viscosity in very thin layers, or thin films, has been performed by Israelachvili (1986). The viscosity of water was found to retain its bulk viscosity value to within 10% even in a film as thin as 5 nm. Concentrated and dilute NaCl/KCl solutions were also tested to assess the impact of double-layer forces on the value of viscosity near a surface. The viscosity of these solutions also remained only minimally affected until the last molecular layer near the wall. Based on these measurements, the viscosity of fluid in the wall region is not expected to vary significantly from the bulk value, even in the presence of possible charging effects, bringing the explanations of Mala and Li (1999) and Qu et al. (2000) into question.

As previously mentioned, it is possible that the very high shear rates in these microchannels cause normally Newtonian fluids to behave in a non-Newtonian fashion. The shear rates in Sharp et al. (2000) were as high as  $7.2 \times 10^5 \text{ s}^{-1}$ . Measuring the rheology of fluids at very high shear rates is challenging. Novotny and Eckert (1974), using a flat plate rheometer, determined that the relationship between shear stress and shear rate is still linear for water at a shear rate of  $10,000 \text{ s}^{-1}$ . The possibility that anomalous effects are caused by non-Newtonian behavior above shear rates of  $10^4 \text{ s}^{-1}$  needs to be explored.

A model based upon micropolar fluid theory has been implemented by Papautsky et al. (1999a) in order to interpret their experimental results (Reynolds numbers 1 to 20). Eringen (1964) first proposed this type of theory, which takes into account microvolume elements capable of independently translating, rotating and deforming. The equations for a “micropolar fluid” include additional terms accounting for the independent behavior of these elements. The equations have been solved numerically in Papautsky

et al. (1999a) for flow in rectangular channels. The model predicts an increase in flow resistance, in better agreement with their data than conventional predictions.

One explanation often offered to explain the increase of flow resistance in microchannels is that scaling considerations somehow trigger the transition to turbulence at a critical Reynolds number lower than the value of 1800 to 2000 commonly accepted in macroscale pipe flows. If the critical Reynolds number is lower, then disturbances introduced into the flow by unsteadiness in the flow source, sharp inlet conditions or any other source would begin to grow and eventually the flow would become fully turbulent. The majority of flow behavior studies thus far have relied upon bulk flow measurements and have not been able to quantitatively assess the spatial or temporal instabilities in the microflows. Thus, the evidence suggesting “early transition to turbulence” has been based solely on the trends in the resistance data (see, for example, the discussion of the experiment of Peng et al. [1994] presented previously). “Early transition to turbulence” has also been suggested as an explanation for anomalous behavior of the relationship between the pressure gradient,  $\Delta p/L$ , and  $Q$  by Mala and Li (1999), who reported a transition to turbulence at  $Re > 300$  to 900 and fully developed turbulent flows at  $Re \geq 1000$  to 1500.

In Sharp et al.’s (2000) resistance experiments, there is no evidence that transition to turbulence occurs for  $Re < 2000$ . The magnitude of spatial and temporal variations measured using micro-particle image velocimetry (PIV) is also inconsistent with a transition to turbulence for  $Re < 2000$ .

Certainly, the inclusion or exclusion of entrance effects could affect the magnitude of the measured friction factor. For example, the  $L/D$  ratio in Peng et al.’s (1994) experiments ranged from 145 to 376. The Reynolds number range was 50 to 4000. The entrance length can be approximated as  $L_e/D = 0.06 \times Re$  [White, 1994], which brings into question the validity of certain regions of the results. In particular, in certain experiments ( $D_h = 267 \mu\text{m}$ ) of Peng et al. (1994), the entrance length is estimated at half the length of the test section for the higher Reynolds number data by the above criterion.

Regardless of the geometry, it is extremely difficult to accurately measure the dimensions of these microchannels, particularly when one of the dimensions is on the order of a couple of microns. The pressure drop in a round capillary is inversely proportional to  $D^4$  (Eq. (21), where  $D = 2a$ ), so an inaccuracy of 5% in measuring  $D$  can bias resistance results by 20%, enough to explain the majority of the discrepancies between the conventional macroscopic resistance predictions and the observed values in [Figure 6.5](#).

## 6.2.2 Measurements of Velocity in Microchannels

Along with the growth of research in microdevices, rapid development of experimental techniques for investigating flows in such devices is also underway, including modification of experimental techniques commonly applied at the macroscale and development of new techniques. Measurements of velocities in microchannels have been obtained using bulk flow, point-wise and field measurements. Each technique has certain advantages making it more suitable to provide a specific type of flowfield information.

The majority of flow resistance data to date has been obtained through the use of bulk flow measurements. This type of measurement generally includes a method for measuring flowrate, such as an in-line flowmeter, the timed collection of fluid at the outlet and pressure taps located at the inlet and outlet or simply at the inlet if the pressure at the outlet is known. Bulk flow measurements require no optical access to the microchannel, there are no restrictions on the geometrical parameters of the channel, and no seeding is required. However, given the disagreement in results regarding microscale effects on flow resistance in particular, bulk flow measurements are lacking in detail sufficient to discern potential mechanisms causing deviation from macroscale theory. Detailed measurements of flow velocity are also useful for optimizing the design of complex microdevices for mixing, separation, reaction and thermal control.

The first micro-PIV measurements were made by Santiago et al. (1998) in a Hele–Shaw cell. These velocity field measurements were resolved to  $6.9 \mu\text{m}$  in the lateral directions and  $1.5 \mu\text{m}$  in the depth direction and demonstrated the applicability of the well-established PIV technique for microflows. Micro-PIV measurements in a rectangular glass microchannel with 200-nm fluorescent tracer particles ( $Re < 1$ ) have been described in Meinhart et al. (1999). With improved acquisition and analysis, the lateral resolution was  $13.6 \mu\text{m}$  in the streamwise direction and significantly better,  $0.9 \mu\text{m}$ , in the cross-stream

direction, the direction of highest velocity variation. The first application of micro-PIV to a circular capillary was performed by Koutsiaris et al. (1999) in a 236- $\mu\text{m}$ -diameter channel with  $Re \ll 1$ . The seeding particles were 10- $\mu\text{m}$  glass spheres, and the resolution of the measurements was 26.2  $\mu\text{m}$  in the cross-stream direction. The measured velocity profiles agreed well with the predicted laminar parabolic profiles. More recently, micro-PIV has been used to study the velocity profiles and turbulence statistics of water flows in circular channels with  $D \sim 100$  to 250  $\mu\text{m}$  and  $Re$  up to 3000 by Sharp et al. (2000), using 2- $\mu\text{m}$  fluorescent particles.

Alternate visual methods applied to microchannel velocity measurements have been demonstrated by numerous researchers [Brody et al., 1996; Ovrzyn, 1999; Paul et al., 1998b; Taylor and Yeung, 1993; Webb and Maynes, 1999]. Molecular tagging velocimetry (MTV) was adapted to the microscale by Webb and Maynes (1999), where velocity profiles were obtained in circular tubes with  $D = 705 \mu\text{m}$  for  $Re = 800$  to 2200. The spatial resolution of these measurements was 2.1  $\mu\text{m}$ . The measured velocity profiles were consistent with macroscale laminar predictions for  $Re \leq 1600$ . A departure from laminar flow theory was noted at  $Re = 2168$ . Relevant development issues for microscale MTV are similar to those for PIV, namely, optical access and index of refraction compensation, particularly for curved surfaces, and optimized detection of the tracking particles (PIV) or beams (MTV).

Particle tracking, streak quantification or dye visualization can be relatively simple to implement given optical access and the ability to illuminate the flow. Care must be exercised in the extraction of quantitative data, particularly if the depth of field of the imaging device is large, if optical complications exist due to complex microchannel geometries, or if the particles or molecules are not accurately following the flow due to charge, size or density effects. Implementations of such techniques may be found in Taylor and Yeung (1993) and Brody et al. (1996).

Novel three-dimensional measurement techniques for microchannel flows are currently in development [Hitt and Lowe, 1999; Ovrzyn, 1999]. Building upon a technique already developed for the study of microscale structures, Hitt and Lowe (1999) used confocal imaging to build up a three-dimensional map of the "separation surface" following a bifurcation, where the "separation surface" describes the interfacial boundary between two components from different branches of the bifurcation. Using two laser scanning confocal microscopes, a series of thin (4.5 or 7.1  $\mu\text{m}$ ) horizontal slices were acquired and reconstruction software was used to combine these slices into a three-dimensional map. Again, optical access and effects are primary issues in the implementation of this method, and it is not suitable for unsteady flows. Ovrzyn (1999) sought to resolve and interpret the scattering pattern of a particle to determine its three-dimensional position, and he has applied this technique to laminar flow.

X-ray imaging techniques do not require optical access in the channel, though a contrast medium detectable by X-rays must be used as the working fluid. Lanzillotto et al. (1996) obtained flow displacement information from microradiograph images of emulsion flow through a 640- $\mu\text{m}$ -diameter tube and iododecane flow through a silicon V-groove chip.

The level of complexity increases when electrokinetic flows are considered. Paul et al. (1998b), Cummings et al. (1999) and Taylor and Yeung (1993) performed visual measurements in this environment. Paul et al. (1998b) seeded the flow with an uncaged fluorescent dye. Once the dye was uncaged by an initial ultraviolet (UV) laser pulse, the flow was illuminated by succeeding pulses of blue light for charge-coupled device (CCD) image acquisition, causing only the uncaged dye molecules to be excited. This technique was applied to both pressure-driven and electrokinetic flows in circular capillaries with diameters of the order 100  $\mu\text{m}$ . Since the dye transport represented both convection and diffusion, requisite care was necessary to separate the effects, as in Paul et al. (1998b). This method can also be used to acquire quantitative information regarding diffusion effects. Micro-PIV and nuclear magnetic resonance (NMR) techniques have also been applied to the measurement of velocities in electro-osmotic flow (Cummings et al., 1999; Manz et al., 1995).

Point-wise velocity measurements techniques have been applied at the microscale by Chen et al. (1997), Yazdanfar et al. (1997) and Tieu et al. (1995). Optical Doppler tomography, a point-wise measurement technique demonstrated by Chen et al. (1997), combines elements of Doppler velocimetry with optical coherence tomography in an effort to develop a system that can quantify the flow in biological tissues.

Chen et al. (1997) applied the technique to a 580- $\mu\text{m}$ -diameter conduit seeded with 1.7- $\mu\text{m}$  particles. An approximate parabolic profile was measured in the first test, and in the second it was shown that fluid particle velocities could be measured even with the conduit submerged in a highly scattering medium, as would be the case for particles in biological tissues. A similar measurement technique has been used for *in vivo* measurements in Yazdanfar et al. (1997). An adaptation of laser Doppler anemometry (LDA) techniques to microscale flows was demonstrated by Tieu et al. (1995), and point-wise data were obtained in a 175- $\mu\text{m}$  channel.

### 6.2.3 Nonlinear Channels

For practical MEMS applications, it is often useful to consider mixing or separation of components in microchannels. Numerous designs have been proposed, including T- and H-shaped channels, zigzag-shaped channels, two- and three-dimensional serpentine channels and multilaminators.

For example, Weigl and Yager (1999) have designed a T-sensor for implementation of assays in microchannels, as shown in Figure 6.6. A reference stream, a detection stream and a sample stream have been introduced through multiple T-junctions into a common channel. The design relied upon the differential diffusion of different-sized molecules to separate components in the sample stream. Differential diffusion rates are also fundamental to the design of the H-filter, used to separate components [Schulte et al., 2000]. Application of a slightly different T-channel design has been demonstrated for measurement of diffusion coefficients of a species in a complex fluid [Galambos and Forster, 1998].

A layering approach has been implemented by Branebjerg et al. (1996), splitting the streams and re-layering to increase interfacial area, thus promoting mixing. Adding complexity to the flowfield also has potential to increase the amount of mixing between streams, as demonstrated by Branebjerg et al.'s (1995) zigzag channel and the serpentine channels introduced by Liu et al. (2000). The three-dimensional serpentine channel in Liu et al. (2000) was designed to introduce chaotic advection into the system and further enhance mixing over a two-dimensional serpentine channel. A schematic of the three-dimensional serpentine channel is shown in Figure 6.7.

### 6.2.4 Capacitive Effects

While liquids are incompressible, the systems through which they flow may expand or contract in response to pressure in the liquid. This behavior can be described by analogy to flow in electrical circuits. In this analogy, fluid pressure corresponds to electrical voltage,  $p \sim V$ ; the volume flow rate corresponds to electrical current,  $Q \sim I$ ; and the flow resistance through a fluid element corresponds to an electrical resistor,  $R_{\text{flow}} \sim R_{\text{elec}}$ . Thus, for capillary flow,  $\Delta p = R_{\text{flow}}Q$ , where  $R_{\text{flow}} = 8\mu L/\pi a^4$  (cf. Eq. (21)), whereas in the electrical analogy  $\Delta V = R_{\text{elec}}I$ . If a fluid element is able to change its volume (expansion of plastic tubing, flexing in pressure transducer diaphragm, etc.), fluid continuity implies that:

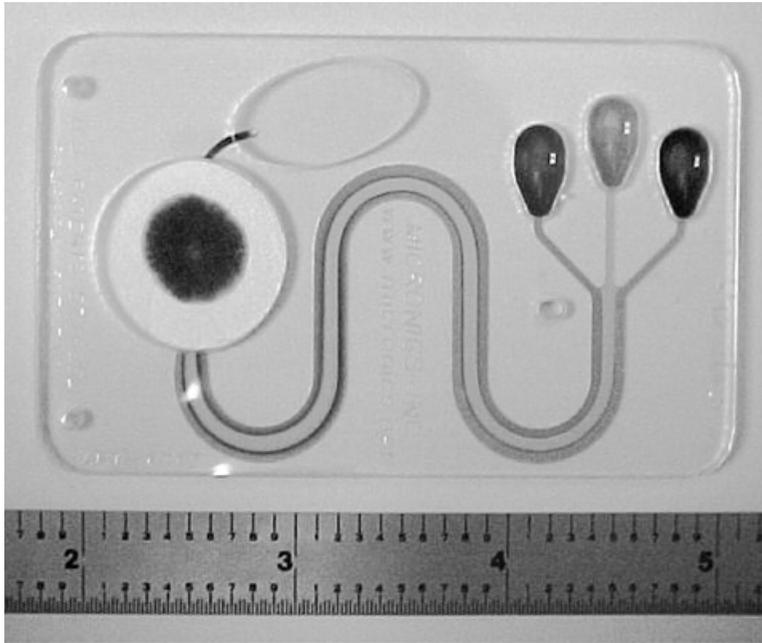

$$\Delta Q = C_{\text{flow}} \frac{dp}{dt} \quad (6.29)$$

where  $C_{\text{flow}}$  is the capacitance of the fluid element. The corresponding electrical law is  $I = C_{\text{elec}} dV/dt$ , where  $C_{\text{elec}}$  is the electrical capacitance.

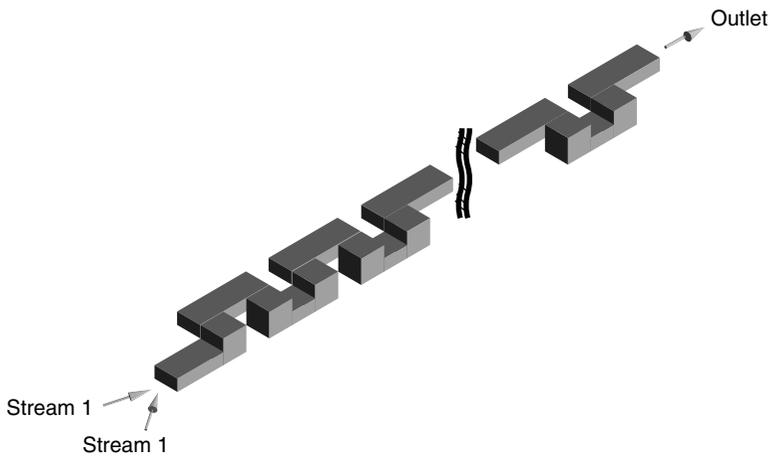

It is well known, in the context of electrical circuits, that a resistor and capacitor in combination cause transients whose time constant,  $\tau$ , is proportional to  $R_{\text{elec}}C_{\text{elec}}$ . In a microfluidic circuit, any capacitive element in combination with a flow resistance leads to analogous transients whose time constant is proportional to  $R_{\text{flow}}C_{\text{flow}}$ . Since  $R_{\text{flow}}$  can be very large in microchannels, the time constant can be surprisingly large (i.e.,  $10^3$  s). Consequently, capacitive effects can cause significant and inconveniently long transients.

## 6.3 Electrokinetics Background

The first demonstration of electrokinetic phenomena is attributed to F.F. Reuss, who demonstrated electro-osmotic flow through a sand column in a paper published in the *Proceedings of the Imperial Society*

**FIGURE 6.6** T-Sensor™ – Self-calibrating microchemical reactor and sensor. This design allows for self-calibration through the simultaneous flow of a reference solution on the opposite flank of the indicator stream from the sample to be analyzed. (Courtesy of Micronics, Inc., Redmond, WA.)

**FIGURE 6.7** Three-dimensional serpentine channel. (From Liu, R.H., et al. (2000) *J. MEMS* 9, 190–197, ASME, New York. With permission.)

of *Naturalists of Moscow* in 1809 [Probstein, 1994]. In the latter part of the 20th century, the main applications of electrokinetic phenomena have been fairly wide ranging, from the dewatering of soils and waste sludges using electric fields [Hiemenz and Rajagopalan, 1997] to the study of the stability of colloidal suspensions for household paint to devices that use electrophoretic mass transfer of colloidal suspensions to produce images on a planar substrate [Kitahara and Watanabe, 1984]. A community that has paid particular attention to the study of mass and momentum transport using electrokinetic effects is the developers of capillary electrophoresis (CE) devices [Manz et al., 1994]. CE devices are used to

separate biological and chemical species by their electrophoretic mobility (roughly speaking, by their mass-to-charge ratio). These traditional CE systems incorporate on-line detection schemes such as ultraviolet radiation scatter/absorption and laser-induced fluorescence [Baker, 1995].

Electrokinetics is the general term describing phenomena that involve the interaction between solid surfaces, ionic solutions and macroscopic electric fields. Two important classes of electrokinetics are electrophoresis and electro-osmosis, where the motions of solid bodies and fluids, respectively, occur when an external electric field is applied to the system. Electrophoresis is the induced motion of colloidal particles or molecules suspended in liquids that results from the application of an electric field. Electro-osmosis describes the motion of electrolyte liquids with respect to a fixed solid that results when an electric field is applied parallel to the surface. An example of electro-osmosis is the fluid pumping that occurs in a microcapillary when an electric field is applied along the axis of the capillary [Probstein, 1994]. Two other phenomena also classified under electrokinetics are flows with a finite streaming potential and sedimentation potential. These phenomena are counter-examples of electro-osmosis and electrophoresis, respectively. Streaming potential is the spontaneous generation of an electric potential from a pressure-driven flow in a charged microchannel [Hunter, 1981; Scales et al., 1992]. Sedimentation potential is the generation of an electric potential that results from the sedimentation (e.g., due to gravity) of a charged particle [Russel et al., 1999]. All of the phenomena classified under the term electrokinetics are manifestations of the electrostatic component of the Lorentz force (on ions and surface charges) and Newton's second law of motion. These interactions between charged particles and electric fields often involve electric double layers formed at liquid/solid interfaces and an introduction to this phenomenon is presented below.

### 6.3.1 Electrical Double Layers

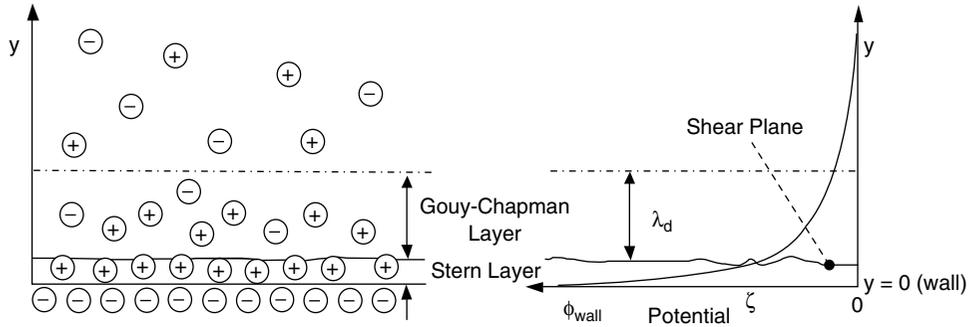

Most solid surfaces acquire a surface electric charge when brought into contact with an electrolyte (liquid). Mechanisms for the spontaneous charging of surface layers include the differential adsorption of ions from an electrolyte onto solid surfaces (e.g., ionic surfactants), the differential solution of ions from the surface to the electrolyte, and the deprotonation/ionization of surface groups [Hunter, 1981]. The most common of these in microfluidic electrokinetic systems is the deprotonation of surface groups on the surface of materials such as silica, glass, acrylic and polyester. In the case of glass and silica, the deprotonation of surface silanol groups (SiOH) determines the generated surface charge density. The magnitude of the net surface charge density at the liquid–solid interface is a function of the local pH. The equilibrium reaction associated with this deprotonation can be represented as:

Models describing this reaction have been proposed for several types of glass and silica [Hayes et al., 1993; Huang et al., 1993; Scales et al., 1992]. In practice, the full deprotonation of the glass surface, and therefore the maximum electro-osmotic flow mobility, is achieved for pH values greater than about 9.

In response to the surface charge generated at a liquid–solid interface, nearby ions of opposite charge in the electrolyte are attracted by the electric field produced by the surface charge, and ions of like charge are repelled. The spontaneously formed surface charge therefore forms a region near the surface called an electrical double layer (EDL) that supports a net excess of mobile ions with a polarity opposite to that of the wall. Figure 6.8 shows a schematic of the EDL for a negatively charged wall (e.g., as in the case of a glass surface). The region of excess charge formed by the counterions shielding the electric field of the wall can be used to impart a force (through ion drag) on the bulk fluid.

As shown in Figure 6.8, counterions reside in two regions divided into the Stern and Gouy–Chapman diffuse layers [Adamson and Gast, 1997]. The Stern layer counterions are adsorbed onto the wall, while the ions of the Gouy–Chapman diffuse layer are free to diffuse into the bulk fluid and therefore are available to impart work on the fluid. The plane separating the Stern and Gouy–Chapman layers is called the *shear plane*. The bulk liquid far from the wall is assumed to have net neutral charge. Also shown in Figure 6.8 is a sketch of the potential associated with the EDL. The magnitude of this potential is a maximum at the wall and drops rapidly through the Stern layer. The potential at the shear plane, which is also the

**FIGURE 6.8** Schematic of the electrical double layer (EDL): (Left) Distribution of co- and counterions near a charged wall. The Stern and Gouy–Chapman layers are shown with the Gouy–Chapman thickness roughly approximated as the Debye length of the solution. (Right) A plot of the negative potential distribution near a glass wall indicating the zeta potential, wall potential and location of the shear plane.

boundary of the fluid flow problem, is called the *zeta potential*,  $\zeta$ . Because of the difficulties associated with predicting the properties of the Stern layer [Hunter, 1981], the zeta potential is typically determined empirically from electro-osmotic or streaming potential flow measurements.

The simple treatment of the physics of the diffuse portion of the EDL presented here assumes a liquid with constant properties (i.e., constant viscosity and electrical permittivity). A more detailed model of the diffuse portion of the electrical double layer should include noncontinuum effects such as finite ion size effects and gradients in the dielectric strength and viscosity of the fluid [Hunter, 1981]. The width of the diffuse portion of the EDL is determined by the opposing forces of electrostatic attraction and thermal diffusion. This balance between electromigration and diffusive fluxes, together with the Nernst–Einstein equation relating ion diffusivity and mobility [Hiemenz and Rajagopalan, 1997], can be used to show that the concentration profile is described by the Boltzmann distribution. For an EDL on a flat plate, the Boltzmann distribution of ions of species  $i$ ,  $c_i$ , is

$$c_i(y) = c_{\infty,i} \exp\left(-\frac{ze\phi(y)}{kT}\right) \quad (6.31)$$

where  $c_{\infty,i}$  is the molar concentration of ion  $i$  in the bulk,  $z$  is the valance number of the ion,  $\phi$  is the local potential,  $T$  is temperature,  $e$  is the charge of an electron and  $k$  is Boltzmann’s constant. The coordinate  $y$  is perpendicular to the wall, and the origin is at the shear plane of the EDL. The net charge density in the EDL,  $\rho_E$ , is related to the molar concentrations of  $N$  species using the relation:

$$\rho_E = F \sum_{i=1}^N z_i c_i \quad (6.32)$$

where  $F$  is Faraday’s constant. The net charge density can also be related to the local potential in the diffuse EDL by the Poisson equation:

$$\nabla^2 \phi = \frac{-\rho_E}{\epsilon} \quad (6.33)$$

where  $\epsilon$  is the permittivity of the liquid. Substituting Eqs. (6.31) and (6.32) into Eq. (6.33), we find that:

$$\frac{d^2 \phi}{dy^2} = \frac{-F}{\epsilon} \sum_{i=1}^N z_i c_{\infty,i} \exp\left(-\frac{ze\phi(y)}{kT}\right) \quad (6.34)$$

For the simple case of a symmetric electrolyte with (two) monovalent ions, this relation becomes:

$$\frac{d^2\phi}{dy^2} = \frac{2Fz_i c_\infty}{\epsilon} \sinh\left(\frac{ze\phi(y)}{kT}\right) \quad (6.35)$$

where  $c_\infty$  is the molar concentration of each of the two ion species in the bulk. This relation is the nonlinear Poisson–Boltzmann equation. A closed form, analytical solution of this equation for the EDL on a flat wall is given by Adamson and Gast (1997).

A well-known approximation to the Poisson–Boltzmann solution, known as the Debye–Huckle limit, is to consider the case where the potential energy of ions in the EDL is small compared to their thermal energy so that the argument of the hyperbolic sine function in Eq. (6.35) is small. Applying this approximation, Eq. (6.35) becomes:

$$\frac{d^2\phi}{dy^2} = \frac{\phi(y)}{\lambda_D^2} \quad (6.36)$$

where  $\lambda_D$  is the Debye length of the electrolyte defined as:

$$\lambda_D \equiv \left(\frac{\epsilon kT}{2z^2 F^2 c_\infty}\right)^{\frac{1}{2}} \quad (6.37)$$

for a symmetric, monovalent electrolyte. The Debye length describes the characteristic thickness of the EDL which varies inversely with the square root of ion molar concentration. At typical biochemical, singly ionized buffer concentrations of 10 mM, the thickness of the EDL is therefore on the order of a few nanometers [Hiemenz and Rajagopalan, 1997]. In analyzing electrokinetic flow in microchannels, the Debye length should be compared to the characteristic dimension of the microchannel in order to classify the pertinent flow regime. Overbeek (1952a) points out that the Debye–Huckle approximation of the potential of the EDL holds remarkably well for values of the ratio  $ze\phi/(kT)$  up to approximately 2. This value is equivalent to a zeta potential of about 50 mV which is within the typical range of microfluidic applications.

Models of the physics of the EDLs can be used to extrapolate the zeta potential of particles and microchannels across a significant range of buffer concentration, fluid viscosity, electrical permittivity of electrolytes, and field strengths given only a few measurements. One of the most difficult zeta potential extrapolations to make is across different values of pH, as pH changes the equilibrium reactions associated with the charge at the liquid/solid interface.

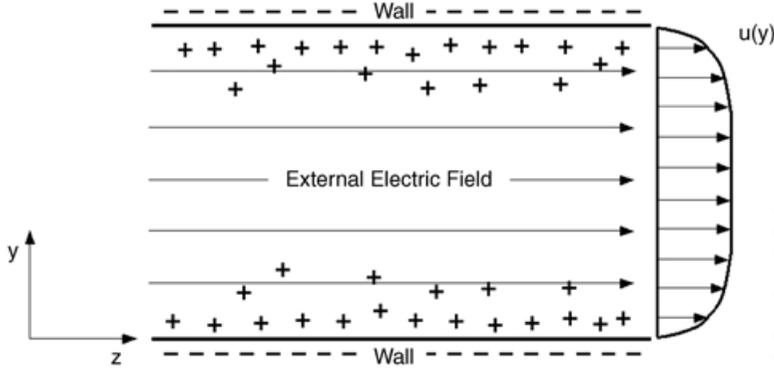

A full formulation of the coupled system of equations describing electro-osmotic and electrokinetic flow includes the convective diffusion equations for each of the charged species in the system, the Poisson equation for both the applied electric field and the potential of the EDL and the equations of fluid motion. A few solutions to this transport problem relevant to microfluidic systems are presented below.

### 6.3.2 EOF with Finite EDL

Electro-osmotic flow (EOF) results when an electric field is applied through a liquid-filled microchannel having an EDL at the channel surfaces, as described above. This applied electric field introduces an electrostatic Lorentz body force:

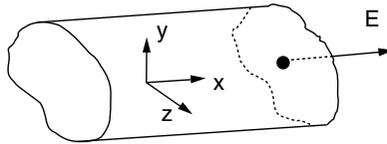

$$\rho \mathbf{b} = \rho_E \mathbf{E} \quad (6.38)$$

into the equation of motion for the fluid, Eq. (6.3). Within the EDL, the electric field exerts a net force on the liquid, causing the fluid near the walls to move. Alternatively, one can describe the effect as simply the ion drag on the fluid associated with the electrophoresis of the ions in the EDL. The fluid in the EDL exerts a viscous force on the rest of the (net zero charge) liquid in the bulk of the channel. For EDLs

**FIGURE 6.9** Schematic of an electro-osmotic flow channel with a finite EDL. The charges drawn in the figure indicate net charge. The boundary layers on either wall have a thickness on the order the Debye length of the solution. For nonoverlapping EDLs, the region near the center of the channel is net neutral.

much smaller than the channel dimension  $D$ , the fluid velocity reaches steady state in a short time  $t$  that is on the order of  $D^2/\nu$ , where  $\nu$  is the kinematic viscosity of the fluid. The resulting bulk electro-osmotic flow is depicted schematically in [Figure 6.9](#).

**FIGURE 6.10** Illustration of a section of a long, straight channel having an arbitrary cross section.

The equation of motion for steady, low Reynolds number flow in the microchannel is given by:

$$\nabla p = \mu \nabla^2 \mathbf{u} + \rho_e \mathbf{E} \quad (6.39)$$

Substituting Eq. (6.33) for the charge density results in:

$$\nabla^2 \left( \mathbf{u} - \frac{\epsilon \mathbf{E}}{\mu} \phi \right) = \frac{\nabla p}{\mu} \quad (6.40)$$

In Eq. (6.40), the electric field,  $\mathbf{E}$ , can be brought into the Laplace operator because  $\nabla \cdot \mathbf{E} = \nabla \times \mathbf{E} = 0$ . Equation (6.40) is linear so the velocities caused by the pressure gradient and the electric field can be considered separately and then superposed as follows:

$$\nabla^2 \left( \mathbf{u}_{\text{EOF}} - \frac{\epsilon \mathbf{E}}{\mu} \phi \right) = 0 \quad (6.41)$$

$$\nabla^2 \mathbf{u}_{\text{pressure}} = \frac{\nabla p}{\mu} \quad (6.42)$$

Together with Eq. (6.2), these are the general equations for electro-osmotic flow in a microchannel. Evaluation of the pressure-driven flow component of velocity in a microchannel can leverage analytical solutions available for channels of various cross sections [White, 1991]. The pressure gradient can be

applied externally or may arise internally because of variations in the zeta-potential at the channel walls [Herr et al., 2000].

Now consider electro-osmosis in a long, straight microchannel with a finite width electrical double layer and an arbitrary cross section that remains constant along the flow direction ( $x$ -axis), as shown in [Figure 6.10](#). The applied electric field is assumed to be uniform and along the  $x$ -axis of the microchannel. For the case where the potential at the wall is uniform, the solution to Eq. (6.41) is

$$u_{\text{EOF}} - \frac{\varepsilon E \zeta}{\mu} \phi = \frac{-\varepsilon E \zeta}{\mu} \quad (6.43)$$

with the zeta potential,  $\zeta$ , being the value of  $\phi$  at the top of the double layer. In Eq. (6.43),  $u_{\text{EOF}}$  and  $E$  are the unidirectional velocity and unidirectional applied electric field, respectively. The general expression for the electro-osmotic velocity, implicit in the potential, is then

$$u_{\text{EOF}}(y, z) = \frac{-\varepsilon E \zeta}{\mu} \left( 1 - \frac{\phi(y, z)}{\zeta} \right) \quad (6.44)$$

To compute values for the velocity given in Eq. (6.44), an expression for the potential  $\phi(y, z)$  is required. In general,  $\phi(y, z)$  can be computed numerically from Eq. (6.34), but analytical solutions exist for several geometries. Using the Boltzmann equation for a symmetric analyte and the Debye–Huckel approximation discussed in the previous section, Rice and Whitehead (1965) give the solution for electro-osmosis in a long cylindrical capillary:

$$u_{\text{EOF}}(r) = \frac{-\varepsilon E \zeta}{\mu} \left( 1 - \frac{I_0(r/\lambda_D)}{I_0(r/a)} \right) \quad (6.45)$$

In Eq. (6.45),  $I_0$  is the zero-order modified Bessel function of the first kind,  $r$  is the radial direction and  $a$  is the radius of the cylindrical capillary. This solution can be superposed with the solution of Eq. (6.42) for a constant pressure gradient. The resulting composite solution is

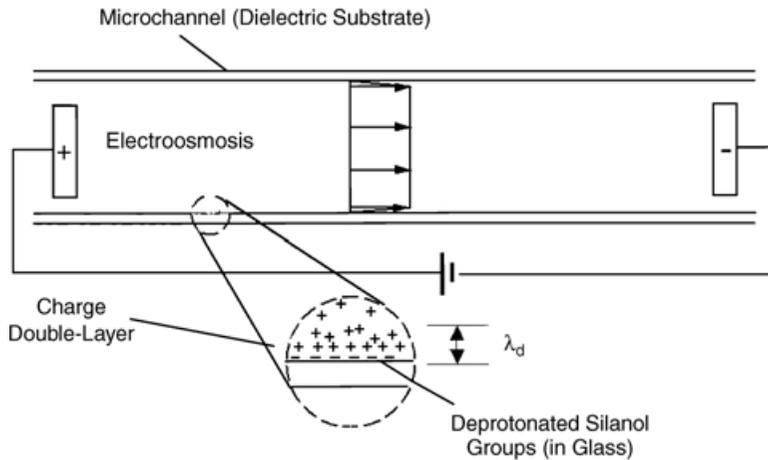

$$u(r) = \frac{-\varepsilon E \zeta}{\mu} \left( 1 - \frac{I_0(r/\lambda_D)}{I_0(r/a)} \right) - \frac{dp}{dx} \frac{a^2}{4\mu} \left( 1 - \frac{r^2}{a^2} \right) \quad (6.46)$$

Burgen and Nakache (1964) give a solution for electro-osmotic flow between two long, parallel plates for a finite EDL thickness. For other more complex geometries and many unsteady problems, numerical solutions for the electro-osmotic flow are required. However, when the Debye length is finite, but much smaller than other dimensions (e.g., the width of the microchannel), the disparate length scales can make numerical solutions difficult [Bianchi et al., 2000; Patankar and Hu, 1998]. In many cases, EOF in complex geometries can be determined numerically using a thin double-layer assumption described in the next section.

### 6.3.3 Thin EDL Electro-Osmotic Flow

This section presents a brief analysis of electro-osmotic flow in microchannels with thin EDLs. [Figure 6.11](#) shows a schematic of an electro-osmotic flow in a microchannel with zero pressure gradient. As shown in the figure, the Debye length of typical electrolytes used in microfabricated electrokinetic systems is much smaller than the hydraulic diameter of the channels. Typical ratios of Debye length-to-channel diameter are less than  $10^{-4}$ . For low Reynolds number, electro-osmotic flow in a cylindrical channel in the presence of a constant axial pressure gradient and a Debye length much smaller than the capillary radius, the solution of the velocity field is simply:

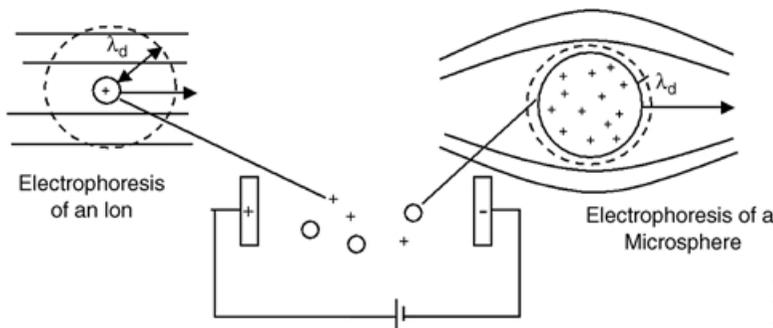

$$u(r) = \frac{\varepsilon \zeta E}{\mu} \frac{dp}{dx} \frac{(a^2 - r^2)}{4\mu} \quad (6.47)$$

**FIGURE 6.11** Schematic of electro-osmotic flow in a glass microchannel with a thin EDL. A zero pressure gradient “plug flow” is shown. The electrodes on the ends of the channel indicate the polarity of the electric field.

This equation can be derived by evaluating Eq. (6.46) in the limit of a thin EDL (i.e., a small value of  $\lambda_D/a$ ).

The zeta potential typically determines flow velocities and flow rates in common thin EDL systems. As mentioned above, this quantity can often be interpreted as an empirically measured mobility parameter that determines the local velocity of the flow at the top of the electrical double layer. The zeta potential

**FIGURE 6.12** Two limiting limits of electrophoresis in an electrolyte. Shown are electrophoretic particles in the electric field generated between two electrodes. On the left is the detail of a charged ion with a characteristic dimension much smaller than the Debye length of the electrolyte. On the right is a charged microsphere with a diameter much larger than the Debye length.

can be approximately related to the local surface charge density on the wall and the bulk fluid properties by applying continuum field and flow theory. Theoretically, the zeta potential is defined as the value of the electrostatic potential at the plane that separates double-layer counterions that are mobile from those that are fixed. For the case of zero applied pressure gradients, Eq. (6.47) reduces to the well-known Helmholtz–Smolouchowski relation for electro-osmotic flow:  $u = \epsilon\zeta E/\mu$  [Probstein, 1994].

### 6.3.4 Electrophoresis

Many electrokinetic microfluidic systems leverage the combination of electro-osmotic and electrophoresis to achieve biological separations and to transport charged particles (e.g., biological assay microbeads)

and ions. Because of this, we present here a short introduction to electrophoresis. Electrophoresis is the induced motion of colloidal particles or molecules suspended in polar solutions that results from application of an electric field. Two important regimes of electrophoresis depicted in Figure 6.12 are for the electromigration of species that are either large or small compared to the Debye length of the ionic solution in which they are suspended.

Electrophoresis of ionic molecules and macromolecules can be described as a simple balance between the electrostatic force on the molecule and the viscous drag associated with its resulting motion. As a result, the electrophoretic mobility (velocity-to-electric-field ratio) of molecules is a function of the size/molecular weight of the molecule and directly proportional to their valence number, or

$$u = \frac{qE}{3\pi\mu d} \quad (d \ll \lambda_d) \quad (6.48)$$

where  $q$  is the total molecule charge and  $d$  is the Stokes diameter of the particle (the diameter of a sphere of equal drag). In comparison, the electrophoresis of relatively large solid particles, such as 100- to 10,000-nm-diameter polystyrene spheres and single-celled organisms is a function of the electrostatic forces on the surface charge, the electrostatic forces on their charge double layers, and the viscous drag associated with both the motion of the body and the motion of the ionic cloud. For a wide range of cases where the ratio of particle diameter to Debye length is large so that, locally, the ionic cloud near the particle surface can be approximated by the EDL relations for a flat plate, the velocity of an electrophoretic particle reduces simply to:

$$u = \frac{\varepsilon\zeta E}{\mu} \quad (d \gg \lambda_d) \quad (6.49)$$

where the dimension  $d$  in the inequality condition is a characteristic dimension of the particle (e.g., its Stokes diameter). This equation was shown by Smoluchowski (1903) to be independent of particle shape. The reader will note that this, again, is the Helmholtz–Smoluchowski equation introduced earlier (with a change of sign).

The two expressions above describing the electrophoresis of particles can be expressed in terms of a mobility  $v_{\text{eph}}$  equal to  $q/(3\pi\mu d)$  and  $\varepsilon\zeta/\mu$  for characteristic particle dimensions much smaller and much larger than the Debye length, respectively. Note also that for the simple case of a fluid with uniform properties, the solution of the drift velocity of electrophoretic particles with respect to the bulk liquid are similar (i.e., parallel and directly proportional) to lines of electric field.

Several solutions of the particle velocity and velocity field in the region of an electrophoretic particle with a finite EDL exist [Hunter, 1981; Russel et al., 1999]. A well-known solution is that of Henry (1948) for the flow around an electrophoretic sphere in the Debye–Huckel limit. The  $d \gg \lambda_d$  limit of Henry’s solution results in Eq. (6.49).

### 6.3.5 Similarity between Electric and Velocity Fields for Electro-Osmosis and Electrophoresis

The previous sections have described the solution for electro-osmotic velocity field in straight, uniform cross-section channels. In general, solving for the electro-osmotic velocity field in more complex geometries requires a solution of the electric field and charge density in the microchannel, together with a solution to the Navier–Stokes equations. For simple electro-osmotic flows, however, Overbeek (1952b) has argued that the fluid velocity is parallel to the electric field everywhere. This concept has also been discussed by Cummings et al. (2000) and Santiago (2001). A set of sufficient conditions for which there exists a velocity field solution that is similar to the electric field is

- Uniform zeta potential

- Electric double-layers thin compared to channel dimension
- Electrically insulating channel walls
- Low Reynolds number
- Low product of Reynolds and Strouhal numbers
- Parallel flow at inlets and outlets
- Uniform fluid properties

When these conditions are met, the electro-osmotic streamlines exactly correspond to the electric field-lines. The approximation is applicable to systems with a microchannel length scale less than 100  $\mu\text{m}$ , a Debye length less than 10 nm, a velocity scale less than 1 mm/s and a characteristic forcing function time scale greater than 10 ms [Santiago, 2001]. An important part of this similarity proof is to show the applicability of the Helmholtz–Smoulochowski equation in describing the local velocity field at the slip surface that bounds the “internal” flow of the microchannel which excludes the EDL. The Helmholtz–Smoulochowski equation can be shown to hold for most microfluidic systems where the motion of the EDL is dominated by the Lorentz and viscous forces. In such systems, we can consider the velocity field of the fluid outside of the EDL as a three-dimensional, unsteady flow of a viscous fluid of zero net charge that is bounded by the following slip velocity condition:

$$u_{\text{slip}} = -\frac{\epsilon \zeta}{\mu} E_{\text{slip}} \quad (6.50)$$

where the subscript “slip” indicates a quantity evaluated at the slip surface at the top of the EDL (in practice, a few Debye lengths from the wall). The velocity along this slip surface is, for thin EDLs, similar to the electric field. This equation and the condition of similarity also hold for inlets and outlets of the flow domain which have zero imposed pressure gradients.

The complete velocity field of the flow bounded by the slip surface (and inlets and outlets) can be shown to be similar to the electric field [Santiago, 2001]. We nondimensionalize the Navier–Stokes equations by a characteristic velocity and length scale  $U_s$  and  $L_s$ , respectively. The pressure  $p$  is nondimensionalized by the viscous pressure  $\mu U_s/L_s$ . The Reynolds and Strouhal numbers are  $Re = \rho L_s U_s/\mu$  and  $St = L_s/\tau U_s$ , respectively, where  $\tau$  is the characteristic time scale of a forcing function. The equation of motion is

$$Re St \frac{\partial \mathbf{u}'}{\partial t'} + (Re \mathbf{u}' \cdot \nabla \mathbf{u}') = -\nabla p' + \nabla^2 \mathbf{u}' \quad (6.51)$$

Note that the right-most term in Eq. (6.51) can be expanded using a well-known vector identity:

$$\nabla^2 \mathbf{u}' = \nabla(\nabla \cdot \mathbf{u}') - \nabla \times \nabla \times \mathbf{u}' \quad (6.52)$$

We can now propose a solution to Eq. (6.52) that is proportional to the electric field and of the form:

$$\mathbf{u}' = \frac{c_o}{U} \mathbf{E} \quad (6.53)$$

where  $c_o$  is a proportionality constant and  $\mathbf{E}$  is the electric field driving the fluid. Because we have assumed that the EDL is thin, the electric field at the slip surface can be approximated by the electric field at the wall. The electric field bounded by the slip surface satisfies Faraday’s and Gauss’ laws:

$$\nabla \cdot \mathbf{E} = \nabla \times \mathbf{E} = 0 \quad (6.54)$$

Substituting Eqs. (6.53) and (6.54) into Eq. (6.51) yields:

$$Re St \frac{\partial \mathbf{u}'}{\partial t'} + Re(\mathbf{u}' \cdot \nabla \mathbf{u}') = -\nabla p' \quad (6.55)$$

This is the condition that must hold for Eq. (6.53) to be a solution to Eq. (6.51). One limiting case where this holds is for very high Reynolds number flows where inertial and pressure forces are much larger than viscous forces. Such flows are not applicable to microfluidics. Another limiting case applicable here is when  $Re$  and  $ReSt$  are both small, so that the condition for Eq. (6.53) to hold becomes:

$$\nabla p' = 0 \quad (6.56)$$

Therefore, we see that for small  $Re$  and  $ReSt$  and the pressure gradient at the inlets and outlets equal to zero, Eq. (6.53) is a valid solution to the flow bounded by the slip surface, inlets and outlets (note that these arguments do not show the uniqueness of this solution). We can now consider the boundary conditions required to determine the value of the proportionality constant  $c_o$ . Setting Eq. (6.50) equal to Eq. (6.53) we see that  $c_o = \varepsilon\zeta/\eta$ , so that if the simple flow conditions are met, then the velocity everywhere in the fluid bounded by the slip surface is given by:

$$\mathbf{u}(x, y, z, t) = -\frac{\varepsilon\zeta}{\mu} \mathbf{E}(x, y, z, t) \quad (6.57)$$

Equation (6.57) is the Helmholtz–Smoluchowski equation shown to be a valid solution to the quasi-steady velocity field in electro-osmotic flow with  $\zeta$  the value of the zeta potential at the slip surface. This result greatly simplifies the modeling of simple electro-osmotic flows, as simple Laplace equation solvers can be used to solve for the electric potential and then, using Eq. (6.57), for the velocity field. This approach has been applied to the optimization of microchannel geometries and verified experimentally [Molho et al., 2000]. Figure 6.13 shows the superposition of particle pathlines/streamlines and predicted electric fieldlines [Devasenathipathy and Santiago, 2000] in a steady flow that meets the simple electro-osmotic flow conditions summarized above. As shown in the figure, the electro-osmotic flow field streamlines are very well approximated by electric fieldlines.

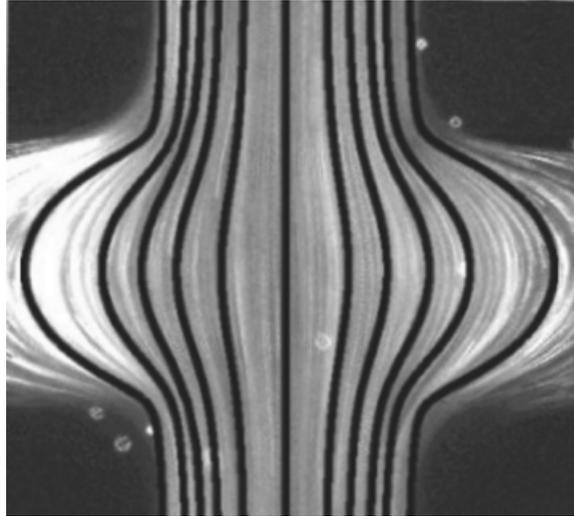

Note that for the simple electro-osmotic flow conditions analyzed here, the electrophoretic drift velocities (with respect to the bulk fluid) are also similar to the electric field, as mentioned above. Therefore, the time-averaged, total (drift plus fluid) velocity field of electrophoretic particles can be shown to be

$$\mathbf{u}_{\text{particle}} = \left( \mathbf{v}_{\text{eph}} - \frac{\varepsilon\zeta}{\mu} \right) \mathbf{E} \quad (6.58)$$

Here, we use the electrophoretic mobility  $\mathbf{v}_{\text{eph}}$  that was defined earlier and  $-\varepsilon\zeta/\mu$  is the electro-osmotic flow mobility of the microchannel walls.

### 6.3.6 Electrokinetic Microchips

The advent of microfabrication and microelectromechanical systems (MEMS) technology has seen an application of electrokinetics as a method for pumping fluids on microchips [Jacobson et al., 1994; Manz et al., 1994]. On-chip electro-osmotic pumping is easily incorporated into electrophoretic and chromatographic separations and these “laboratories on a chip” offer distinct advantages over the traditional, free-standing capillary systems. Advantages include reduced reagent use, tight control of geometry, the ability to network and control multiple channels on a chip, the possibility of massively parallel analytical

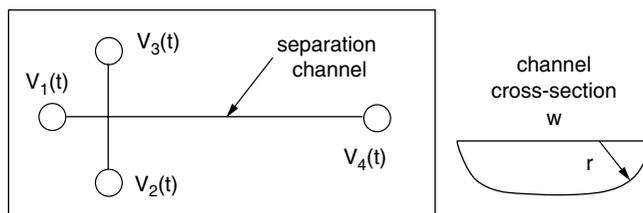

**FIGURE 6.13** Comparison between experimentally determined electrokinetic particle pathlines at a microchannel intersection and predicted electric field lines. The light streaks show the path lines of 0- to 5- $\mu\text{m}$ -diameter particles advecting through an intersection of two microchannels. The electrophoretic drift velocities and electro-osmotic flow velocities of the particles are approximately equal. The channels have a trapezoidal cross section having a hydraulic diameter of 18  $\mu\text{m}$  (130  $\mu\text{m}$  wide at the top, 60  $\mu\text{m}$  wide at the base and 50  $\mu\text{m}$  deep). The superposed, heavy black lines correspond to a prediction of electric field lines in the same geometry. The predicted electric field lines very closely approximate the experimentally determined pathlines of the flow. (From Devasenathipathy, S. and Santiago, J.G., unpublished results, Stanford University, Stanford, CA. With permission.)

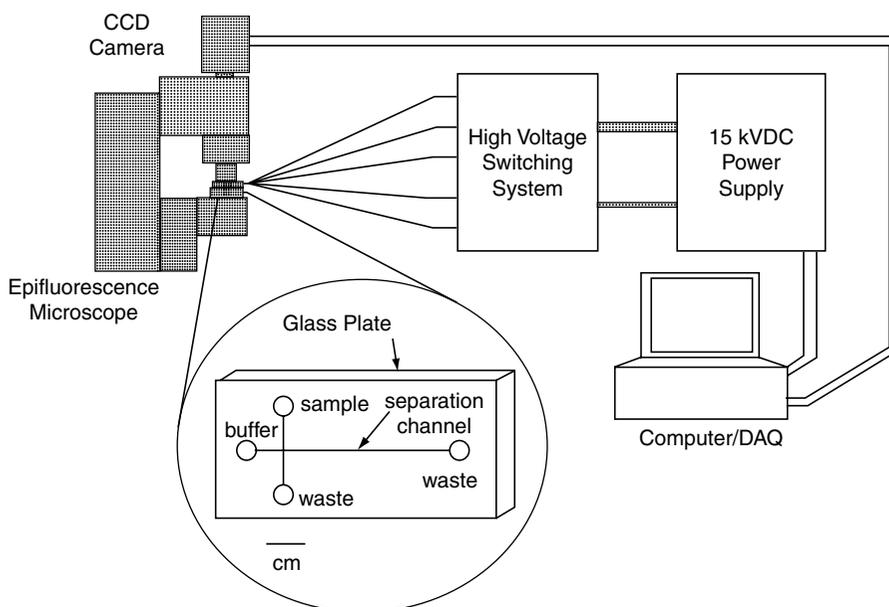

process on a single chip, the use of chip substrate as a heat sink (for high field separations) and the many advantages that follow the realization of a portable device [Khaledi, 1998]. Electrokinetic effects significantly extend the current design space of microsystems technology by offering unique methods of sample handling, mixing, separation and detection of biological species including cells, microparticles and molecules.

This section presents typical characteristics of a microchannel network fabricated using microlithographic techniques (see description of fabrication in the next section). Figure 6.14 shows a top view schematic of a typical microchannel fluidic chip used for capillary electrophoresis [Manz et al., 1994]. In this simple example, the channels are etched on a dielectric substrate and bonded to a plate (coverslip) of the same material. The circles in the schematic represent liquid reservoirs that connect with the channels through holes drilled through the coverslip. The parameters  $V_1$  through  $V_4$  are time-dependent voltages applied at each reservoir “well.” A typical voltage switching system may apply voltages with on/off ramp profiles of approximately 10,000 V/s or less so that the flow can often be approximated as quasi-steady.

The four-well system shown in Figure 6.14 can be used to perform an electrophoretic separation by injecting a sample from well #3 to well #2 by applying a potential difference between these wells. During this injection phase, the sample is confined or “pinched” to a small region within the separation channel by flowing solution from well #1 to #2 and from well #4 to well #2. The amount of desirable pinching is generally a trade-off between separation efficiency and sensitivity. Alarie et al. (2000) have found that the pinching was optimized (implying a minimization of the injected sample plug) when the flow rate of sample from well #3 was 44% of the total amount of flow entering the intersection. Next, the injection phase potential is deactivated and a potential is applied between well #1 and well #4 to dispense the injection plug into the separation channel and begin the electrophoretic separation. The potential between wells #1 and #2 is referred to as the *separation potential*. During the separation phase, potentials are applied at wells #2 and #3 which “retract” or “pull back” the solution-filled streams on either side of the separation channel. As with the pinching described above, the amount of “pull back” is a trade-off between

**FIGURE 6.14** Schematic of a typical electrokinetic microchannel chip.  $V_1$  through  $V_5$  represent time-dependent voltages applied to each microchannel. The channel cross section shown is for the [common case] of an isotropically etched glass substrate with a mask line width of  $(w - 2r)$ .

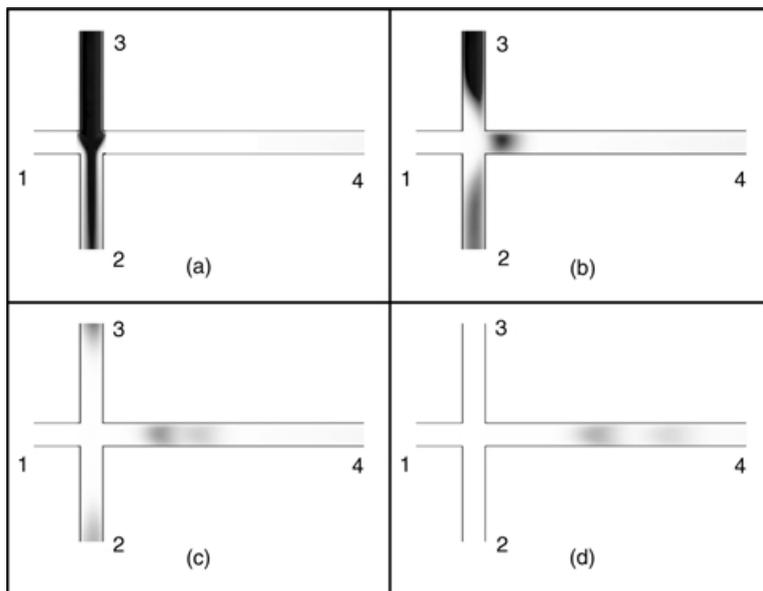

**FIGURE 6.15** Schematic of microfabricated capillary electrophoresis system, flow imaging system, high voltage control box and data acquisition computer.

separation efficiency and sensitivity. Alarie et al. (2000) have found that dispensing the sample plug into the separation channel was optimized when the flow rate of sample toward well #4 was 48% of the total amount of flow entering the intersection.

Figure 6.15 shows a schematic of a system that was used to perform and image an electrophoretic separation in a microfluidic chip. The microchip depicted schematically in Figure 6.15 is commercially available from Micralyne, Inc., Alberta, Canada. The width and depth of the channels are 50 and 20  $\mu\text{m}$ , respectively. The separation channel is 80 mm from the intersection to the waste well (well #4 in Figure 6.14). A high-voltage switching system allows for rapid switching between the injection and separation voltages and a computer, epifluorescent microscope and CCD camera are used to image the electrophoretic separation. The system depicted in Figure 6.15 is used to design and characterize electrokinetic injections; in a typical electrophoresis application, the CCD camera would be replaced with a point detector (e.g., a photomultiplier tube) near well #4.

Figure 6.16 shows an injection and separation sequence of 200  $\mu\text{M}$  solutions of fluorescein and Bodipy dyes (Molecular Probes, Inc., Eugene, OR). Images (a) through (d) are each 20-ms exposures separated by 250 ms. In Figure 6.16a, the sample is injected applying 0.5 kV and ground to well #3 and well #2, respectively. The sample volume at the intersection is “pinched” by flowing buffer from well #1 and well #4. Once a

**FIGURE 6.16** Separation sequence of Bodipy and fluorescein in a microfabricated capillary electrophoresis system. The channels shown are 50  $\mu\text{m}$  wide and 20  $\mu\text{m}$  deep. The fluorescence images are 20-ms exposures, and consecutive images are separated by 250 ms. A background image has been subtracted from each of the images, and the channel walls were drawn in for clarity. (From Bharadwaj, R., and Santiago, J.G., unpublished results, Stanford University, Stanford, CA. With permission.)

steady flow condition is achieved, the voltages are switched to inject a small sample plug into the separation channel. During this separation phase, the voltages applied at well #1 and well #4 are 2.4 kV and ground, respectively. The sample remaining in the injection channel is “retracted” from the intersection by applying 1.4 kV to both well #2 and well #3. During the separation, the electric field strength in the separation channel is about 200 V/cm. The electrokinetic injection introduces an approximately 400-pL volume of the homogenous sample mixture into the separation channel, as seen in Figure 6.16b. The Bodipy dye is neutral so its species velocity is identical to that of the electro-osmotic flow velocity. The relatively high electro-osmotic flow velocity in the capillary carries both the neutral Bodipy and negatively charged fluorescein toward well #4. The negative electrophoretic mobility of the fluorescein moves it against the electro-osmotic bulk flow, so it travels more slowly than the Bodipy dye. This difference in electrophoretic mobilities results in a separation of the two dyes into distinct analyte bands, as seen in Figures 6.16c and 6.16d. The zeta potential of the microchannel walls for the system used in this experiment was estimated at  $-50$  mV from the velocity of the neutral Bodipy dye [Bharadwaj and Santiago, 2000].

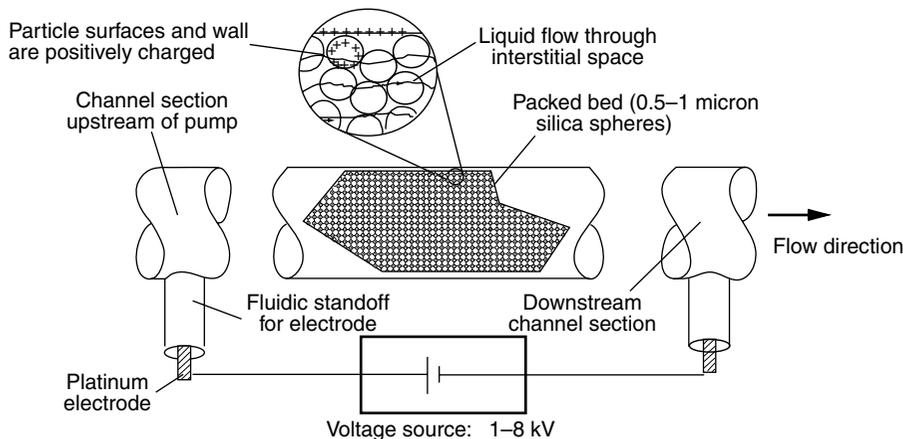

### 6.3.7 Engineering Considerations: Flowrate and Pressure of Electro-Osmotic Flow

As we have seen, the velocity field of systems with thin EDLs is approximately independent of the location in the microchannel and is therefore a “plug flow” profile for any cross section of the channel. The volume flow rate of such a flow is well approximated by the product of the electro-osmotic flow velocity and the cross-sectional area of the inner capillary:

$$Q = -\frac{\epsilon\zeta EA}{\mu} \quad (6.59)$$

For the typical case of electrokinetic systems with a bulk ion concentration in excess of about  $100 \mu\text{M}$  and characteristic dimension greater than about  $10 \mu\text{m}$ , the vast majority of the current carried within the microchannel is the electromigration current of the bulk liquid. For such typical flows, we can rewrite the fluid flow rate in terms of the net conductivity of the solution,  $\sigma$ :

$$Q = -\frac{\epsilon\zeta I}{\mu\sigma} \quad (6.60)$$

**FIGURE 6.17** Schematic of electrokinetic pump fabricated using a glass microchannel packed with silica spheres. The interstitial spaces of the packed bead structure create a network of submicron microchannels which can be used to generate pressures in excess of 5000 psi.

where  $I$  is the current consumed, and we have made the reasonable assumption that the electromigration component of the current flux dominates. The flow rate of a microchannel is therefore a function of the current carried by the channel and otherwise independent of geometry.

Another interesting case is that of an electrokinetic capillary with an imposed axial pressure gradient. For this case, we can use Eq. (6.47) to show the magnitude of the pressure that an electrokinetic microchannel can achieve. To this end, we solve Eq. (6.47) for the maximum pressure generated by a capillary with a sealed end and an applied voltage  $\Delta V$ , noting that the electric field and the pressure gradient can be expressed as  $\Delta V/L$  and  $\Delta p/L$ , respectively. Such a microchannel will produce zero net flow but will provide a significant pressure gradient in the direction of the electric field (in the case of a negatively charged wall). Imposing a zero net flow condition  $Q = \int_A \mathbf{u} \cdot d\mathbf{A} = 0$ , the solution for pressure generated in a thin EDL microchannel is then:

$$\Delta p = -\frac{8\epsilon\zeta\Delta V}{a^2} \quad (6.61)$$

which shows that the generated pressure will be directly proportional to voltage and inversely proportional to the square of the capillary radius. Eq. (6.61) dictates that decreasing the characteristic radius of the microchannel will result in higher pressure generation. This principle has, for example, been demonstrated effectively by electrokinetic pumps that have been built recently [Paul et al., 1998a; Zeng et al., 2000]. Pressures in excess of 20 atm have been demonstrated. Figure 6.17 shows a schematic of one of these pumps. This structure achieves a network of submicron-diameter microchannels by packing 0.5- to 1- $\mu\text{m}$  spheres in fused silica capillaries, using the interstitial spaces in these packed beds as flow passages.

### 6.3.8 Electrical Analogy and Microfluidic Networks

There is a strong analogy between electro-osmotic and electrophoretic transport and resistive electrical networks of microchannels with long axial-to-radial-dimension ratios. As described above, the electro-osmotic flowrate is directly proportional to the current. This analogy holds provided that the previously described conditions for electric/velocity field similarity also hold. Therefore, Kirchoff's current and voltage laws can be used to predict flow rates in a network of electro-osmotic channels given voltage at endpoint "nodes" of the system. In this one-dimensional analogy, all of the current, and hence all of the flow entering a node, must also leave that node. The resistance of each segment of the network can be determined by knowing the cross-sectional area, the conductivity of the liquid buffer and the length of the segment. Once the resistances and applied voltages are known, the current and electro-osmotic flow rate in every part of the network can be determined using Eq. (6.60).

### 6.3.9 Practical Considerations

A few practical considerations should be considered in the design, fabrication and operation of electrokinetic microfluidic systems. These considerations include the dimensions of the system, the choice of liquid and buffer ions, the field strengths used and the characteristics of the flow reservoirs and interconnects. A few examples of these design issues are given here.

In the case of microchannels used to generate pressure, Eq. (6.60) shows that a low liquid conductivity is essential for increasing thermodynamic efficiency of an electrokinetic pump, as Joule heating is an important contributor to dissipation [Zeng et al., 2000]. In electrokinetic systems for chemical analysis, on the other hand, the need for a stable pH requires a finite buffer strength, and typical buffer strengths are in the 1- to 100-mM range. The need for a stable pH, therefore, often conflicts with a need for high fields to achieve high-efficiency separations because of the effects of Joule heating of the liquid.

Joule heating of the liquid in electrokinetic systems can be detrimental in two ways. First, temperature gradients within the microchannel cause a nonuniformity in the local mobility of electrophoretic particles because the local viscosity is a function of temperature. This nonuniformity in mobility results in a dispersion associated with the transport of electrophoretic species [Bosse and Arce, 2000; Grushka et al., 1989; Knox, 1988]. The second effect of Joule heating is the rise in the absolute temperature of the buffer. This temperature rise results in higher electro-osmotic mobilities and higher sample diffusivities. In microchip electrophoretic separations, the effect of increased diffusivity on separation efficiency is somewhat offset by the associated decrease in separation time. In addition, the authors have found that an important limitation to the electric field magnitude in microchannel electrokinetics is that the associated elevated temperatures and decreases in gas solubility of the solution often result in the nucleation of gas bubbles in the channel. This effect of driving gas out of solution typically occurs well before the onset of boiling and can be catastrophic to the electrokinetic system, as gas bubbles grow and eventually break the electrical circuit required to drive the flow. This effect can be reduced by outgassing of the solution and is, of course, a strong function of the channel geometry, buffer conductivity and the thermal properties of the substrate material.

Finally, an important consideration in electrokinetic experiments is the inadvertent application and/or generation of pressure gradients in the microchannel. Probably the most common cause of this is a mismatch in the height of the fluid level at the reservoirs. Note that, although there may not be a mismatch of fluid level at the start of an experiment, the flow rates created by electro-osmotic flow may eventually create a fluid level mismatch. Also, the fluid level in each reservoir, particularly in reservoirs of 1 mm diameter or less, may be affected by electrolytic gas generation at each electrode. Because electro-osmotic flowrate scales as channel diameter squared and pressure-driven flow scales as channel diameter to the fourth power, this effect is greatly reduced by decreasing the characteristic channel diameter. Another common method of reducing this pressure head effect is to increase the length of the channel for a given cross section. This length increase, of course, implies an increase in operating voltages to achieve the same flowrate. A second source of pressure gradients is a nonuniformity in the surface charge in the channel. An elegant, closed-form solution for the flow in a microchannel with arbitrary axial zeta potential distribution is presented by Anderson and Idol (1985). Recently, Herr et al. (2000) have

visualized this effect and offered a simple analytical expression to the pressure-driven flow components associated with zeta potential gradients in fully developed channel flows.

## 6.4 Summary and Conclusions

---

In microchannels, the flow of a liquid differs fundamentally from that of a gas, primarily due to the effects of compressibility and potential rarefaction in gases. Although significant differences from continuum macroscale theory have been reported, Sharp et al. (2000) have shown that in the range of accepted laminar flow behavior, the friction factor agrees with classical continuum hydrodynamic theory to within small or negligible differences. Transition to turbulence occurs at  $Re = 2000$  [Sharp et al., 2000].

However, large differences in observed pressure drop in microchannels have been reported by many investigators. These differences may be due to imperfections in the flow system of the experiment. Because imperfections may well occur in real engineering systems, it is essential to understand the sources of the observed discrepancies in order to avoid them, control them or factor them into the designs.

The development of measurement techniques for liquid flows is advancing quickly, both as macroscale methods are adapted to these smaller scales and as novel techniques are being developed. Further insight into phenomena present in the microscale flows, including those due to imperfections in channels or flow systems, is likely to occur rapidly given the evolving nature of the measurement techniques. Complex, nonlinear channels can be used efficiently to design for functionality.

Electrokinetics is a convenient and easily controlled method of achieving sample handling and separations on a microchip. Because the body force exerted on the liquid is limited to a region within a few nanometers from the wall, the resulting profiles, in the absence of imposed pressure gradients, are typically plug-like for channel dimensions greater than about  $10\ \mu\text{m}$  and ion concentrations greater than about  $10\ \mu\text{M}$ . For simple electro-osmotic flows with thin EDLs, low Reynolds number, uniform surface charge and zero imposed pressure gradients, the velocity field of these systems is well approximated by potential flow theory. This significant simplification can, in many cases, be used to predict and optimize the performance of electrokinetic systems. Further, electrokinetics can be used to generate large pressures ( $>20\ \text{atm}$ ) on a microfabricated device. In principle, the handling and rapid mixing of less than  $1\ \text{pL}$  of sample volumes should be possible using electrokinetic systems built with current microfabrication technologies.

## Nomenclature

---

$\delta$	lattice spacing
$\varepsilon$	surface roughness or permittivity of liquid
$\phi$	local potential
$\kappa$	thermal diffusivity
$\lambda$	mean free path
$\lambda_D$	Debye length
$\mu$	dynamic viscosity
$\mu_r$	roughness viscosity
$\nu$	kinematic viscosity
$\nu_{\text{eph}}$	electrophoretic mobility
$\rho$	density
$\rho_E$	net charge density in EDL
$\sigma$	net conductivity of solution
$\tau$	time constant or characteristic time scale of a forcing function
$\tau_{ij}$	stress tensor
$\tau_w$	local wall shear stress
$\bar{\tau}_w$	wall shear stress, averaged around the perimeter
$\zeta$	zeta potential

$\Phi$	rate of conversion of mechanical energy to thermal energy (viscous dissipation function)
$a$	radius of cylindrical capillary, $=D/2$
$b_i$	body force per unit mass in the $i$ th direction
$\mathbf{b}$	body force per unit mass
$c_i$	Boltzmann distribution of ions of species $i$
$c_o$	proportionality constant
$c_p$	specific heat at constant pressure
$c_{\infty,i}$	molar concentration of ion $i$ in the bulk
$d$	Stokes diameter of the particle
$e$	charge of an electron
$f$	Darcy friction factor
$g_i$	gravitational acceleration in the $i$ th direction
$\mathbf{g}$	gravitational acceleration
$k$	thermal conductivity or Boltzmann's constant
$\mathbf{n}$	local unit vector
$p$	pressure
$\mathbf{q}$	heat flux
$q$	total molecule charge
$r$	radial coordinate
$t$	time
$u_{\text{crit}}$	critical velocity
$u_{\text{EOF}}$	electro-osmotic velocity
$u_i$	$i$ th component of velocity
$u_{\text{max}}$	maximum $u$ velocity
$u_{\text{particle}}$	total velocity of electrophoretic particles
$u_{\text{pressure}}$	pressure-driven velocity
$u_{\text{slip}}$	velocity evaluated at slip surface at the top of the EDL
$\mathbf{u}$	velocity vector
$x$	streamwise coordinate
$x_i$	coordinate in the $i$ th direction
$y$	coordinate perpendicular to the streamwise direction
$z$	coordinate perpendicular to the streamwise direction or valance number of the ion
$A$	cross-sectional area
$C_{\text{elec}}$	electrical capacitance
$C_{\text{flow}}$	capacitance of a fluid element
$C^*$	normalized friction coefficient
$D$	characteristic channel dimension (usually diameter)
$D_h$	hydraulic diameter
$\mathbf{E}$	electric field driving the fluid
$E_{\text{slip}}$	electric field evaluated at slip surface at the top of the EDL
$F$	Faraday's constant
$H$	channel height
$I$	electrical current
$I_0$	zero-order modified Bessel function of the first kind
$K$	pressure drop parameter
$Kn$	Knudsen number
$L$	channel length
$L_s$	characteristic length scale
$L_e$	entrance length

$N_A$	Avogadro's number
$P$	perimeter
$Q$	flux
$PO$	Poiseuille number
$R_{\text{flow}}$	flow resistance
$R_{\text{elec}}$	electrical resistance
$Re$	Reynolds number
$Re_{\text{crit}}$	critical Reynolds number
$St$	Strouhal number
$T$	temperature
$U_s$	characteristic velocity scale
$\bar{U}$	area-averaged velocity
$V$	voltage
$V_1$	molar volume
$V_i$	time-dependent voltage applied to a reservoir "well"
$W$	channel width
STP	standard temperature and pressure

### 7.1 Abstract

---

In recent years, interest in computing gas flows at high Knudsen numbers in microdevices has been considerable. At low Knudsen numbers, models based on the solution of compressible Navier–Stokes equations with slip-boundary conditions are adequate. At high Knudsen numbers, either higher order (beyond Navier–Stokes) continuum equations or the particle methods such as direct simulation Monte Carlo (DSMC) are employed to compute the flows. Higher order continuum approximations are based on the Chapman–Enskog expansion of the Boltzmann equation (leading to Burnett and super-Burnett equations), or moment methods based on taking the moments of the Boltzmann equation with flow variables (leading to Grad’s 13-moment equations or Levermore’ moment equations, for example). In this chapter, the history of the Burnett equations and a variety of Burnett approximations (conventional Burnett equations, augmented Burnett equations and BGK–Burnett equations) are presented. The physical and numerical issues related to these approximations are discussed. Traditionally, Burnett equations have been employed to compute the high-altitude, low-density hypersonic flows in the continuum–transition regime. Therefore, some Navier–Stokes and Burnett solutions are presented for hypersonic shock structure and blunt-body flows and rarefied subsonic airfoil flow to provide some perspective on the applicability and suitability of Burnett equations for computing flows at high Knudsen numbers. Calculations are then presented for both subsonic and supersonic flows in microchannels. These computations are compared with Navier–Stokes solutions with slip-boundary conditions and DSMC solutions.

The computations provide some assessment of Burnett equations for computing microchannel flows at high Knudsen numbers.

## 7.2 Introduction

Microelectromechanical systems (MEMS) are currently attracting a great deal of interest and attention because of their great potential in many industrial and medical applications. As a result, considerable effort is being devoted to the design and fabrication of MEMS. MEMS refer to devices that have characteristic length of less than 1 mm but more than 1  $\mu\text{m}$ , that combine electrical and mechanical components and that are fabricated using integrated-circuit, batch-processing technologies. A few examples of MEMS are microsensors, microactuators, micromotors, microvalves, micropumps, microducts etc. Fluid flows in the microdevices such as microvalves, micropumps and microducts are significantly different from those in macroscopic devices due to their small characteristic sizes. Hence, understanding of the physics of the flows in the microdevices is very important in their development and design.

Various regimes of fluid flows can be broadly classified into the continuum, continuum–transition, transition and free molecular regimes as shown in Table 7.1. For a large class of flows, Navier–Stokes equations based on the continuum approximation are adequate to model the fluid behavior. Continuum approximation implies that the mean free path of the molecules  $\lambda$  in a gas is much smaller than the characteristic length  $L$  of interest (say, the body dimension); that is, the Knudsen number  $Kn$  ( $=\lambda/L$ ) is very small ( $\ll 1$ ). However, for a variety of flows, this assumption is not valid; Knudsen number is of  $O(1)$ . In these flows, the gas is neither completely in the continuum regime nor in the rarefied (free molecular flow) regime. Therefore, such flows have been categorized as continuum–transition or transitional flows. Examples of such flows include the hypersonic flows about space vehicles in low Earth orbit [Ivanov and Gimelshein, 1998] or flows in microchannels of MEMS [Gad-el-Hak, 1999].

In high-altitude hypersonic flows, low density gives rise to high Knudsen number effects, while in microscale flows, which usually occur at atmospheric conditions, small length scales create regions of high Knudsen numbers. In the case of high-altitude hypersonic flows, the shock layer thickness at the nose of the space vehicle (shuttle) is much thicker than that predicted from the Navier–Stokes equations. In a long microchannel, the pressure gradient is observed to be nonconstant and the experimentally measured mass flow rate is higher than that predicted from the conventional continuum flow model [Arkilic et al., 1997; Harley et al., 1995; Liu et al., 1993; Pong et al., 1994]. In such a microscale flow, the mean free path of the molecules can be of the same order of magnitude as the characteristic length of the microchannel:  $Kn \sim O(1)$ . For a microchannel defined by ratio  $\epsilon = H/L$ , where  $H$  and  $L$  are width

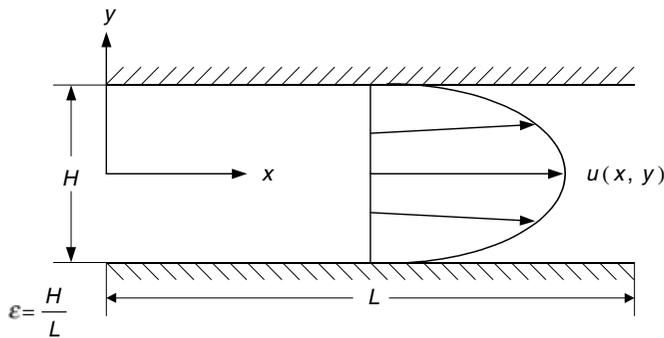

**TABLE 7.1** Flow Regimes and Fluid Models

Knudsen Number	Fluid Model
$Kn \rightarrow 0$ (continuum, no molecular diffusion)	Euler equations
$Kn \leq 10^{-3}$ (continuum with molecular diffusion)	Navier–Stokes equations with no-slip-boundary conditions
$10^{-3} \leq Kn \leq 10^{-1}$ (continuum–transition)	Navier–Stokes equations with slip-boundary conditions
$10^{-1} \leq Kn \leq 10$ (transition)	Burnett equations with slip-boundary conditions Moment equations DSMC
$Kn > 10$ (free molecular flow)	Lattice Boltzmann Collisionless Boltzmann DSMC Lattice Boltzmann

**TABLE 7.2** Flow Regimes in a Microchannel for Different Knudsen Numbers

$M$	$Re$		
	$O(\epsilon)$	$O(1)$	$O(1/\epsilon)$
$O(\epsilon)$	$Kn = O(1)$ ; creeping microflow	$Kn = O(\epsilon)$ ; moderate microflow	$Kn = O(\epsilon^2)$ ; low $M$ Fanno flow
$O(1)$	$Kn = O(1/\epsilon)$ ; transonic free molecular flow	$Kn = O(1)$ ; transonic microflow	$Kn = O(\epsilon)$ ; transonic Fanno flow
$O(1/\epsilon)$	$Kn = O(1/\epsilon^2)$ ; hypersonic free molecular flow	$Kn = O(1/\epsilon)$ ; hypersonic free molecular flow	$Kn = O(1)$ ; hypersonic Fanno (transitional) flow

**FIGURE 7.1** Flow in a microchannel. Relevant flow parameters: Mach number, Reynolds number and Knudsen number are  $M = \bar{u} / c$ ,  $Re = \bar{\rho} \bar{u} H / \mu$ , and  $Kn = (\pi \gamma / 2)^{0.5} M / Re$ , respectively. “—” denotes the average outlet conditions.

and length of the channel, respectively, as shown in Figure 7.1, Arkilic et al. (1997) have characterized various flow regimes depending upon the Reynolds number  $Re$  and Mach number  $M$  of the flow as shown in Table 7.2. Tables 7.1 and 7.2 together now can be used to select an appropriate fluid model for simulation of the flowfield in a microchannel. It should be noted here that both low-density and microscale effects can be local in a flow so that the entire flow is in both the continuum and transition regimes. (Readers may refer to Chapter 4 in this handbook for further understanding of the physics of the flows in microdevices and appropriate models for various flow regimes.)

As shown in Table 7.1, Navier–Stokes equations are not adequate to model the flows in the continuum–transition regime; the Boltzmann equation describes the flow in all the regimes—continuum, continuum–transition and free molecular. The techniques available for solving the Boltzmann equation can be classified into particulate methods and moment methods. The direct simulation Monte Carlo (DSMC) method falls in the category of particulate methods [Bird, 1994]. Moment methods derive the higher order fluid dynamics approximations beyond Navier–Stokes equations to account for departures from thermal equilibrium. The higher order fluid dynamic models are known as the extended hydrodynamic equations (EHE) or generalized hydrodynamic equations (GHE). However, both classes of methods have significant limitations, either in describing the physics or in terms of the computational resources needed for accurate simulation, for modeling flows in continuum–transition regime. Currently, the DSMC method, perhaps, can be considered as the most accurate and widely used technique for computation of low-density flows. However, in the continuum–transition regime, where the densities are not “low enough,” the DSMC method requires a large number of particles for accurate simulation, making the technique prohibitively expensive both in terms of computational time and memory requirements. For example, it has been shown by Koppenwallner (1987) that the nose-up pitching moment of the space shuttle was predicted inaccurately by the DSMC method in the continuum–transition regime due to the inadequate number of particles used in modeling. The nose-up pitching moment could be corrected by deflecting the body flap to 15 degrees—twice the amount predicted by DSMC. A similar situation may

occur in microscale flows due to the relatively high density and low velocity requiring enormous computational power and resulting in large statistical scatter in the DSMC simulations [Nance et al., 1998].

At present, the majority of the computations with the DSMC method, especially in two and three dimensions for  $Kn = O(1)$ , are beyond the currently available computing power. As an alternative, higher order extended or generalized hydrodynamic equations have been proposed that can perform equally well in both the continuum and continuum–transition regimes. The extended hydrodynamic equations have been derived from the Boltzmann equation using either one of the following approaches. In one approach, higher order constitutive relations (beyond Navier–Stokes) for stress and heat transfer terms are obtained using the Chapman–Enskog expansion of the Boltzmann equation with the Knudsen number as a parameter. In the Chapman–Enskog expansion, the first-term represents the Maxwellian (equilibrium) distribution function  $f_0$ . The first moment of the Boltzmann equation with the collision invariant vector, with  $f_0$  as the approximation for the distribution function, results in the Euler equations. The first two terms in the Chapman–Enskog expansion—( $f_0 + Kn f_1$ )—give a distribution function corresponding to the Navier–Stokes equations, representing a first-order departure from thermal equilibrium. The first three terms ( $f_0 + Kn f_1 + Kn^2 f_2$ ) in the expansion give a distribution function, which results in the so-called “Burnett equations,” representing a second-order departure from the equilibrium.

Burnett equations have been a subject of considerable investigation in recent years and are the main subject of this chapter. Higher order approximations beyond Burnett equations, the so-called “super-Burnett equations” etc., can be derived by continuing the Chapman–Enskog expansion to higher orders. However, at the present time, the complexity of the highly nonlinear Burnett stress and heat transfer terms itself is enormously challenging both computationally and in terms of understanding the physics, so the consideration of super-Burnett equations and beyond is meaningless.

Burnett stress and heat transfer terms contain higher than second-order derivatives. Therefore, an additional boundary condition is necessary for the solution to the Burnett equations to be uniquely determined; different solutions can result based on the choice of boundary values [Lee, 1994]. Furthermore, it has also been shown that the conventional Burnett equations can violate the second law of thermodynamics at high Knudsen numbers [Comeaux et al., 1995]. Because the focus of this chapter is on Burnett equations, these are described in detail in Section 7.3.

In another approach, the extended hydrodynamic equations are derived using the moment method, which employs the equations of transfer instead of dealing with the distribution function. In the moment method, the distribution function  $f$  is expanded in moments of physical variables (density, velocity, pressure, temperature etc.) and the evolution equations for moments are derived from the Boltzmann equation. In principle, this approach should result in a set of macroscopic equations consistent with the second law of thermodynamics, but many of the methods (for example, Grad’s 13-moment method [Grad, 1949]) result in the entropy equation violating the Gibb’s relation [Holway, 1964; Weiss, 1996]. This problem was addressed in the recent work of Levermore (1996) and Levermore and Morokoff (1998) on the so-called “Gaussian closure.” The Gaussian closure is based on a more elegant choice of a finite-dimensional linear subspace and yields a hyperbolic system of moment equations. Because the hyperbolic equations are easier to solve numerically, Groth et al. (1995) have developed some computational models based on this closure. However, the Gaussian closure is of limited practical interest, as the primary system with ten variables admits no heat flux. Other moment systems (for example, the 35-moment system of Brown [1996]) do not yield numerical solutions above Mach numbers of approximately two. Furthermore, it should be noted here that the application of the 13- or 35-moment systems to three-dimensional problems remains computationally prohibitive at present.

Because of the physical and numerical difficulties associated with the Burnett equations and moment equations, Myong (1999) has recently suggested yet another set of generalized hydrodynamic equations based on the work of Eu (1992). Eu’s equations are based on a nonequilibrium canonical distribution function and a cumulant expansion of the collision integral in Boltzmann equation. These equations can be considered as the most thermodynamically consistent macroscopic equations, as the second law of thermodynamics is satisfied to every order of approximation. It also turns out that they recover the correct behavior at both the continuum and free molecular limits. Myong (1999) has recently developed

a computational model based on Eu's evolution equations within the framework of 13 moments. This model so far has been applied to some one-dimensional problems, but the full potential of this set of equations for calculating two- and three-dimensional flows in the continuum–transition regime remains to be determined and will require several years of intensive computational effort. Furthermore, the solution of Eu's equations for a three-dimensional problem will remain computationally prohibitive in the near future.

Because of the limitations of the DSMC method due to the requirements of computing power (currently unavailable) and the difficulties associated with higher order fluid dynamics models as described above, a hybrid approach has been suggested by many investigators in recent years [Oran et al., 1998; Roveda et al., 1998]. The hybrid method couples a Euler or Navier–Stokes solver with DSMC. The hybrid codes have been developed for problems that contain disconnected nonequilibrium regions embedded in a continuum flow [Roveda et al., 1998]. However, the development of a hybrid code is not simple, as two issues need to be resolved before implementation: (1) when to switch between the two methods, and (2) how to pass information from one method to the other [Boyd et al., 1995]. Furthermore, a conceptual inconsistency remains, as the hybrid method must recover both the continuum and free molecular limits. (For molecular-based microfluidic simulation models, the reader is referred to Chapter 8 in this handbook.)

In recent years, several modifications to the original Burnett equations that have been proposed are discussed in Section 7.3. Sections 7.4 and 7.5 describe the governing equations and the wall-boundary conditions, respectively. Section 7.6 deals with the linearized stability analysis of one-dimensional Burnett equations. Section 7.7 briefly describes the numerical scheme and other computational aspects of the three-dimensional Burnett solver. In Section 7.8, computational results are presented for one- and two-dimensional problems. They include computations for hypersonic shock structures, blunt body flows, subsonic flow past an airfoil, and subsonic and supersonic flow in a microchannel. Although the focus of this chapter is on flows in microdevices, the hypersonic flow computations for blunt body flows etc. are presented here because traditionally the Burnett equations have been applied to compute this class of flows over the past decade and computational results from Navier–Stokes and DSMC simulations can be used for the purpose of comparison. These solutions are instructive in providing some assessment of the accuracy and applicability of Burnett equations for computing flows in the continuum–transition regime.

### 7.3 History of Burnett Equations

---

Table 7.3 briefly traces the history of Burnett equations. In 1935, Burnett (1935) developed constitutive relationships for the stress and heat transfer terms by applying the Chapman–Enskog expansion to the Boltzmann equation for second-order departures from collisional equilibrium. These equations are referred to as the *original* Burnett equations. In 1939, Chapman and Cowling (1970) replaced the material derivatives in the original Burnett equations by spatial derivatives obtained from inviscid Euler equations. This alternative form of the original Burnett equations is referred to as the *conventional* Burnett equations. Expressing the material derivatives in terms of the spatial derivatives was considered acceptable as the Navier–Stokes and Burnett equations were considered to be first- and second-order corrections to the Euler equations. The use of Euler equations to express the material derivatives retained the second-order accuracy of the Burnett equations. For reasons unknown, the conventional Burnett equations and not the original Burnett equations became the set of higher order constitutive relations studied during the past six decades.

In recent years, Fisco and Chapman (1988) and Zhong (1991) have employed the conventional Burnett equations to extend the numerical methods for continuum flow into the continuum–transition regime by incorporating the additional linear and nonlinear stress and heat transfer terms in the standard Navier–Stokes solvers. In one of the earliest attempts to numerically solve the conventional Burnett equations, Fisco and Chapman (1988) solved the hypersonic shock structure problem by relaxing an initial solution to steady state. They obtained solutions for a variety of Mach numbers and concluded

**TABLE 7.3** Brief History of Burnett Set of Equations

Equations	Ref.	Comments
Burnett equations	Burnett (1935)	Derived from Boltzmann equation by considering the first three terms of the Chapman–Enskog expansion; appearance of material derivatives, $D(\cdot)/Dt$ , in the second-order (Burnett) flux vectors.
Conventional Burnett equations	Chapman and Cowling (1970)	Euler equations were used to express the material derivatives in terms of the spatial derivatives.
Conventional Burnett equations	Fisco and Chapman (1988)	Encountered problem of small wavelength instability as the grids were refined.
Augmented Burnett equations	Zhong (1991)	Linearized third-order terms were added to stabilize the Burnett equations; not entirely successful for computing blunt body wakes and flat plate boundary layers.
Conventional Burnett equations	Welder et al. (1993)	Due to the nonlinear terms in the Burnett equations, linear stability analysis alone is not sufficient to explain the instability at high Knudsen numbers.
Conventional Burnett equations	Comeaux et al. (1995)	Burnett equations can violate the second law of thermodynamics at high Knudsen numbers.
BGK–Burnett equations	Balakrishnan and Agarwal (1996)	Nonlinear collision integral in the Boltzmann equation was simplified by representing it with the Bhatnagar–Gross–Krook (BGK) model; material derivatives expressed in terms of the spatial derivatives using Navier–Stokes equations; linear stability analysis shows unconditional stability for all Knudsen numbers; when Euler equations are used to express the material derivatives, they guarantee unconditional stability for monatomic gases; entropy consistent (satisfies the Boltzmann’s H-theorem) for a wide range of Knudsen numbers.

that the conventional Burnett equations do indeed describe the normal shock structure better than the Navier–Stokes equations at high Mach numbers. They, however, experienced stability problems when the computational grids were made progressively finer.

In a subsequent attempt, Zhong (1991) showed that the conventional Burnett equations could be stabilized by adding linear third-order terms from the super-Burnett equations, in order to maintain second-order accuracy, to the stress and heat transfer terms in the Burnett equations. This set of equations was termed the augmented Burnett equations. The coefficients (weights) of these linear third-order terms were determined by carrying out a linearized stability analysis of the augmented Burnett equations. The augmented Burnett equations did not present any stability problems when they were used to compute the hypersonic shock structure and hypersonic blunt body flows. However, attempts at computing the flowfields for blunt body wakes and flat-plate boundary layers with the augmented Burnett equations have not been entirely successful. Furthermore, the *ad hoc* addition of the linear super-Burnett terms and their necessity raises the question of whether the approximation used to create the *conventional* Burnett equations from the original Burnett equations introduces the small wavelength instabilities. It has been noted by Welder et al. (1993) that linear stability analysis alone is not sufficient to explain the instability of Burnett equations with increasing Knudsen numbers as this analysis does not take into account many nonlinear terms, products of first- and higher-order derivatives, that are present in the conventional Burnett equations. Comeaux et al. (1995) have recently surmised that this instability may also be attributed to the fact that the *conventional* Burnett equations can violate second law of thermodynamics at high Knudsen numbers.

In order to overcome the difficulties associated with the conventional Burnett equations (violation of the second law of thermodynamics and instability at high Knudsen numbers), Balakrishnan and Agarwal (1996; 1997) have recently derived a new set of Burnett equations designated as “BGK–Burnett” equations, which are entropy consistent and satisfy the Boltzmann H-theorem. The highly nonlinear nature of the collision integral in the Boltzmann equation presents the biggest hurdle in devising a higher order distribution function. This problem can be circumvented by representing the collision integral in the

Bhatnagar–Gross–Krook (BGK) form [Bhatnagar et al., 1954]. This approximation assumes that any slight departure from the equilibrium distribution will eventually settle down to the equilibrium distribution exponentially. This approximation also assumes that the gas is dilute, hence the collision processes are predominantly binary in nature. Because only binary collisions are considered, the time taken for the nonequilibrium distribution to settle down to the equilibrium level is equal to the reciprocal of the collision frequency. With the BGK approximation to the collision integral, the exact closed-form analytical expression for the distribution function to any order can be obtained.

Balakrishnan and Agarwal (1997) have derived the BGK–Burnett equations by considering the first three terms in the Chapman–Enskog expansion. In this derivation, Euler equations were used to approximate the material derivatives in the first-order distribution function. Moments of the first-order distribution function with the collision invariant vector yield the Navier–Stokes equations. In order to keep in step with the iterative refinement technique, it was conjectured that the Navier–Stokes equations could be used to approximate the material derivatives in the second-order distribution function. It has been shown that this formulation ensures a positive entropy change. The BGK–Burnett equations are obtained by taking moments of this second-order distribution function with the collision invariant vector. This set of equations contains all the stress and heat transfer terms reported by Fisco and Chapman (1988) and has additional terms which are similar to the super-Burnett terms. Using linearized stability analysis, it has been shown that these additional terms make the BGK–Burnett equations unconditionally stable for monatomic as well as polyatomic gases. In order to check if the entropy production is positive throughout the flowfield, the Boltzmann H-theorem was applied to the second-order distribution function. It was shown that “H” is a monotonically decreasing function, thereby ensuring that the equations do not violate the second law of thermodynamics [Balakrishnan et al., 1997]. Thus the BGK–Burnett equations overcome the problems associated with the conventional Burnett equations—namely, violation of the second law of thermodynamics and instability at high Knudsen numbers.

## 7.4 Governing Equations

In this section, the augmented Burnett and BGK–Burnett equations are presented. For original and conventional Burnett equations, the reader is referred to papers by Burnett (1935) and Chapman and Cowling (1970), respectively. Here, we present only the two-dimensional augmented and BGK–Burnett equations for the sake of brevity; three-dimensional augmented Burnett equations and BGK–Burnett equations are given in Yun et al. (1998).

The governing equations for two-dimensional, unsteady, compressible, viscous flow can be written in Cartesian coordinates as:

$$\frac{\partial \mathbf{Q}}{\partial t} + \frac{\partial \mathbf{E}}{\partial x} + \frac{\partial \mathbf{F}}{\partial y} = 0 \quad (7.1)$$

where

$$\mathbf{Q} = \begin{bmatrix} \rho \\ \rho u \\ \rho v \\ e_t \end{bmatrix} \quad (7.2)$$

In Eq. (7.1),  $\mathbf{E}$  and  $\mathbf{F}$  are the flux vectors of the flow variables  $\mathbf{Q}$  in the  $x$  and  $y$  directions, respectively. These flux vectors can be written as:

$$\begin{aligned} \mathbf{E} &= \mathbf{E}_I + \mathbf{E}_V \\ \mathbf{F} &= \mathbf{F}_I + \mathbf{F}_V \end{aligned} \quad (7.3)$$

where  $\mathbf{E}_I$  and  $\mathbf{F}_I$  are the inviscid-flux terms and  $\mathbf{E}_V$  and  $\mathbf{F}_V$  are the viscous-flux terms given as follows:

$$\mathbf{E}_I = \begin{bmatrix} \rho u \\ \rho u^2 + p \\ \rho uv \\ (e_t + p)u \end{bmatrix}, \quad \mathbf{E}_V = \begin{bmatrix} 0 \\ \sigma_{11} \\ \sigma_{12} \\ \sigma_{11}u + \sigma_{12}v + q_1 \end{bmatrix} \quad (7.4)$$

$$\mathbf{F}_I = \begin{bmatrix} \rho v \\ \rho uv \\ \rho v^2 + p \\ (e_t + p)v \end{bmatrix}, \quad \mathbf{F}_V = \begin{bmatrix} 0 \\ \sigma_{21} \\ \sigma_{22} \\ \sigma_{21}u + \sigma_{22}v + q_2 \end{bmatrix} \quad (7.5)$$

The constitutive equations for a gas flow near thermodynamic equilibrium can be derived as approximate solutions of the Boltzmann equation using the Chapman–Enskog expansion. This method yields the general constitutive relations for the stress tensor  $\sigma_{ij}$  and the heat-flux vector  $q_i$  as follows:

$$\begin{aligned} \sigma_{ij} &= \sigma_{ij}^{(0)} + \sigma_{ij}^{(1)} + \sigma_{ij}^{(2)} + \sigma_{ij}^{(3)} + \cdots + \sigma_{ij}^{(n)} + O(Kn^{n+1}) \\ q_i &= q_i^{(0)} + q_i^{(1)} + q_i^{(2)} + q_i^{(3)} + \cdots + q_i^{(n)} + O(Kn^{n+1}) \end{aligned} \quad (7.6)$$

where  $n$  represents the order of accuracy with respect to  $Kn$ .  $Kn$  is defined as:

$$Kn = \lambda/L \quad (7.7)$$

where  $L$  is the macroscopic characteristic length, and the mean free path  $\lambda$  is given by:

$$\lambda = \frac{16\mu}{5\rho\sqrt{2\pi RT}} \quad (7.8)$$

In the case of  $Kn \approx 0$ , only the first terms in Eq. (7.6) are important. The zeroth-order approximation ( $n = 0$ ) results in the Euler equations with:

$$\sigma_{ij}^{(0)} = 0 \quad \text{and} \quad q_i^{(0)} = 0 \quad (7.9)$$

When  $Kn < 0.1$ , the first two terms in Eq. (7.6) become important for the accurate representation of the stress and heat transfer properties of the gas flow. This first-order approximation represents the Navier–Stokes equations. The stress tensor and the heat-flux terms ( $n = 1$ ) are given as:

$$\begin{aligned} \sigma_{11}^{(1)} &= -\mu(\delta_1 u_x + \delta_2 v_y) \\ \sigma_{12}^{(1)} &= \sigma_{21}^{(1)} = -\mu(u_y + v_x) \\ \sigma_{22}^{(1)} &= -\mu(\delta_1 v_y + \delta_2 u_x) \\ q_1^{(1)} &= -\kappa T_x \\ q_2^{(1)} &= -\kappa T_y \end{aligned} \quad (7.10)$$

where  $( )_x = \partial/\partial x$  and  $( )_y = \partial/\partial y$ . The coefficients  $(\delta_1, \delta_2)$  are  $(1.333, -0.666)$  and  $(1.6, -0.4)$  for the augmented Burnett equations and the BGK–Burnett equations (for  $\gamma = 1.4$ ), respectively.

As  $Kn$  becomes larger ( $>0.1$ ), additional higher order terms in Eq. (7.6) are required. The second-order approximation yields the Burnett equations that retain the first three terms in Eq. (7.6). The expression for stress and heat-flux terms ( $n = 2$ ) are obtained as [Yun et al., 1998]:

$$\begin{aligned} \sigma_{11}^{(2)} = \frac{\mu^2}{p} & \left( \alpha_1 u_x^2 + \alpha_2 u_x v_y + \alpha_3 v_y^2 + \alpha_4 u_x v_y + \alpha_5 u_y^2 + \alpha_6 v_x^2 + \alpha_7 RT_{xx} + \alpha_8 RT_{yy} + \alpha_9 \frac{RT}{\rho} \rho_{xx} \right. \\ & \left. + \alpha_{10} \frac{RT}{\rho} \rho_{yy} + \alpha_{11} \frac{RT}{\rho^2} \rho_x^2 + \alpha_{12} \frac{R}{\rho} T_x \rho_x + \alpha_{13} \frac{R}{T} T_x^2 + \alpha_{14} \frac{RT}{\rho^2} \rho_y^2 + \alpha_{15} \frac{R}{\rho} T_y \rho_y + \alpha_{16} \frac{R}{T} T_y^2 \right) \end{aligned} \quad (7.11)$$

$$\begin{aligned} \sigma_{22}^{(2)} = \frac{\mu^2}{p} & \left( \alpha_1 v_y^2 + \alpha_2 u_x v_y + \alpha_3 u_x^2 + \alpha_4 u_y v_x + \alpha_5 v_x^2 + \alpha_6 u_y^2 + \alpha_7 RT_{yy} + \alpha_8 RT_{xx} + \alpha_9 \frac{RT}{\rho} \rho_{yy} \right. \\ & \left. + \alpha_{10} \frac{RT}{\rho} \rho_{xx} + \alpha_{11} \frac{RT}{\rho^2} \rho_y^2 + \alpha_{12} \frac{R}{\rho} T_y \rho_y + \alpha_{13} \frac{R}{T} T_y^2 + \alpha_{14} \frac{RT}{\rho^2} \rho_x^2 + \alpha_{15} \frac{R}{\rho} T_x \rho_x + \alpha_{16} \frac{R}{T} T_x^2 \right) \end{aligned} \quad (7.12)$$

$$\begin{aligned} \sigma_{12}^{(2)} = \sigma_{21}^{(2)} = \frac{\mu^2}{p} & \left( \beta_1 u_x u_y + \beta_2 u_y v_y + \beta_2 u_x v_x + \beta_1 v_x v_y + \beta_3 RT_{xy} + \beta_4 \frac{RT}{\rho} \rho_{xy} \right. \\ & \left. + \beta_5 \frac{R}{T} T_x T_y + \beta_6 \frac{RT}{\rho^2} \rho_x \rho_y + \beta_7 \frac{R}{\rho} \rho_x T_y + \beta_7 \frac{R}{\rho} T_x \rho_y \right) \end{aligned} \quad (7.13)$$

$$\begin{aligned} q_1^{(2)} = \frac{\mu^2}{\rho} & \left( \gamma_1 \frac{1}{T} T_x u_x + \gamma_2 \frac{1}{T} T_x v_y + \gamma_3 u_{xx} + \gamma_4 u_{yy} + \gamma_5 v_{xy} + \gamma_6 \frac{1}{T} T_y v_x \right. \\ & \left. + \gamma_7 \frac{1}{T} T_y u_y + \gamma_8 \frac{1}{\rho} \rho_x u_x + \gamma_9 \frac{1}{\rho} \rho_x v_y + \gamma_{10} \frac{1}{\rho} \rho_y u_y + \gamma_{11} \frac{1}{\rho} \rho_y v_x \right) \end{aligned} \quad (7.14)$$

$$\begin{aligned} q_2^{(2)} = \frac{\mu^2}{\rho} & \left( \gamma_1 \frac{1}{T} T_y u_y + \gamma_2 \frac{1}{T} T_y v_x + \gamma_3 v_{yy} + \gamma_4 v_{xx} + \gamma_5 u_{xy} + \gamma_6 \frac{1}{T} T_x u_y \right. \\ & \left. + \gamma_7 \frac{1}{T} T_x v_x + \gamma_8 \frac{1}{\rho} \rho_y v_y + \gamma_9 \frac{1}{\rho} \rho_y u_x + \gamma_{10} \frac{1}{\rho} \rho_x v_x + \gamma_{11} \frac{1}{\rho} \rho_x u_y \right) \end{aligned} \quad (7.15)$$

Both the augmented Burnett and BGK–Burnett equations have the same forms of the stress tensor and heat-flux terms in the second-order approximation; however, the two sets of equations have different values of the coefficients. The coefficients for the augmented Burnett equations (for a hard sphere gas) are  $\alpha_1 = 1.199$ ,  $\alpha_2 = 0.153$ ,  $\alpha_3 = -0.600$ ,  $\alpha_4 = -0.115$ ,  $\alpha_5 = 1.295$ ,  $\alpha_6 = -0.733$ ,  $\alpha_7 = 0.260$ ,  $\alpha_8 = -0.130$ ,  $\alpha_9 = -1.352$ ,  $\alpha_{10} = 0.676$ ,  $\alpha_{11} = 1.352$ ,  $\alpha_{12} = -0.898$ ,  $\alpha_{13} = 0.600$ ,  $\alpha_{14} = -0.676$ ,  $\alpha_{15} = 0.449$ ,  $\alpha_{16} = -0.300$ ,  $\beta_1 = -0.115$ ,  $\beta_2 = 1.913$ ,  $\beta_3 = 0.390$ ,  $\beta_4 = -2.028$ ,  $\beta_5 = 0.900$ ,  $\beta_6 = 2.028$ ,  $\beta_7 = -0.676$ ,  $\gamma_1 = 10.830$ ,  $\gamma_2 = 0.407$ ,  $\gamma_3 = -2.269$ ,  $\gamma_4 = 1.209$ ,  $\gamma_5 = -3.478$ ,  $\gamma_6 = -0.611$ ,  $\gamma_7 = 11.033$ ,  $\gamma_8 = -2.060$ ,  $\gamma_9 = 1.030$ ,  $\gamma_{10} = -1.545$ , and  $\gamma_{11} = -1.545$ .

The coefficients for the BGK–Burnett equations (for  $\gamma = 1.4$ ) are  $\alpha_1 = -2.24$ ,  $\alpha_2 = -0.48$ ,  $\alpha_3 = 0.56$ ,  $\alpha_4 = -1.20$ ,  $\alpha_5 = 0.0$ ,  $\alpha_6 = 0.0$ ,  $\alpha_7 = -19.6$ ,  $\alpha_8 = -5.6$ ,  $\alpha_9 = -1.6$ ,  $\alpha_{10} = 0.4$ ,  $\alpha_{11} = 1.6$ ,  $\alpha_{12} = -19.6$ ,  $\alpha_{13} = -18.0$ ,  $\alpha_{14} = -0.4$ ,  $\alpha_{15} = -5.6$ ,  $\alpha_{16} = -6.9$ ,  $\beta_1 = -1.4$ ,  $\beta_2 = -1.4$ ,  $\beta_3 = 0.0$ ,  $\beta_4 = -2.0$ ,  $\beta_5 = 2.0$ ,  $\beta_6 = 2.0$ ,  $\beta_7 = 0.0$ ,  $\gamma_1 = -25.241$ ,  $\gamma_2 = -0.2$ ,  $\gamma_3 = -1.071$ ,  $\gamma_4 = -2.0$ ,  $\gamma_5 = -2.8$ ,  $\gamma_6 = -7.5$ ,  $\gamma_7 = -11.0$ ,  $\gamma_8 = -1.271$ ,  $\gamma_9 = 1.0$ ,  $\gamma_{10} = -3.0$ , and  $\gamma_{11} = -3.0$ .

The third-order approximation ( $n = 3$ ) represents the super-Burnett equations; however, not all of the third-order terms of the super-Burnett equations are used in the augmented Burnett and the BGK–Burnett equations. In the augmented Burnett equations, the third-order terms are added on an *ad hoc* basis to

obtain stable numerical solutions while maintaining second-order accuracy of the solutions. The third-order terms in the augmented Burnett equations are given as [Yun et al., 1998]:

$$\sigma_{11}^{(a)} = \frac{\mu^3}{p^2} RT(\alpha_{17}u_{xxx} + \alpha_{17}u_{xyy} + \alpha_{18}v_{xxy} + \alpha_{18}v_{yyy}) \quad (7.16)$$

$$\sigma_{22}^{(a)} = \frac{\mu^3}{p^2} RT(\alpha_{17}v_{yyy} + \alpha_{17}v_{xxy} + \alpha_{18}u_{xyy} + \alpha_{18}u_{xxx}) \quad (7.17)$$

$$\sigma_{12}^{(a)} = \sigma_{21}^{(a)} = \frac{\mu^3}{p^2} RT(\beta_8u_{xxy} + \beta_8u_{yyx} + \beta_8v_{xyy} + \beta_8v_{xxx}) \quad (7.18)$$

$$q_1^{(a)} = \frac{\mu^3}{p\rho} R\left(\gamma_{12}T_{xxx} + \gamma_{12}T_{xyy} + \gamma_{13}\frac{T}{\rho}\rho_{xxx} + \gamma_{13}\frac{T}{\rho}\rho_{xyy}\right) \quad (7.19)$$

$$q_2^{(a)} = \frac{\mu^3}{p\rho} R\left(\gamma_{12}T_{yyy} + \gamma_{12}T_{xxy} + \gamma_{13}\frac{T}{\rho}\rho_{yyy} + \gamma_{13}\frac{T}{\rho}\rho_{xxy}\right) \quad (7.20)$$

The superscript  $(a)$  denotes the augmented Burnett terms. The coefficients in stress and heat-flux terms are  $\alpha_{17} = 0.2222$ ,  $\alpha_{18} = -0.1111$ ,  $\beta_8 = 0.1667$ ,  $\gamma_{12} = 0.6875$ , and  $\gamma_{13} = -0.625$ .

The BGK–Burnett equations have more additional third-order terms than the augmented Burnett equations. These are not added on an *ad hoc* basis but are derived from the second-order Chapman–Enskog expansion of the BGK–Boltzmann equation. The third-order terms in the BGK–Burnett equations are obtained as [Yun et al., 1998]:

$$\begin{aligned} \sigma_{11}^B &= \frac{\mu^3}{p^2} RT(\theta_1u_{xxx} + \theta_2u_{xyy} + \theta_3v_{xxy} + \theta_4v_{yyy}) \\ &\quad - \frac{\mu^3 RT}{p^2 \rho} (\theta_1\rho_x u_{xx} + \theta_5\rho_x v_{xy} + \theta_6\rho_x u_{yy} + \theta_7\rho_y v_{xx} + \theta_8\rho_y u_{xy} + \theta_4\rho_y v_{yy}) \\ &\quad + \frac{\mu^3}{p^2} (\theta_9u_x^3 + 3\theta_{10}u_x^2v_y + \theta_{11}u_xv_y^2 - \theta_4u_xu_y^2 - 2\theta_4u_xu_yv_x \\ &\quad - \theta_4u_xv_x^2 + \theta_{10}v_y^3 - \theta_{12}v_yu_y^2 - 2\theta_{12}u_yv_xv_y - \theta_{12}v_x^2v_y) \\ &\quad + \frac{\mu^3}{p^2} R(\theta_{13}u_xT_{xx} + \theta_{13}u_xT_{yy} + \theta_{14}v_yT_{xx} + \theta_{14}v_yT_{yy}) \end{aligned} \quad (7.21)$$

$$\begin{aligned} \sigma_{22}^B &= \frac{\mu^3}{p^2} RT(\theta_1v_{yyy} + \theta_2v_{xxy} + \theta_3u_{xyy} + \theta_4u_{xxx}) \\ &\quad - \frac{\mu^3 RT}{p^2 \rho} (\theta_1\rho_y v_{yy} + \theta_5\rho_y u_{xy} + \theta_6\rho_y v_{xx} + \theta_7\rho_x u_{yy} + \theta_8\rho_x v_{xy} + \theta_4\rho_x u_{xx}) \\ &\quad + \frac{\mu^3}{p^2} (\theta_9v_y^3 + 3\theta_{10}v_y^2u_x + \theta_{11}v_yu_x^2 - \theta_4v_yv_x^2 - 2\theta_4v_yv_xu_y \\ &\quad - \theta_4v_yu_y^2 + \theta_{10}u_x^3 - \theta_{12}u_xv_x^2 - 2\theta_{12}v_xu_yu_x - \theta_{12}u_y^2u_x) \\ &\quad + \frac{\mu^3}{p^2} R(\theta_{13}v_yT_{yy} + \theta_{13}v_yT_{xx} + \theta_{14}u_xT_{yy} + \theta_{14}u_xT_{xx}) \end{aligned} \quad (7.22)$$

$$\begin{aligned}
\sigma_{12}^{(B)} &= \frac{\mu^3}{\rho^2} RT (\theta_{15} u_{xxy} + u_{yyy} + \theta_{15} v_{xyy} + v_{xxx}) \\
&\quad - \frac{\mu^3 RT}{\rho^2 \rho} (\theta_6 \rho_y u_{xx} + \theta_{16} \rho_y v_{xy} + \rho_y u_{yy} + \rho_x v_{xx} + \theta_{16} \rho_x u_{xy} + \theta_6 \rho_x v_{yy}) \\
&\quad - \frac{\mu^3}{\rho^2} (u_y + v_x) (\theta_4 u_x^2 + 2\theta_{12} u_x v_y + 2\theta_7 u_y v_x + \theta_7 u_y^2 + \theta_7 v_x^2 + \theta_4 v_y^2) \\
&\quad + \frac{\mu^3}{\rho^2} R (\theta_{17} u_y T_{xx} + \theta_{17} u_y T_{yy} + \theta_{17} v_x T_{xx} + \theta_{17} v_x T_{yy})
\end{aligned} \tag{7.23}$$

$$\begin{aligned}
q_1^{(B)} &= \frac{\mu^3}{\rho \rho} R \left( \theta_{18} T_{xxx} + \theta_{18} T_{xyy} - \theta_{18} \frac{1}{\rho} \rho_x T_{xx} - \theta_{18} \frac{1}{\rho} \rho_x T_{yy} \right) \\
&\quad + \frac{\mu^3}{\rho \rho} (\theta_{19} u_x u_{xx} + \theta_{20} u_x v_{xy} + \theta_6 u_x u_{yy} + \theta_{21} v_y u_{xx} + \theta_{22} v_y v_{xy} + \theta_7 v_y u_{yy} \\
&\quad + \theta_{23} u_y v_{xx} + \theta_{24} u_y u_{xy} + \theta_6 u_y v_{yy} + \theta_{23} v_x v_{xx} + \theta_{24} v_x u_{xy} + \theta_6 v_x v_{yy}) \\
&\quad - \frac{\mu^3}{\rho \rho} \left( \frac{1}{\rho} \rho_x + \frac{1}{T} T_x \right) (\theta_{13} u_x^2 + 2\theta_{14} u_x v_y + 2\theta_{17} u_y v_x + \theta_{17} u_y^2 + \theta_{17} v_x^2 + \theta_{13} v_y^2) \\
&\quad + \frac{\mu^3}{\rho \rho} \frac{R}{T} (\theta_{18} T_x T_{xx} + \theta_{18} T_x T_{yy})
\end{aligned} \tag{7.24}$$

$$\begin{aligned}
q_2^{(B)} &= \frac{\mu^3}{\rho \rho} R \left( \theta_{18} T_{yyy} + \theta_{18} T_{xxy} - \theta_{18} \frac{1}{\rho} \rho_y T_{yy} - \theta_{18} \frac{1}{\rho} \rho_y T_{xx} \right) \\
&\quad + \frac{\mu^3}{\rho \rho} (\theta_{19} v_y v_{yy} + \theta_{20} v_y u_{xy} + \theta_6 v_y v_{xx} + \theta_{21} u_x v_{yy} + \theta_{22} u_x u_{xy} + \theta_7 u_x v_{xx} \\
&\quad + \theta_{23} v_x u_{yy} + \theta_{24} v_x v_{xy} + \theta_6 v_x u_{xx} + \theta_{23} u_y u_{yy} + \theta_{24} u_y v_{xy} + \theta_6 u_y u_{xx}) \\
&\quad - \frac{\mu^3}{\rho \rho} \left( \frac{1}{\rho} \rho_y + \frac{1}{T} T_y \right) (\theta_{13} u_x^2 + 2\theta_{14} u_x v_y + 2\theta_{17} u_y v_x + \theta_{17} u_y^2 + \theta_{17} v_x^2 + \theta_{13} v_y^2) \\
&\quad + \frac{\mu^3}{\rho \rho} \frac{R}{T} (\theta_{18} T_y T_{xx} + \theta_{18} T_y T_{yy})
\end{aligned} \tag{7.25}$$

The superscript  $(B)$  denotes third-order stress and heat-flux terms in the BGK–Burnett equations. The  $\theta_i$  are given as follows for  $\gamma = 1.4$ :  $\theta_1 = 2.56$ ,  $\theta_2 = 1.36$ ,  $\theta_3 = 0.56$ ,  $\theta_4 = -0.64$ ,  $\theta_5 = 0.96$ ,  $\theta_6 = 1.6$ ,  $\theta_7 = -0.4$ ,  $\theta_8 = -0.24$ ,  $\theta_9 = 1.024$ ,  $\theta_{10} = -0.256$ ,  $\theta_{11} = 1.152$ ,  $\theta_{12} = 0.16$ ,  $\theta_{13} = 2.24$ ,  $\theta_{14} = -0.56$ ,  $\theta_{15} = 3.6$ ,  $\theta_{16} = 0.6$ ,  $\theta_{17} = 1.4$ ,  $\theta_{18} = 4.9$ ,  $\theta_{19} = 7.04$ ,  $\theta_{20} = -0.16$ ,  $\theta_{21} = -1.76$ ,  $\theta_{22} = 4.24$ ,  $\theta_{23} = 3.8$ , and  $\theta_{24} = 3.4$ .

Finally, governing Eq. (7.1) is nondimensionalized by a reference length and freestream variables written in a curvilinear coordinate system  $(\xi, \eta)$  by employing a coordinate transformation:

$$\tau = t, \quad \xi = \xi(x, y), \quad \eta = \eta(x, y) \tag{7.26}$$

## 7.5 Wall-Boundary Conditions

The no-slip-/no-temperature-jump boundary conditions are employed at the wall when solving the continuum Navier–Stokes equations for  $Kn < 0.001$ . In the continuum–transition regimes, the non-slip-boundary conditions are no longer correct. First-order slip/temperature-jump boundary conditions should be applied to both the Navier–Stokes equations and Burnett equations in the range  $0.001 < Kn < 0.1$ .

The transition regime spans the range  $0.01 < Kn < 10$ ; the second-order slip/temperature-jump conditions should be used in this regime with the Navier–Stokes as well as the Burnett equations. It should be noted here that the Navier–Stokes equations are first-order accurate in  $Kn$  while the Burnett equations are second-order accurate in  $Kn$ . Both first- and second-order Maxwell–Smoluchowski slip/temperature-jump boundary conditions are generally employed on the body surface when solving the Burnett equations.

The first-order Maxwell–Smoluchowski slip-boundary conditions in Cartesian coordinates are [Smoluchowski, 1998]:

$$U_s = \frac{2 - \bar{\sigma}}{\bar{\sigma}} \frac{2\mu}{\rho} \sqrt{\frac{\pi}{8RT}} \left( \frac{\partial U}{\partial y} \right)_s + \frac{3}{4} \frac{\mu}{\rho T} \left( \frac{\partial T}{\partial x} \right)_s \quad (7.27)$$

and

$$T_s - T_w = \frac{2 - \bar{\alpha}}{\bar{\alpha}} \frac{2\gamma}{\gamma + 1} \frac{2\mu}{\rho} \sqrt{\frac{\pi}{8RT}} \frac{1}{Pr} \left( \frac{\partial T}{\partial y} \right)_s \quad (7.28)$$

The subscript  $s$  denotes the flow variables on the solid surface of the body. First-order Maxwell–Smoluchowski slip-boundary conditions can be derived by considering the momentum and energy-flux balance on the wall surface. The reflection coefficient  $\bar{\sigma}$  and the accommodation coefficient  $\bar{\alpha}$  are assumed to be equal to unity (for complete accommodation) in the calculations presented in this chapter.

Beskok’s slip-boundary condition [Beskok et al, 1996] is the second-order extension of the Maxwell’s slip-velocity-boundary condition excluding the thermal creep terms, given as:

$$U_s = \frac{2 - \bar{\sigma}}{\bar{\sigma}} \left[ \frac{Kn}{1 - bKn} \left( \frac{\partial U}{\partial y} \right)_s \right] \quad (7.29)$$

where  $b$  is the slip coefficient determined analytically in the slip flow regime and empirically in transitional and free molecular regimes.

Langmuir’s slip-boundary condition has also been employed in the literature [Myong, 1999]. Langmuir’s slip-boundary condition is based on the theory of adsorption phenomena at the solid wall. Gas molecules do not in general rebound elastically but condense on the surface, being held by the field of force of the surface atoms. These molecules may subsequently evaporate from the surface, resulting in some time lag. Slip is the direct result of this time lag. The slip velocity at the wall is given as:

$$U_s = \frac{1}{1 + \beta p} \quad (7.30)$$

where  $\beta$  is the adsorption coefficient determined empirically or by theoretical prediction.

In this chapter, these slip boundary conditions are applied and compared to determine their influence on the solution.

## 7.6 Linearized Stability Analysis of Burnett Equations

It was shown by Bobylev (1982) that the conventional Burnett equations are not stable to small wavelength disturbances; hence, the solutions to conventional Burnett equations tend to blow up when the mesh size is made progressively finer. Balakrishnan and Agarwal (1999) recently performed the linearized stability of one-dimensional original Burnett equations, conventional Burnett equations, augmented equations and the BGK–Burnett equations. They considered the response of a uniform gas subjected to

small one-dimensional periodic perturbations. Burnett equations were linearized by neglecting products and powers of small perturbations, and a linearized set of equations for small perturbation variables  $V' = [\rho', u', T']^T$  was obtained. It was assumed that the solution is of the form:

$$V' = \bar{V} e^{i\omega x} e^{\phi t} \tag{7.31}$$

where  $\phi = \alpha + i\beta$ , and  $\alpha$  and  $\beta$  denote the attenuation and dispersion coefficients, respectively. For stability,  $\alpha \leq 0$  as the Knudsen number increases. Substitution of Eq. (31) in the equations for small perturbation quantities  $V'$  results in a characteristic equation,  $|F(\phi, \omega)| = 0$ . The trajectory of the roots of this characteristic equation is plotted in a complex plane on which the real axis denotes the attenuation coefficient and the imaginary axis denotes the dispersion coefficient. For stability, the roots must lie to the left of the imaginary axis as the Knudsen number increases. Figures 7.2 to 7.5 show the trajectory of

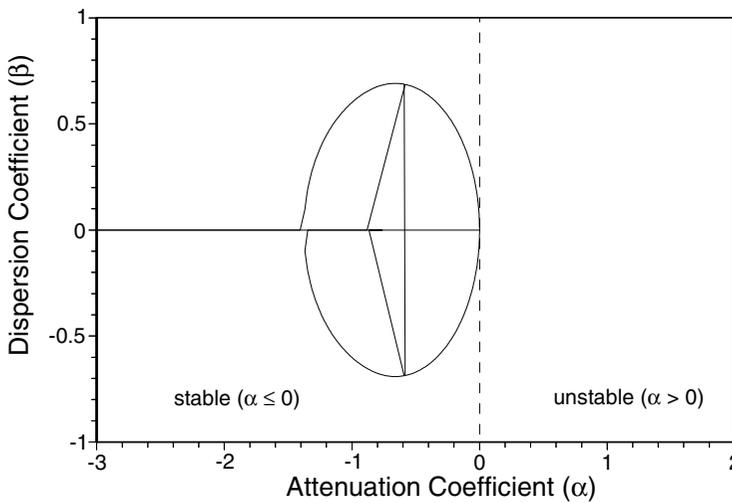

FIGURE 7.2 Characteristic trajectories of the one-dimensional Navier–Stokes equations.

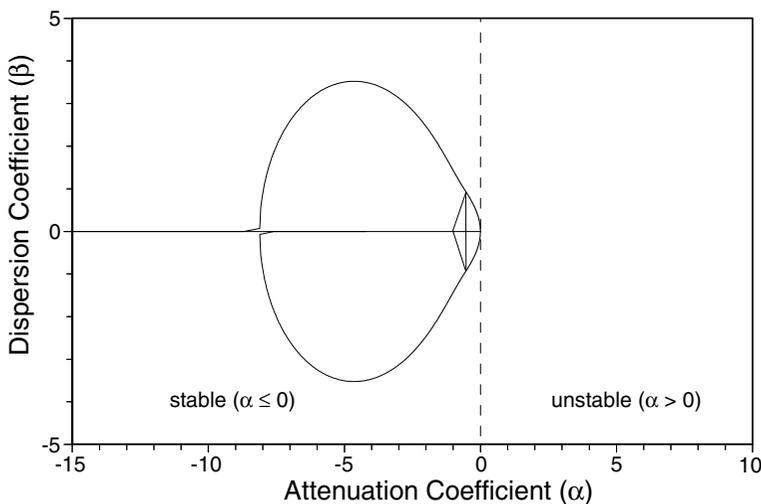

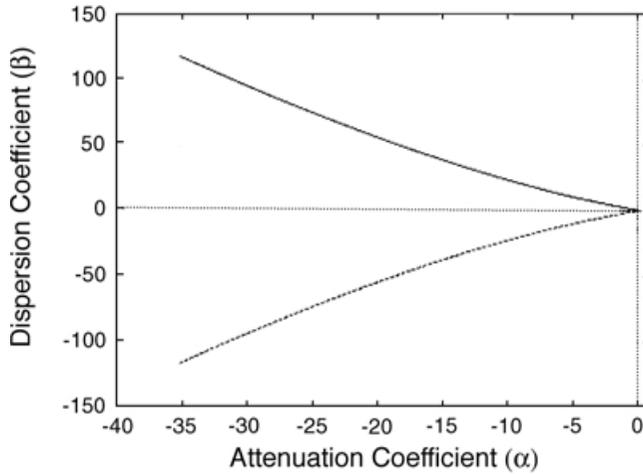

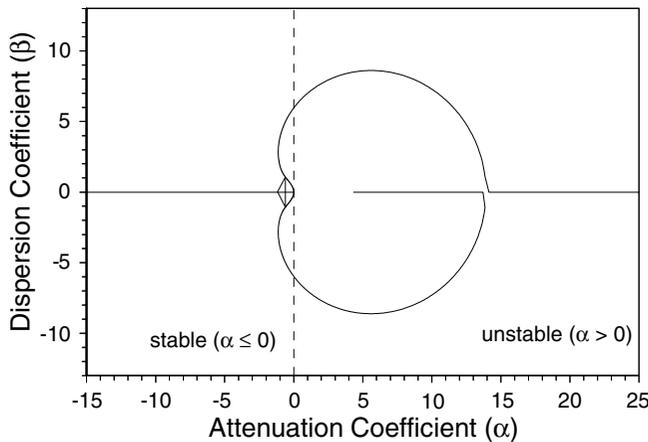

FIGURE 7.3 Characteristic trajectories of the one-dimensional augmented Burnett equations ( $\gamma = 1.667$ ); Euler equations are used to express the material derivatives  $D(\ )/Dt$  in terms of spatial derivatives.

**FIGURE 7.4** Characteristic trajectories of the one-dimensional BGK–Burnett equations ( $\gamma=1.667$ ); Euler equations are used to express the material derivatives  $D(\cdot)/Dt$  in terms of spatial derivatives.

**FIGURE 7.5** Characteristic trajectories of the one-dimensional conventional Burnett equations; Euler equations are used to express the material derivatives  $D(\cdot)/Dt$  in terms of spatial derivatives.

the three roots of the characteristic equations as the Knudsen number increases. From the plots, it can be observed that the Navier–Stokes equations, the augmented Burnett equations and the BGK–Burnett equations (with  $\gamma=1.667$ ) are stable, but the conventional Burnett equations are unstable. Euler equations are employed to approximate the material derivatives in all three types of Burnett equations. It should be noted here that the BGK–Burnett equations, however, become unstable for  $\gamma=1.4$ . On the other hand, if the material derivatives are approximated using the Navier–Stokes equations, the conventional, augmented and BGK–Burnett equations are all stable to small wavelength disturbances.

Based on these observations, we have employed the Navier–Stokes equations to approximate the material derivatives in the conventional, augmented and BGK–Burnett equations presented in Section 7.4. For the detailed analysis behind [Figures 7.2 to 7.5](#), the reader is referred to Balakrishnan and Agarwal (1999). The linearized stability analysis of conventional, augmented and super-Burnett equations has also been performed in three dimensions with similar conclusions [Yun and Agarwal, 2000].

## 7.7 Numerical Method

---

An explicit finite-difference scheme is employed to solve the governing equations of Section 7.4. The Steger–Warming flux-vector splitting method [Steger and Warming, 1981] is applied to the inviscid-flux terms. The second-order, central-differencing scheme is applied to discretize the stress tensor and heat-flux terms. Converged solutions were obtained with a reduction in residuals of six orders of magnitude. All the calculations were performed on a sequence of successively refined grids to assure grid independence of the solutions.

## 7.8 Numerical Simulations

---

Numerical simulations have been performed for both the hypersonic flows and microscale flows in the continuum–transition regime. Hypersonic flow calculations include one-dimensional shock structure, two-dimensional and axisymmetric blunt bodies, and a space shuttle re-entry condition. Microscale flows include the subsonic flow and supersonic flow in a microchannel.

### 7.8.1 Application to Hypersonic Shock Structure

The hypersonic shock for argon was computed using the BGK–Burnett equations. The upstream flow conditions were specified and the downstream conditions were determined from the Rankine–Hugoniot relations. For purposes of comparison, the same flow conditions as in Fisco and Chapman (1988) were used in the computations. The parameters used were

$$T_{\infty} = 300 \text{ K}, \quad P_{\infty} = 1.01323 \times 10^5 \text{ N/m}^2, \quad \gamma_{\text{argon}} = 1.667, \quad \mu_{\text{argon}} = 22.7 \times 10^{-6} \text{ kg/sec} \cdot \text{m}$$

The Navier–Stokes solution was taken as the initial value. This initial Navier–Stokes spatial distribution of variables was imposed on a mesh that encloses the shock. The length of the control volume enclosing the shock was chosen to be  $1000 \times \lambda_{\infty}$  where the mean free path based on the freestream parameters is given by the expression  $\lambda_{\infty} = 16\mu / (5\rho_{\infty}\sqrt{2\pi RT_{\infty}})$ . This is the mean free path that would exist in the unshocked region if the gas were composed of hard elastic spheres and had the same viscosity, density and temperature as of the gas being considered. The solution was marched in time until the observed deviations were smaller than a preset convergence criterion.

A set of computational experiments was carried out to compare the BGK–Burnett solutions with the Burnett solutions of Fisco and Chapman (1988). Tests were conducted at Mach 20 and Mach 35. In order to test for instabilities to small wavelength disturbances, the grid points were increased from 101 to 501 points. Figures 7.6 and 7.7 show variations of specific entropy across the shock wave. It is observed that the BGK–Burnett equations show a positive entropy change throughout the flowfield, while the conventional Burnett equations give rise to a negative entropy spike just ahead of the shock as the number of grid points is increased. This spike increases in magnitude until the conventional Burnett equations break down completely. The BGK–Burnett equations did not exhibit any instabilities for the range of grid points considered. Figure 7.8 shows the variation of reciprocal density thickness with Mach number. BGK–Burnett calculations compare well to those of Woods and simplified Woods equations [Reese et al., 1995] and the experimental data of Alsmeyer (1976). Extensive calculations for one-dimensional hypersonic shock structure using various higher order kinetic formulations are given in the Ph.D. thesis of Balakrishnan (1999).

### 7.8.2 Application to Two-Dimensional Hypersonic Blunt Body Flow

The two-dimensional augmented Burnett code was employed to compute the hypersonic flow over a cylindrical leading edge with a nose radius of 0.02 m in the continuum–transition regime. The grid system ( $50 \times 82$  mesh) used in the computations is shown in Figure 7.9. The results were compared with those of Zhong (1991).

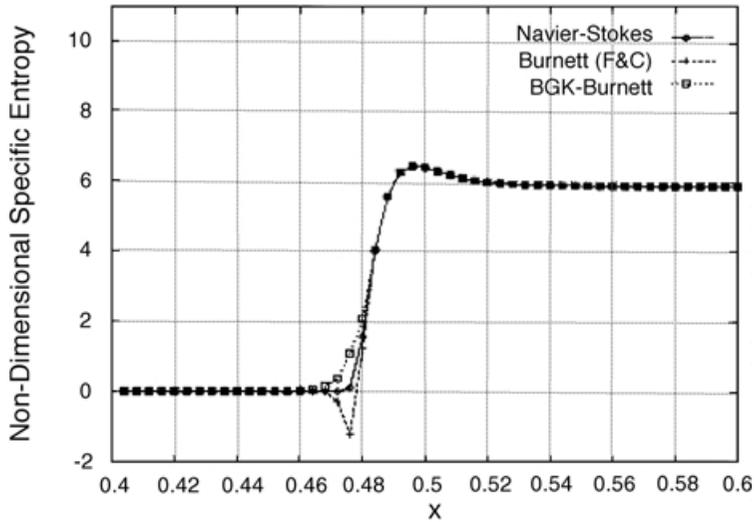

FIGURE 7.6 Specific entropy variation across a Mach 20 normal shock in a monatomic gas (argon),  $\Delta x/\lambda_\infty = 4.0$  and  $\gamma = 1.667$ .

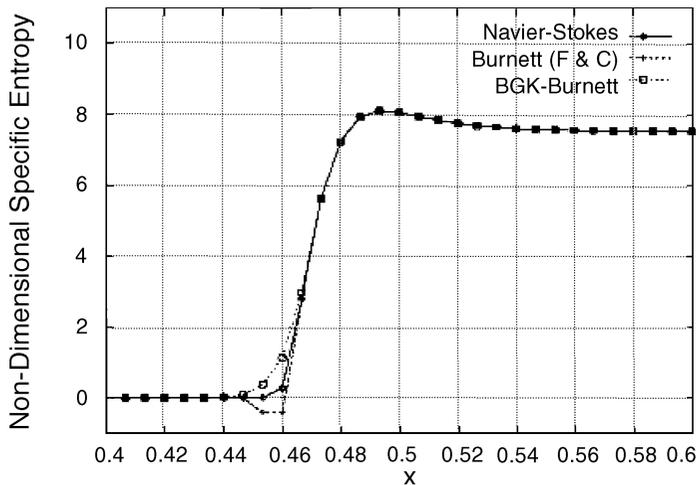

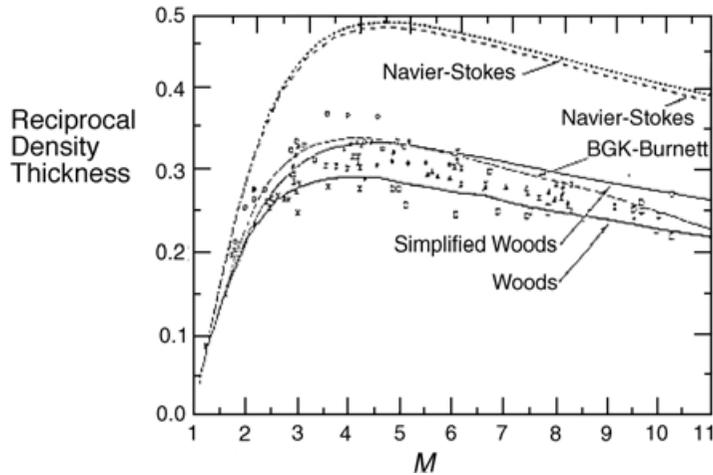

FIGURE 7.7 Specific entropy variation across a Mach 35 normal shock in a monatomic gas (argon),  $\Delta x/\lambda_\infty = 4.0$  and  $\gamma = 1.667$ .

The flow conditions for this case are as follows:

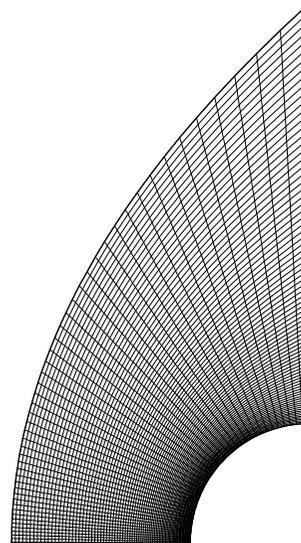

$$M_\infty = 10, \quad Kn_\infty = 0.1, \quad Re_\infty = 167.9,$$

$$P_\infty = 2.3881 \text{ N/m}^2, \quad T_\infty = 208.4 \text{ K}, \quad T_w = 1000.0 \text{ K}$$

The viscosity is calculated by Sutherland's law,  $\mu = c_1 T^{1.5}/(T + c_2)$ . The coefficients  $c_1$  and  $c_2$  for air are  $1.458 \times 10^{-6} \text{ kg}/(\text{sec m K}^{1/2})$  and  $110.4 \text{ K}$ , respectively. Other constants used in this computation for air are  $\gamma = 1.4$ ,  $Pr = 0.72$  and  $R = 287.04 \text{ m}^2/(\text{sec}^2 \text{ K})$ .

**FIGURE 7.8** Plot showing the variation of reciprocal density thickness with Mach number, obtained with the Navier–Stokes, Wood and Simplified Woods [Reese et al., 1995] and BGK–Burnett equations for a monatomic gas (argon). Experimental data were obtained from Alsmeyer (1976). (From Alsmeyer, H. (1976) *J. Fluid Mech.* 74, pp. 497–513, ASME, New York. With permission.)

**FIGURE 7.9** Two-dimensional computational grid ( $50 \times 82$  mesh) around a blunt body,  $r_n = 0.02$  m.

The comparisons of density, velocity and temperature distributions along the stagnation streamline are shown in [Figures 7.10, 7.11 and 7.12](#), respectively. The results agree well with those of Zhong for both the Navier–Stokes and the augmented Burnett computations. Because the flow is in the continuum–transition regime ( $Kn = 0.1$ ), the Navier–Stokes equations become inaccurate, and the differences between the Navier–Stokes and the augmented Burnett solutions are obvious. In particular, the difference between the Navier–Stokes and Burnett solutions for the temperature distribution is significant across the shock. Temperature and Mach number contours of the Navier–Stokes solutions and the augmented Burnett solutions are compared in [Figures 7.13 and 7.14](#), respectively. The shock structure of the augmented Burnett solutions agrees well with that of Zhong. The shock layer of the augmented Burnett solutions is thicker and the shock location starts upstream of that of the Navier–Stokes solutions. However, because the local Knudsen number decreases and the flow tends toward equilibrium as it approaches the wall

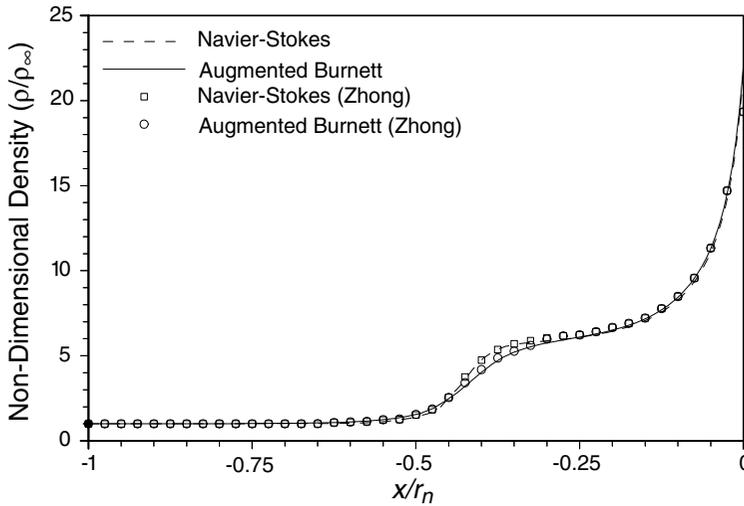

FIGURE 7.10 Density distributions along stagnation streamline for blunt body flow: Air,  $M_\infty = 10$  and  $Kn_\infty = 0.1$ .

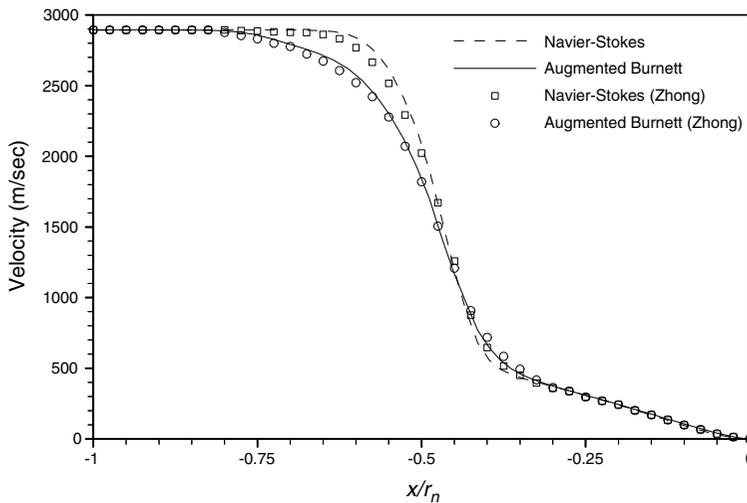

FIGURE 7.11 Velocity distributions along stagnation streamline for blunt body flow: Air,  $M_\infty = 10$  and  $Kn_\infty = 0.1$ .

surface, the differences between the Navier–Stokes and augmented Burnett solutions become negligible near the wall, especially near the stagnation point. Thus, the Maxwell–Smoluchowski slip boundary conditions can be applied for both the Navier–Stokes and the augmented Burnett calculations for the hypersonic blunt body.

### 7.8.3 Application to Axisymmetric Hypersonic Blunt Body Flow

The results of the axisymmetric augmented Burnett computations are compared with the DSMC results obtained by Vogenitz and Takara (1971) for the axisymmetric hemispherical nose. The computed results are also compared with Zhong and Furumoto’s (1995) axisymmetric augmented Burnett solutions. The

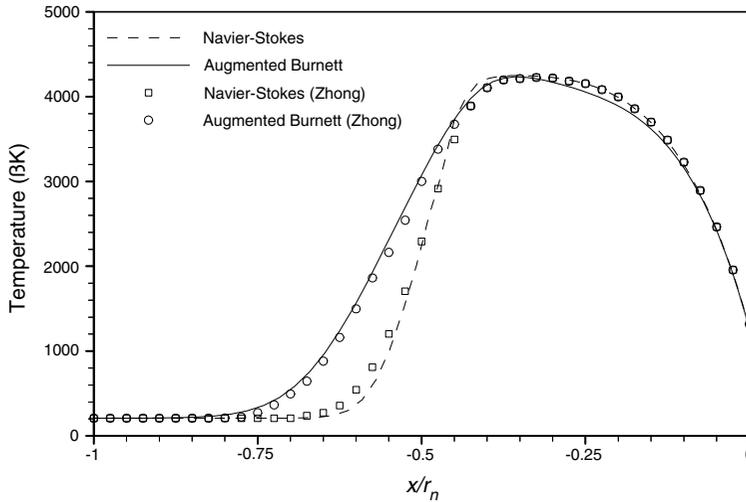

FIGURE 7.12 Temperature distributions along stagnation streamline for blunt body flow: Air,  $M_\infty = 10$  and  $Kn_\infty = 0.1$ .

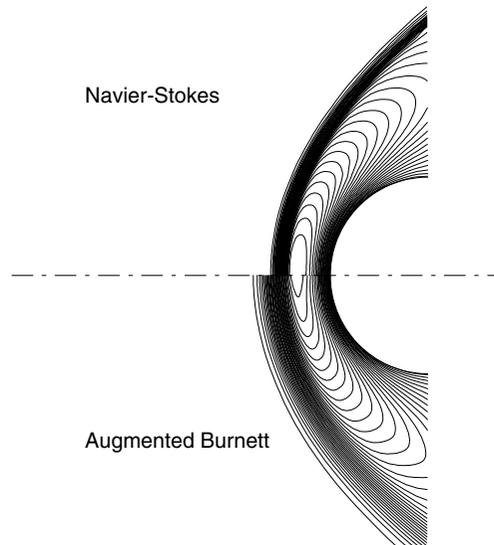

FIGURE 7.13 Comparison of temperature contours for blunt body flow: Air,  $M_\infty = 10$  and  $Kn_\infty = 0.1$ .

flow conditions for this case are

$$M_\infty = 10, \quad Kn_\infty = 0.1$$

$$\frac{T_w}{T_\infty} = 1.0, \quad \frac{T_w}{T_0} = 0.029$$

$T_0$  is the stagnation temperature. The gas is assumed to be a monatomic gas with a hard-sphere model. The viscosity coefficient is calculated by the power law  $\mu = \mu_r (T/T_r)^{0.5}$ . The reference viscosity  $\mu_r$  and the reference temperature  $T_r$  used in this case are  $2.2695 \times 10^{-5}$  kg/(sec m) and 300 K, respectively. Other constants used in this computation are  $\gamma = 1.67$  and  $Pr = 0.67$ .

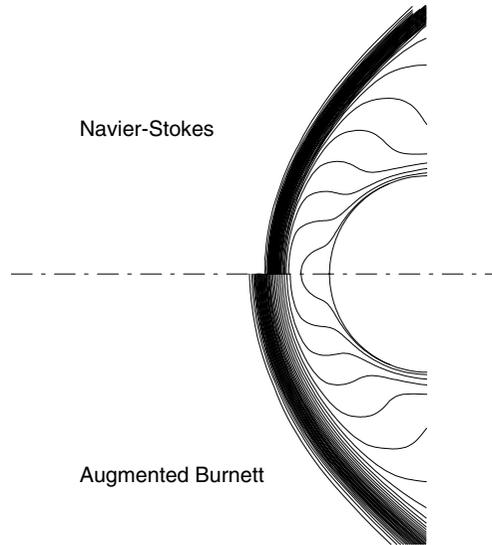

FIGURE 7.14 Comparison of Mach number contours for blunt body flow: Air,  $M_\infty = 10$  and  $Kn_\infty = 0.1$ .

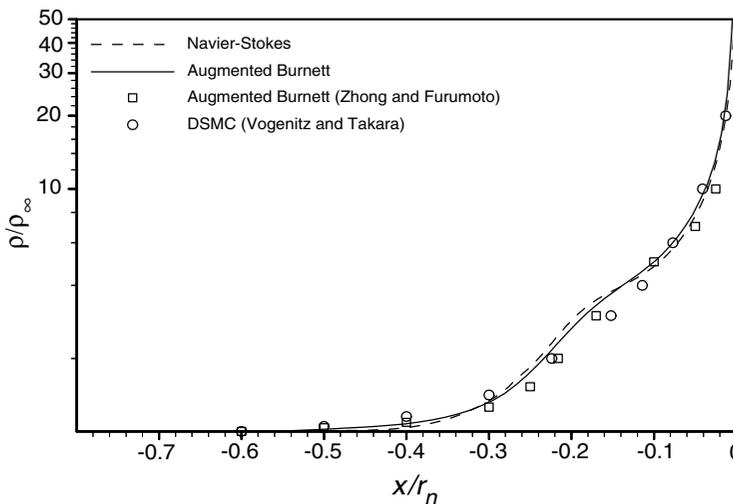

FIGURE 7.15 Density distributions along stagnation streamline for a hemispherical nose: Hard-sphere gas,  $M_\infty = 10$  and  $Kn_\infty = 0.1$ .

The comparisons of density and temperature distributions along the stagnation streamline among the current axisymmetric augmented Burnett solutions, the axisymmetric augmented Burnett solutions of Zhong and Furumoto and the DSMC results are shown in Figures 7.15 and 7.16, respectively. The corresponding Navier–Stokes solutions are also compared in these figures. The axisymmetric augmented Burnett solutions agree well with Zhong and Furumoto’s axisymmetric augmented Burnett solutions in both density and temperature. The density distributions for both the Navier–Stokes and augmented Burnett equations show little differences from the DSMC results. The temperature distributions, however, show that the DSMC method predicts a thicker shock than the augmented Burnett equations. The maximum

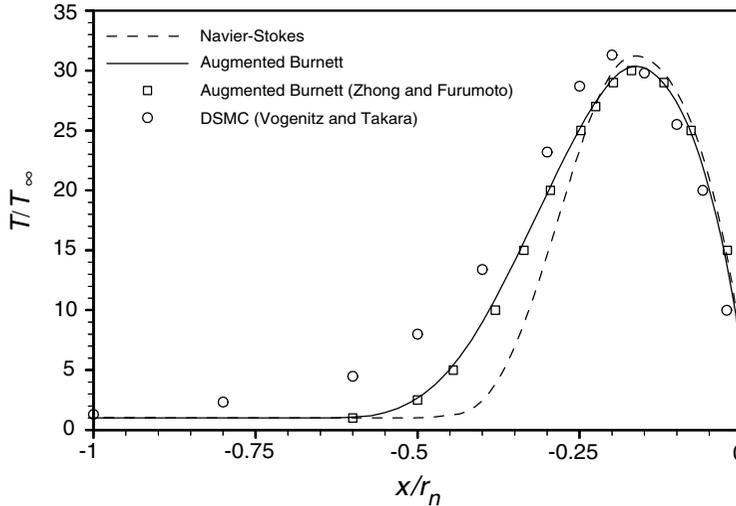

FIGURE 7.16 Temperature distribution along stagnation streamline for a hemispherical nose: Hard-sphere gas,  $M_\infty = 10$  and  $Kn_\infty = 0.1$ .

temperature of the DSMC results is slightly higher than those of the augmented Burnett solutions. However, the augmented Burnett solutions show much closer agreement with the DSMC results than the Navier–Stokes solutions.

In conclusion, the axisymmetric augmented Burnett solutions presented here agree well with Zhong’s axisymmetric augmented Burnett solutions and describe the shock structure closer to the DSMC results than the Navier–Stokes solutions.

As another application to the hypersonic blunt body, the augmented Burnett equations are applied to compute the hypersonic flowfield at re-entry condition encountered by the nose region of the space shuttle. The computations are compared with the DSMC results of Moss and Bird (1984). The DSMC method accounts for the translational, rotational, vibrational and chemical nonequilibrium effects.

An “equivalent axisymmetric body” concept [Moss and Bird, 1984] is applied to model the windward centerline of the space shuttle at a given angle of attack. A hyperboloid with nose radius of 1.362 m and asymptotic half angle of 42.5 degrees is employed as the equivalent axisymmetric body to simulate the nose of the shuttle. Figure 7.17 shows the side view of the grid ( $61 \times 100$  mesh) around the hyperboloid. The freestream conditions at an altitude of 104.93 km as given in Moss and Bird are

$$M_\infty = 25.3, \quad Kn_\infty = 0.227, \quad Re_\infty = 163.8,$$

$$\rho_\infty = 2.475 \times 10^{-7} \text{ kg/m}^3, \quad T_\infty = 223 \text{ K}, \quad T_w = 560 \text{ K}$$

The viscosity is calculated by the power law. The reference viscosity  $\mu_r$  and the reference temperature  $T_r$  are taken as  $1.47 \times 10^{-5}$  kg/(sec m) and 223 K, respectively.

Figures 7.18 and 7.19 show comparisons of the density and temperature distributions along the stagnation streamline between the Navier–Stokes solutions, the augmented Burnett solutions and the DSMC results. The differences between the augmented Burnett solutions and the DSMC results are significant in both density and temperature distributions. In Figure 7.18, the density distribution of the DSMC results is lower and smoother than that of the augmented Burnett solutions. In Figure 7.19, the DSMC method predicts about 30% thicker shock layer and 9% lower maximum temperature than the augmented Burnett equations. The DSMC results can be considered to be more accurate than the augmented Burnett

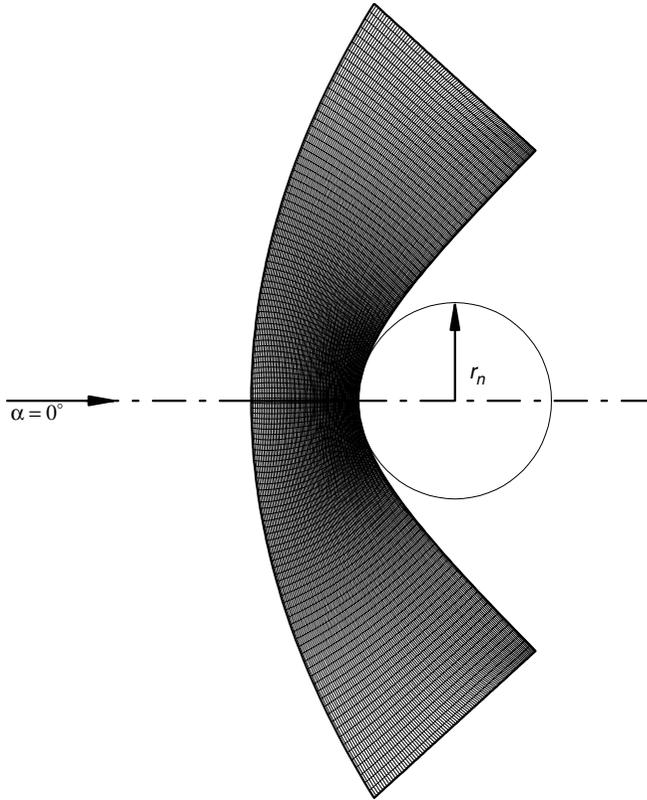

FIGURE 7.17 Side view of the grid ( $61 \times 100$  mesh) around a hyperboloid nose of radius  $r_n = 1.362$  m.

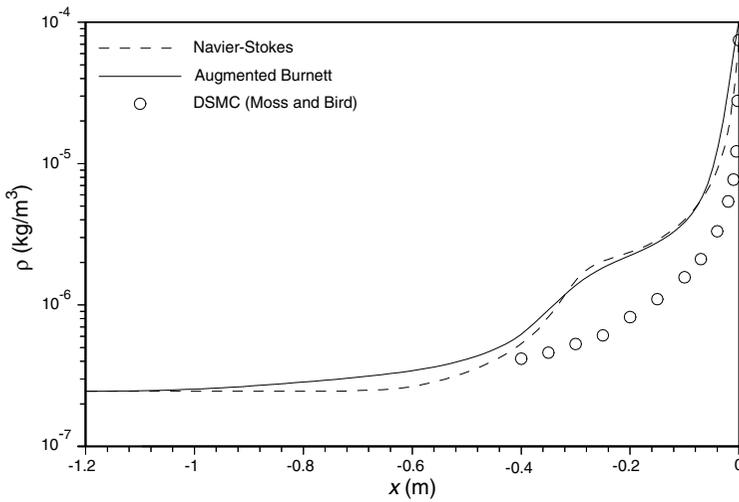

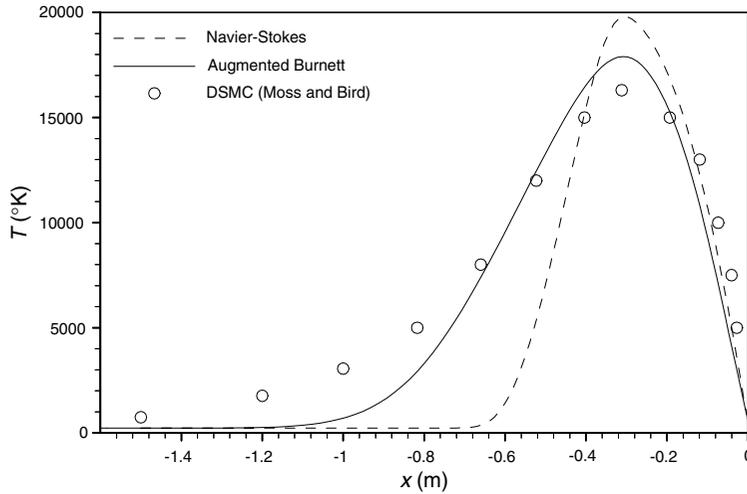

FIGURE 7.18 Density distributions along stagnation streamline for a hyperboloid nose: Air,  $M_\infty = 25.3$  and  $Kn_\infty = 0.227$ .

**FIGURE 7.19** Temperature distributions along stagnation streamline for a hyperboloid nose: Air,  $M_\infty = 25.3$  and  $Kn_\infty = 0.227$ .

solutions, as the DSMC method accounts for all the effects of translational, rotational, vibrational and chemical nonequilibrium, while the augmented Burnett equations do not. However, the augmented Burnett solutions agree much better with the DSMC results than the Navier–Stokes computations. The difference between the Navier–Stokes and the augmented Burnett solutions in temperature distributions is very significant. The shock layer of the augmented Burnett solutions is almost two times thicker than the Navier–Stokes solutions. The augmented Burnett solutions predict about 11% less maximum temperature than the Navier–Stokes solutions.

### 7.8.4 Application to NACA 0012 Airfoil

The Navier–Stokes equations are applied to compute the rarefied subsonic flow over a NACA 0012 airfoil with chord length of 0.04 m. The grid system in the physical domain is shown in Figure 7.20. The flow conditions are

$$M_\infty = 0.8, \quad Re_\infty = 73, \quad \rho_\infty = 1.116 \times 10^{-4} \text{ kg/m}^3, \quad T_\infty = 257 \text{ K}, \quad \text{and} \quad Kn_\infty = 0.014$$

Various constants used in the calculation for air are  $\gamma = 1.4$ ,  $Pr = 0.72$ , and  $R = 287.04 \text{ m}^2/(\text{sec}^2 \text{ K})$ .

Figure 7.21 shows the density contours of the Navier–Stokes solution with the first-order Maxwell–Smoluchowski slip-boundary conditions. These contours using the continuum approach agree well with those of Sun et al. (2000) using the information preservation (IP) particle method. At these Mach and Knudsen numbers, the contours from the DSMC calculations are not smooth due to the statistical scatter. The comparison of pressure distribution along the surface between our Navier–Stokes solution with a slip-boundary condition and the DSMC calculation [Sun et al., 2000] is shown in Figure 7.22; the agreement between the solutions is good. Figure 7.23 compares the surface slip velocity from the DSMC, IP and Navier–Stokes methods as calculated by Sun et al. and by our Navier–Stokes calculation. The slip velocity distribution from our Navier–Stokes calculation shows good agreement with that obtained from the DSMC and IP methods except near the trailing edge. However, there is considerable disagreement between our Navier–Stokes results and those reported in Sun et al. (2000). This calculation again demonstrates that Navier–Stokes equations with slip-boundary conditions can provide accurate flow simulation  $0.001 < Kn < 0.1$ .

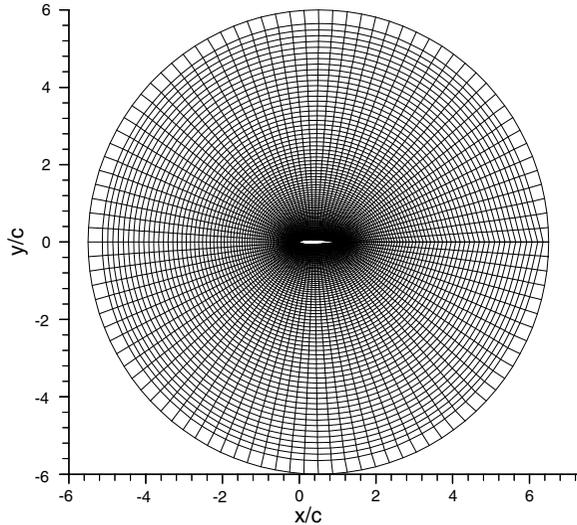

FIGURE 7.20 Grid ( $101 \times 91$  mesh) around a NACA 0012 airfoil,  $c = 0.04$  m.

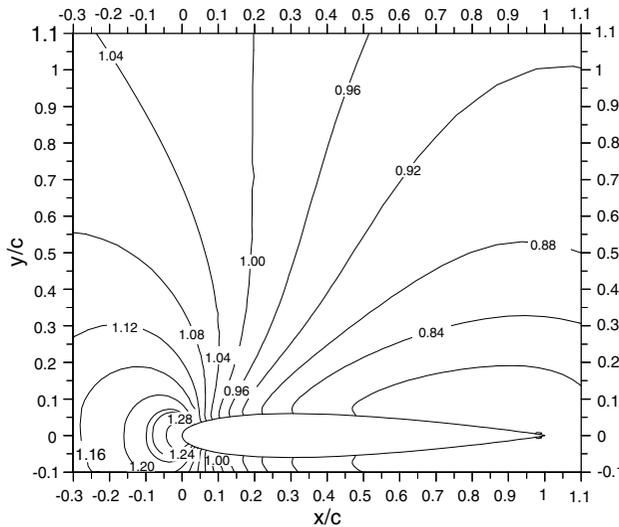

FIGURE 7.21 Density contours for NACA 0012 airfoil: Air,  $M_\infty = 0.8$  and  $Kn_\infty = 0.014$ .

### 7.8.5 Subsonic Flow in a Microchannel

The augmented Burnett equations are employed for computation of subsonic flow in a microchannel with a ratio of channel length to height of 20 ( $L/H = 20$ ). For the wall boundary conditions, Beskok's and Langmuir's boundary conditions are employed and compared. The augmented Burnett solutions are also compared with the Navier–Stokes solutions. Flow conditions at the entrance and exit of the channel are  $Kn_{in} = 0.088$ ,  $Kn_{out} = 0.2$  and  $P_{in}/P_{out} = 2.28$ .

Figure 7.24 compares the velocity profiles at various streamwise locations. Both Navier–Stokes and augmented Burnett equations using either Beskok's or Langmuir's boundary conditions show almost identical velocity profiles. These velocity profiles agree well with the velocity profiles from the  $\mu$  flow calculation by Beskok and Karniadakis (1999). Nondimensional mass flowrates along the microchannel are shown in Figure 7.25. All the mass flowrates from both equations and both slip-boundary conditions

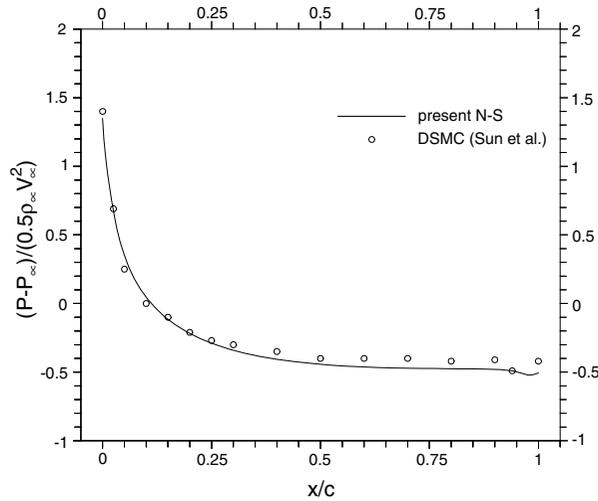

FIGURE 7.22 Pressure distributions along NACA 0012 airfoil surface: Air,  $M_\infty = 0.8$  and  $Kn_\infty = 0.014$ .

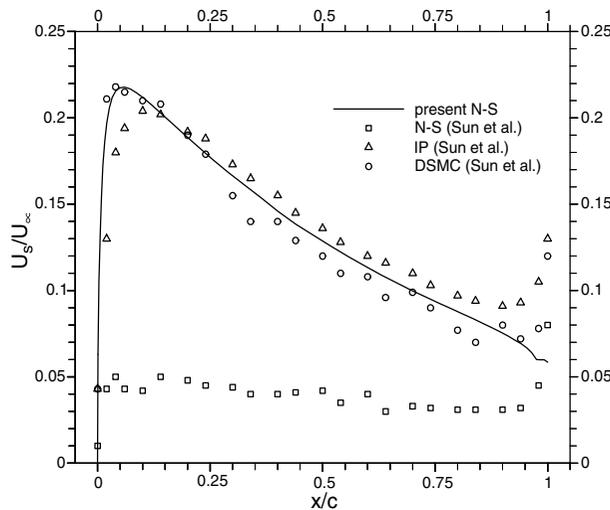

FIGURE 7.23 Slip velocity distributions along NACA 0012 airfoil surface: Air,  $M_\infty = 0.8$  and  $Kn_\infty = 0.014$ .

are about 0.76 and almost constant along the channel, as should be the case. This mass flowrate is 13% higher than that predicted with a no-slip-boundary condition, which is 0.667. Figure 7.26 shows comparison of pressure distribution along the centerline. Both the Navier–Stokes and the augmented Burnett equations show a nonconstant pressure gradient along the channel. The solutions using Beskok’s slip-boundary condition show less change in pressure gradient than those from the Langmuir’s boundary condition. Figure 7.27 compares the streamwise velocity distributions along the centerline. The streamwise velocity distributions are almost identical except near the exit. Figure 7.28 compares the slip velocity distributions along the wall. The slip velocity profiles obtained from both Navier–Stokes and augmented Burnett equations are identical when the same wall-boundary conditions are employed. However, the Beskok’s slip-boundary condition and Langmuir’s slip-boundary condition show a large difference. The Beskok’s slip-boundary condition predicts lower slip velocity near the entrance and higher slip velocity near the exit. As the figures show, there is very little difference between the Navier–Stokes and augmented Burnett

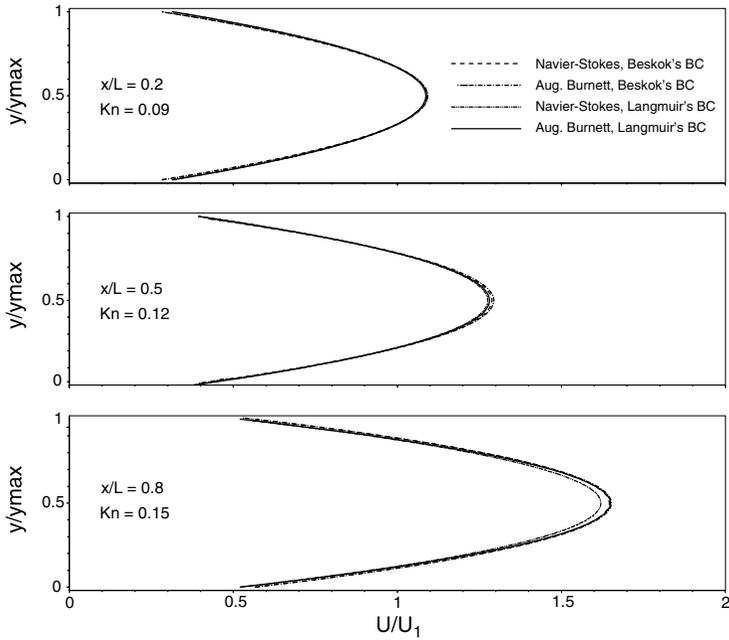

FIGURE 7.24 Comparison of velocity profiles at various streamwise locations:  $Kn_{in} = 0.088$ ,  $Kn_{out} = 0.2$  and  $P_{in}/P_{out} = 2.28$ .

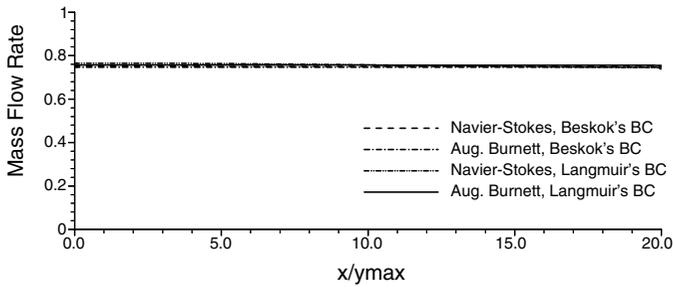

FIGURE 7.25 Comparison of mass flow rates along the microchannel:  $Kn_{in} = 0.088$ ,  $Kn_{out} = 0.2$  and  $P_{in}/P_{out} = 2.28$ .

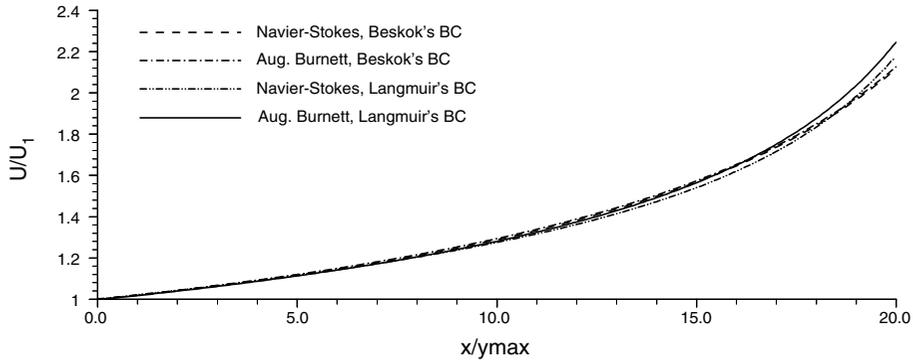

FIGURE 7.27 Comparison of streamwise velocity distributions along the centerline:  $Kn_{in} = 0.088$ ,  $Kn_{out} = 0.2$  and  $P_{in}/P_{out} = 2.28$ .

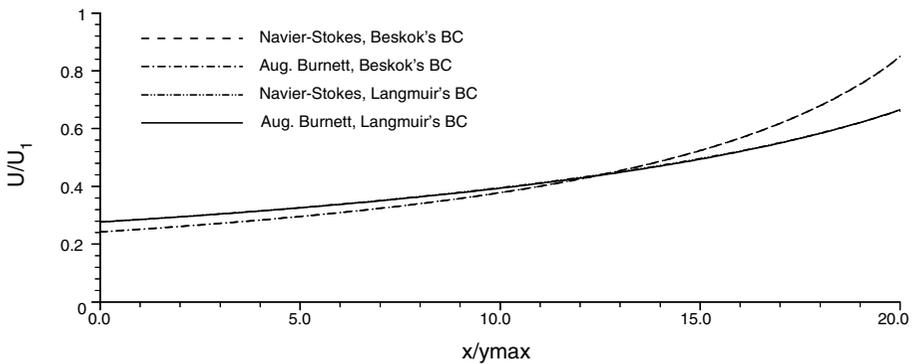

FIGURE 7.28 Comparison of slip velocity distributions along the wall:  $Kn_{in} = 0.088$ ,  $Kn_{out} = 0.2$  and  $P_{in}/P_{out} = 2.28$ .

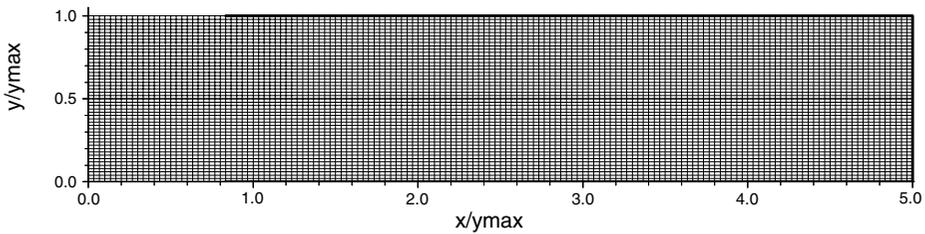

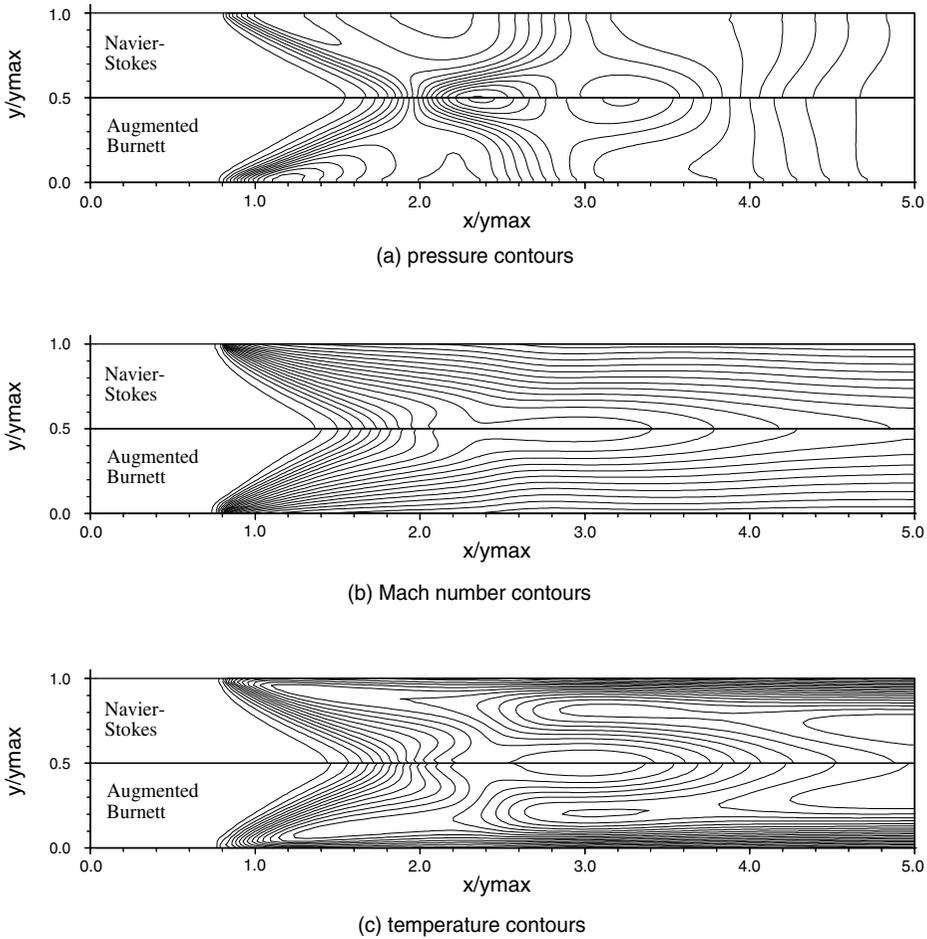

FIGURE 7.29 Microchannel geometry and grid.

solutions at the entrance, but, as the local Knudsen number increases toward the exit of the channel, the difference between the Navier–Stokes and augmented Burnett solutions increases as expected.

### 7.8.6 Supersonic Flow in a Microchannel

The Navier–Stokes equations and the augmented Burnett equations are applied to compute the supersonic flow in a microchannel. The geometry and grid of the microchannel are shown in Figure 7.29. As the flow enters the channel, the tangential velocity component to the wall is retained, while the velocity component normal to the wall is neglected at wall boundaries in the region  $0 \leq x \leq 1 \mu\text{m}$ . The first-order Maxwell–Smoluchowski slip-boundary conditions are employed at the rest of the wall boundaries.

**FIGURE 7.30** Comparisons of contours between Navier–Stokes and augmented Burnett equations: Helium,  $M_\infty = 5$  and  $Kn_\infty = 0.7$ .

The channel height and length are 2.4 and 12  $\mu\text{m}$ , respectively. The flow conditions at the entrance for the helium flow are

$$M_\infty = 5.0, \quad P_\infty = 1.01 \times 10^6 \text{ dyne/cm}^2, \\ Kn_\infty = 0.07, \quad T_\infty = 298 \text{ K}$$

Figures 7.30a-c compare the pressure, Mach number and temperature contours obtained from the Navier–Stokes and augmented Burnett equations. Solutions from the Navier–Stokes and augmented Burnett equations do not show significant differences. These flow property contours also agree well with the DSMC solutions obtained by Oh et al. (1997). Figure 7.31 compares the density, temperature, pressure and Mach number profiles along the centerline of the channel using the Navier–Stokes, augmented Burnett and DSMC formulations [Oh et al., 1997]. The profiles generally agree well with the DSMC results. The temperature and Mach number profiles especially show very close agreement with the DSMC results. The augmented Burnett solutions are closer to the DSMC solutions than the Navier–Stokes solutions in the temperature and Mach number profiles. Figure 7.32 compares the density, temperature, pressure and Mach number profiles along the channel wall using the Navier–Stokes, augmented Burnett and DSMC formulations. Both the Navier–Stokes and augmented Burnett solutions show some difference with the DSMC solutions. Figures 7.33 and 7.34 compare the temperature and velocity profiles across

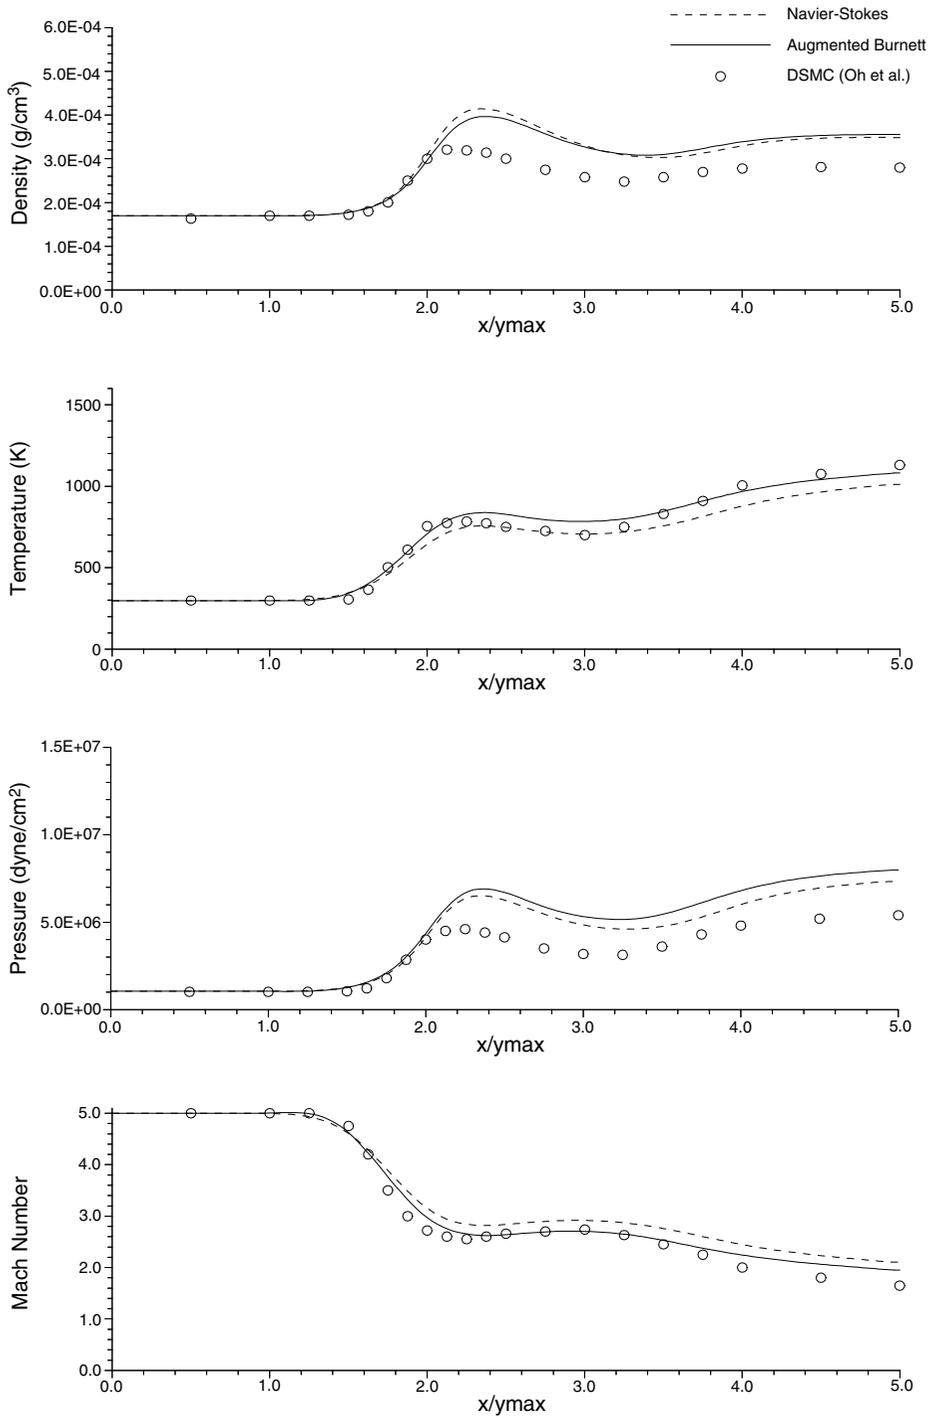

FIGURE 7.31 Comparisons of density, temperature, pressure and Mach number profiles along the centerline of the channel: Helium,  $M_{\infty} = 5$  and  $Kn_{\infty} = 0.7$ .

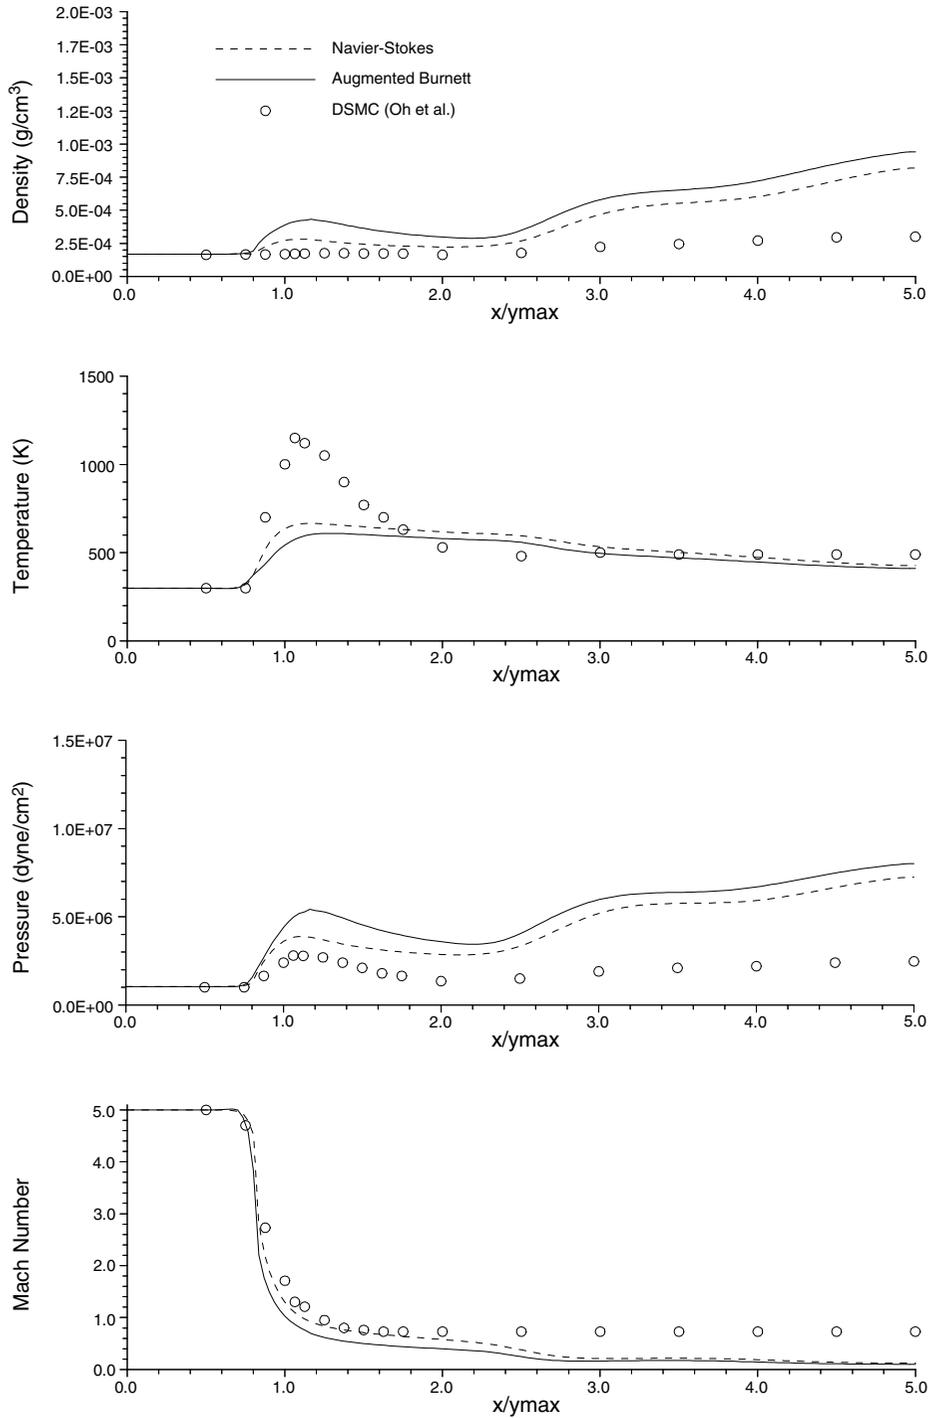

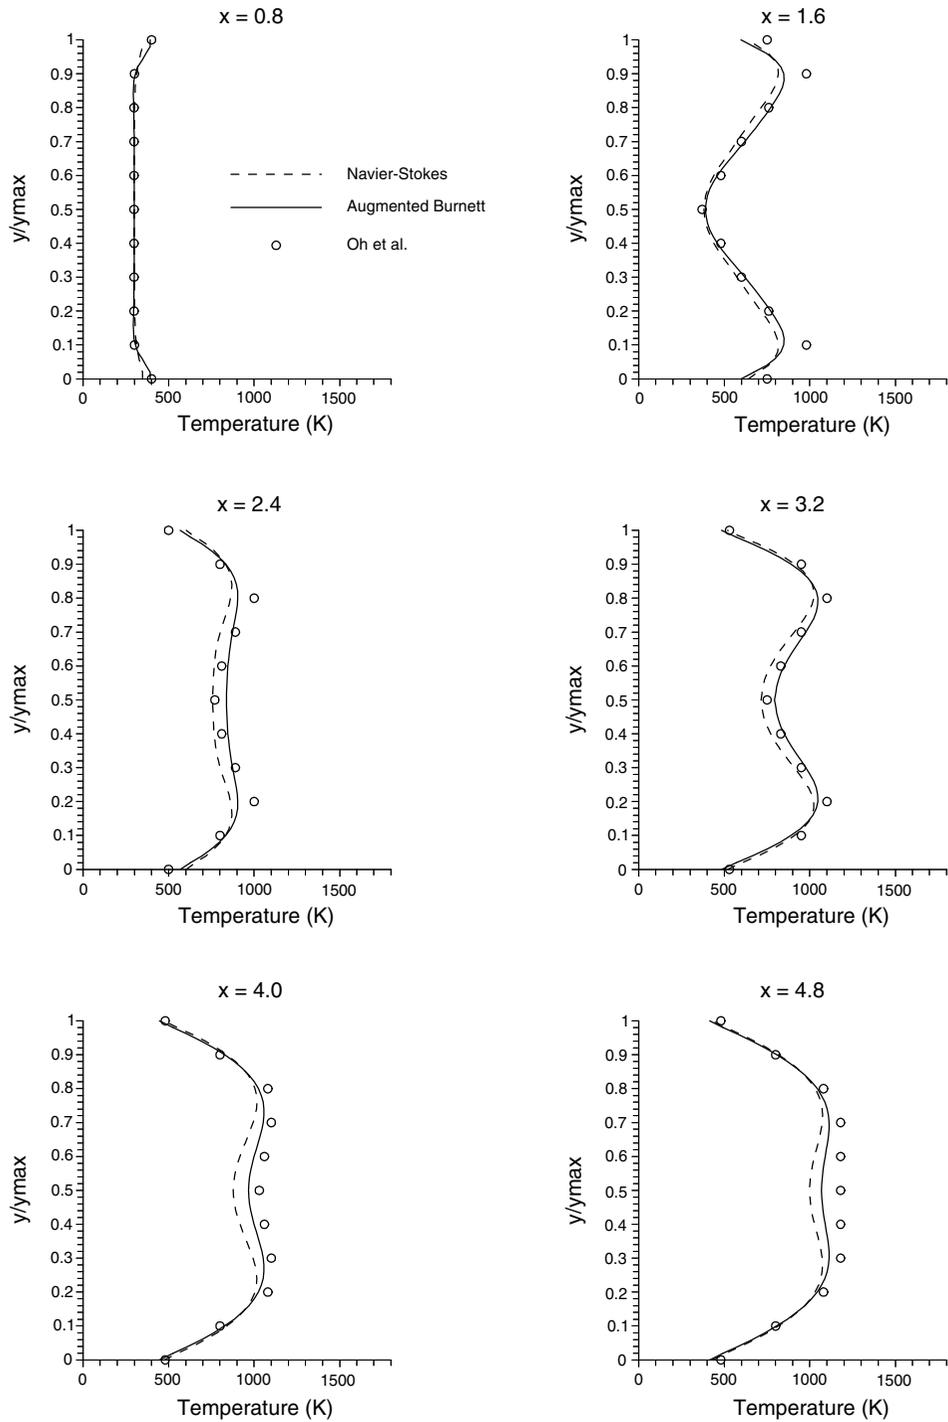

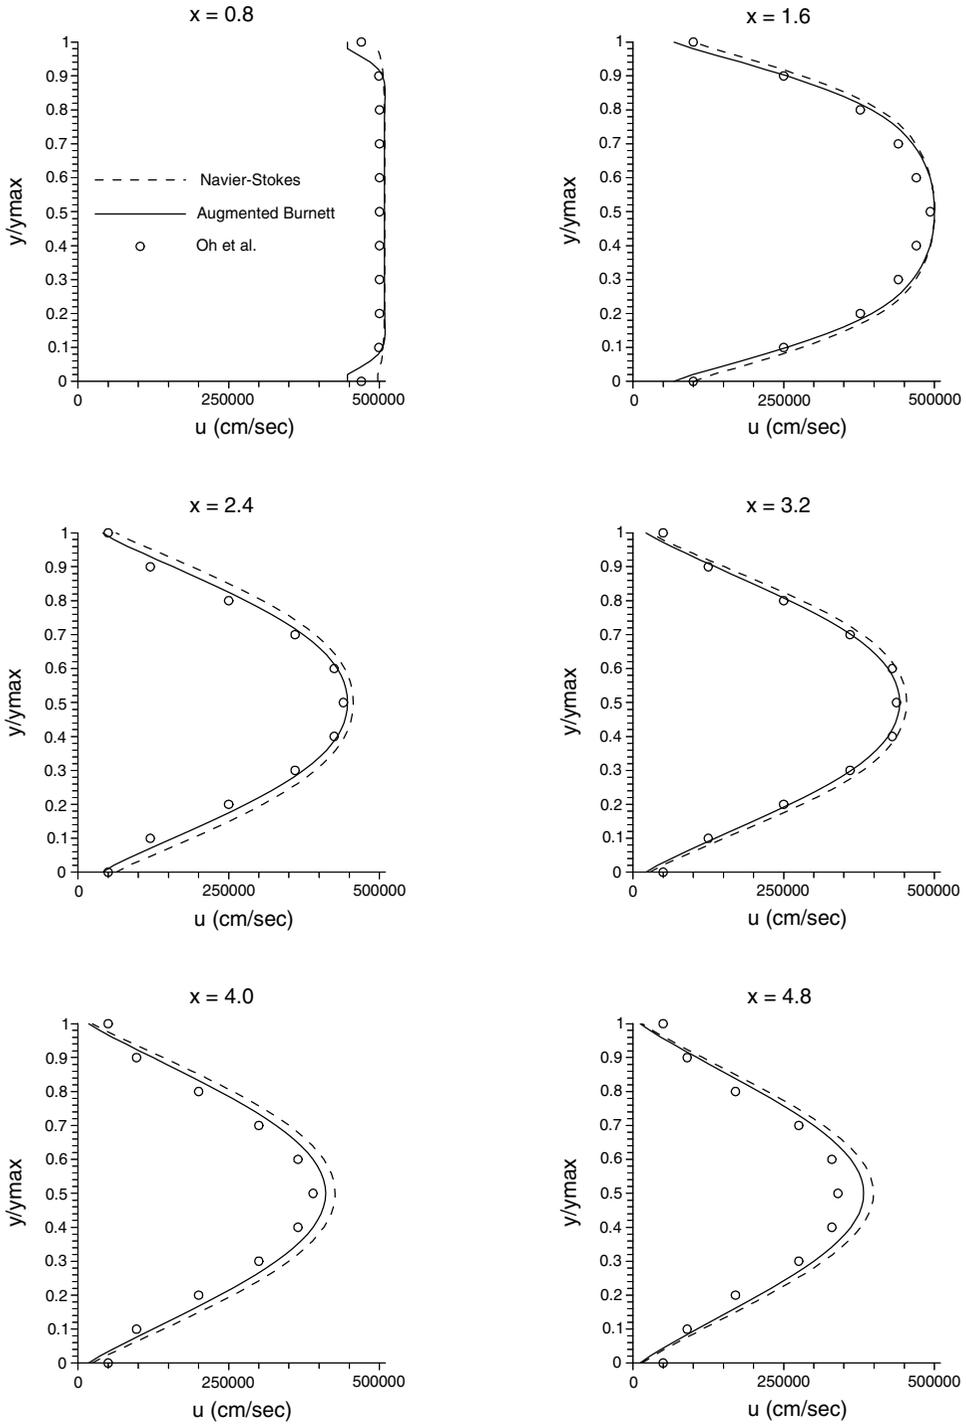

FIGURE 7.32 Comparisons of density, temperature, pressure and Mach number profiles along the wall of the channel: Helium,  $M_{\infty} = 5$  and  $Kn_{\infty} = 0.7$ .

**FIGURE 7.33** Comparisons of temperature profiles across the channel at various locations: Helium,  $M_\infty = 5$  and  $Kn_\infty = 0.7$ .

**FIGURE 7.34** Comparisons of velocity profiles across the channel at various locations: Helium,  $M_\infty = 5$  and  $Kn_\infty = 0.7$ .

the channel at various streamwise locations using the Navier–Stokes, augmented Burnett and DSMC formulations, respectively. The profiles obtained from the augmented Burnett solutions are closer to the DSMC results than the Navier–Stokes solutions.

Unfortunately, experimental data are not available to assess the accuracy of the Navier–Stokes, Burnett and DSMC models for computing the microchannel flows. A substantial amount of both experimental and computational simulation work is needed to determine the applicability and accuracy of various fluid models for computing high Knudsen number flow in microchannels.

## 7.9 Conclusions

---

For computing flows in the continuum–transition regime, higher order fluid dynamics models beyond Navier–Stokes are needed. These models are known as extended or generalized hydrodynamics models in the literature. Some of these models are the Burnett equations, 13-moment Grad’s equations, Gaussian closure or Levermore moment equations, and Eu’s equations. An alternative to generalized hydrodynamic models is the hybrid approach, which combines a Euler or Navier–Stokes solver with the DSMC method. Most of the generalized hydrodynamic models proposed to date suffer from the following drawbacks: They do not capture the physics properly or they are too computationally intensive, or both. In this chapter, the history of a set of extended hydrodynamics equations based on the Chapman–Enskog expansion of Boltzmann equations to  $O(Kn^2)$ , known as the Burnett equations, has been reviewed. The various sets known in the literature as conventional, augmented and BGK–Burnett equations have been considered and critically examined. Computations for hypersonic flows and microscale flows show that both the augmented and BGK–Burnett equations can be effectively applied to accurately compute flows in the continuum–transition regime. However, a great deal of additional work is needed, both experimentally and computationally, to assess the range of applicability and accuracy of Navier–Stokes, Burnett and DSMC approximations for simulating the flows in transition regime.

## Nomenclature

---

$c$	=	speed of sound
$e_t$	=	total energy
$Kn$	=	Knudsen number
$L$	=	characteristic length
$M$	=	Mach number
$Pr$	=	Prandtl number
$p$	=	pressure
$q_i$	=	heat flux
$R$	=	gas constant
$Re$	=	Reynolds number
$T$	=	temperature
$T_w$	=	wall temperature
$t$	=	time
$x, y$	=	Cartesian coordinates
$u, v$	=	velocity components in $x$ and $y$ direction
$\alpha_i, \beta_i$	=	coefficients of stress terms in Burnett equations
$\gamma$	=	specific heat ratio
$\gamma_i$	=	coefficients of heat-flux terms in Burnett equations
$\delta_i$	=	coefficients of stress terms in Navier–Stokes equations
$\theta_i$	=	coefficients of third-order terms in BGK–Burnett equations
$\kappa$	=	thermal conductivity

$\lambda$	=	mean free path of gas molecules
$\mu$	=	coefficient of viscosity
$\rho$	=	density
$\sigma_{ij}$	=	stress tensor

### 8.1 Abstract

---

This chapter concentrates on molecular-based numerical simulation methods for liquid and gas microflows. After a brief introduction of molecular magnitudes, a detailed coverage of the direct simulation Monte Carlo method for gas flows is presented. Brief descriptions of other simulation methodologies, such as the Boltzmann and lattice Boltzmann methods and the molecular dynamics method, are also given. Throughout the chapter, extensive references to books, research and review articles are supplied with the perspective of guiding the reader toward recent literature.

### 8.2 Introduction

---

Simulation of microscale thermal fluidic transport is gaining importance due to the emerging technologies of the 21st century, such as microelectromechanical systems (MEMS) and nanotechnologies. Miniaturization of device scales, for the first time, has enabled the possibility of integration of sensing, computation, actuation, control, communication and power generation within the same microchip. The small size, light weight and high-durability of MEMS, combined with the mass-fabrication ability, result in low-cost systems with a wide variety of applications spanning from control systems to advanced energy systems to biological, medical and chemical applications. Despite these diverse prospects and fast growth

of MEMS, further miniaturization of device scales is faced with the challenge of “better understanding” of micron and submicron scale physics.

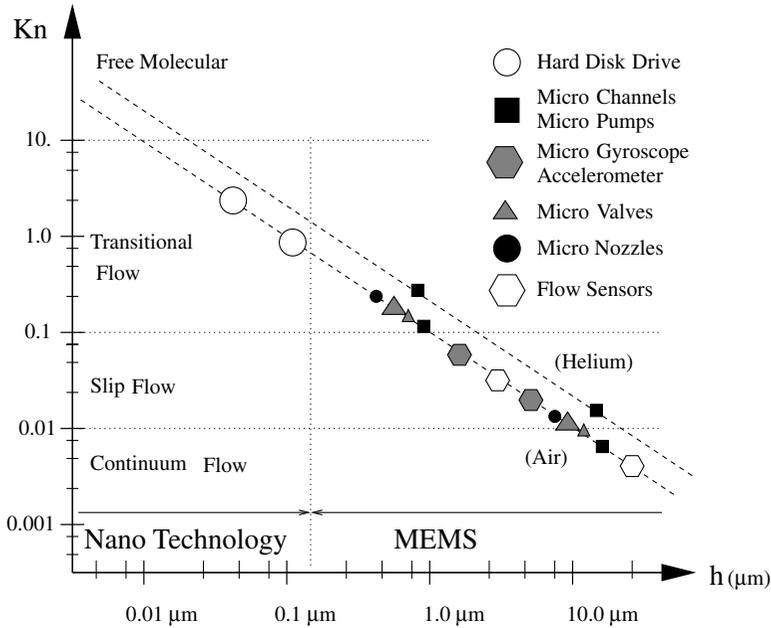

The microscale thermal/fluidic transport phenomenon differs from its larger scale counterparts mainly due to the size, surface and interface effects [Ho and Tai, 1998; Gad-el-Hak, 1999]. Reduction of the characteristic device dimensions to micrometer scale drastically decreases the volume-to-surface area ratio. Hence, the surface forces are more dominant than the body forces in such small scales. The origin of the surface forces is atomistic and based on the short-ranged van der Waals forces and longer ranged electrostatic or Coulombic forces. Although a molecular-simulation-based approach for understanding fluid forces on surfaces is fundamental in nature, it is very difficult to apply to engineering problems due to the vast number of molecules involved in the analysis; however, direct application of the well-known continuum equations is not appropriate, either. For example, the Navier–Stokes level of constitutive relations that model the shear stress, being linearly proportional to the strain rate, is not valid for gases when the Knudsen number  $Kn > 0.1$ , or for liquids when the strain rate exceeds twice the molecular frequency scale [Gad-el-Hak, 1999]. Significant differences between the thermal/fluidic transport of gas and liquid states also exist. For example, dilute gases spend most of their time in free flight with abrupt changes in their direction and speed caused by binary intermolecular collisions. However, the liquid molecules are closely packed, and they experience multiple collisions with large intermolecular forces. The fundamental simulation approaches, from a microscopic point of view, differ for liquid and gas flows. In this chapter, we will address separately the numerical simulation methods relevant for dilute gases and liquids. However, the main emphasis of this chapter is microscale gas transport modeling with the direct simulation Monte Carlo (DSMC) algorithm. Other microscopic simulation methods, such as the Boltzmann equation approach, lattice Boltzmann method and molecular dynamics (MD), are briefly introduced to guide the reader to the appropriate resources in these areas.

### 8.3 Gas Flows

---

The ratio of the gas mean free path ( $\lambda$ ) to a characteristic microfluidic length scale ( $h$ ) is known as the Knudsen number,  $Kn = \lambda/h$ . Because the momentum and energy transfers happen with intermolecular and gas/wall collisions, the mean free path indicates an intrinsic length scale of thermal/fluidic transport for gases. In standard pressure and temperature (STP), the mean free path for air is about 65 nm. For macroscopic devices, the Knudsen number is very small, so the surrounding air can be treated as a continuous medium. However, in microscales, the Knudsen number can be fairly large due to the small length scales. Momentum and energy transport in micron and submicron scales show significant deviations from their larger scale counterparts. For example, recent microchannel experiments show increased mass flowrates compared to the Navier–Stokes-based continuum estimates [Arkilic et al., 1997; Harley et al., 1995; Liu et al., 1993; Pong et al., 1994]. Similarly, in the case of magnetic disk storage units, the head floating about 50 nm above the media exhibits an order of magnitude reduction of load capacity compared to predictions by the continuum Reynolds equations [Fukui and Kaneko, 1990]. These deviations are explained as a function of the Knudsen number by dividing the flow into four regimes: continuum ( $Kn \leq 0.01$ ), slip ( $0.01 \leq Kn \leq 0.1$ ), transitional ( $0.1 \leq Kn \leq 10$ ) and free-molecular ( $Kn > 10$ ). Operation regimes of typical MEMS devices at standard temperature and pressure are shown in [Figure 8.1](#). MEMS operate in a wide variety of flow regimes covering the continuum, slip and early transitional flow regimes. Further miniaturization of MEMS device components and nanotechnology applications [Drexler, 1990] correspond to higher Knudsen numbers, making it necessary to study the mass, momentum and energy transport in the entire Knudsen regime.

It may be misleading to identify the flow regimes as “slip” and “continuum.” Here, we must clarify that within this text and in most of the microscale transport literature “continuum” refers to the Navier–Stokes equations subject to the “no-slip”-boundary conditions. This identification leads to two common misconceptions. First, if the Navier–Stokes equations cannot be applied, then the continuum approximation should break down. This is misleading, as we will see shortly that it is possible to derive

**FIGURE 8.1** The Operation range for typical MEMS and nanotechnology applications under standard conditions spans the entire Knudsen regime (continuum, slip, transition and free molecular flow regimes).

conservation equations with more advanced constitutive laws than the Navier–Stokes equations. One example of this is the Burnett equations. The second misconception is that, in the “slip flow” regime, the boundary conditions suddenly change from no slip to slip. This is also misleading, as the no-slip-boundary condition is just an empirical finding and the Navier–Stokes equations are valid both for “slip” and “continuum” flow regimes. Hence, the slip effects become important gradually with increased  $Kn$ . Nevertheless, the identification of flow regimes was made for rarefied gas flows almost a century ago. For  $Kn \leq 0.1$  flows, the Navier–Stokes equations subject to the velocity-slip and temperature-jump boundary conditions should be used. The slip conditions are [Kennard, 1938; Schaaf and Chambre, 1961]:

$$u_s - u_w = \frac{2 - \sigma_v}{\sigma_v} \frac{1}{\rho(2RT_w/\pi)^{1/2}} \tau_s + \frac{3Pr(\gamma - 1)}{4\gamma\rho RT_w} (-q_s) \quad (8.1)$$

$$T_s - T_w = \frac{2 - \sigma_T}{\sigma_T} \left[ \frac{2(\gamma - 1)}{\gamma + 1} \right] \frac{1}{R\rho(2RT_w/\pi)^{1/2}} (-q_n) \quad (8.2)$$

where  $q_n, q_s$  are the normal and tangential heat-flux components;  $\tau_s$  is the viscous stress component corresponding to the skin friction;  $R$  is the specific gas constant;  $\gamma$  is the ratio of specific heats,  $\rho$  is the density;  $Pr$  is the Prandtl number; and  $T_w$  and  $u_w$  are the wall temperature and velocity, respectively. The gas slip velocity and temperature near the wall (jump) are given by  $u_s$  and  $T_s$ , respectively. The term in the above equation proportional to  $(-q_s)$  is associated with the phenomenon of *thermal creep*, which can cause variations of pressure along tubes in the presence of tangential temperature gradients [Beskok et al., 1995; Sone, 2000; Vargo and Muntz, 1996; Vargo et al., 1998].

In a recent work, a Padé approximation of (1) was developed, resulting in a velocity slip condition valid in the entire Knudsen regime. Excluding the thermal creep terms, this new slip condition is given in the following form [Beskok et al., 1996; Beskok and Karniadakis, 1999]:

$$U_s - U_w = \frac{2 - \sigma_v}{\sigma_v} \left[ \frac{Kn}{1 - bKn} \right] \frac{\partial U}{\partial n} \quad (8.3)$$

where  $U_w$  and  $U_s$  are the wall and gas-slip velocity nondimensionalized with a reference velocity, respectively. Here,  $b$  is the general slip coefficient, determined by the following procedures:

- A perturbation expansion in  $Kn$  for  $Kn < 1$ , such that Eq. (8.3) is equivalent to a second-order slip condition [Beskok et al., 1996].
- Matching the velocity profiles with the direct simulation Monte Carlo (DSMC) results in the transitional and free molecular flow regimes [Beskok and Karniadakis, 1999].

Hence the value of  $b$  is defined analytically in the slip and early transition flow regime, but in the transitional and free molecular flow regimes it is an empirical parameter.

In Eqs. (8.1) and (8.3),  $\sigma_v$ , and  $\sigma_T$  are the tangential momentum and thermal accommodation coefficients, respectively. The accommodation coefficients model the momentum and energy exchange of gas molecules impinging on the walls. Hence, they characterize the surface effects. For example,  $\sigma_v = 0.2$  enhances the apparent slip by almost an order of magnitude! The accommodation coefficients are usually determined experimentally. Due to the difficulties of experimentation in microscales, the accommodation coefficients are obtained by assuming slip flow and matching the value of the accommodation coefficients to maintain the measured mass flow rate. This has resulted in  $\sigma_v = 0.80$  for nitrogen, argon and carbon dioxide in contact with prime silicon crystal [Arkilic et al., 1997]. Lower accommodation coefficients are expected due to the low surface roughness of the prime silicon crystal. However, for a general micromachined surface and gas pair, the values of the accommodation coefficients are not known *a priori*. For low-pressure, rarefied gas flows, the values of the accommodation coefficients are tabulated as a function of the specific gas and surface quality [Seidl and Steinheil, 1974]; under laboratory conditions, values as low as 0.2 have been observed [Lord, 1976]. Very low values of  $\sigma_v$  will increase the slip on the walls considerably, even for small Knudsen number flows.

In the transitional flow regime, the constitutive laws defining the stress tensor and the heat-flux vector must be updated for increased rarefaction effects, resulting in Wood's, Burnett's or Grad's equations. It is also possible to use the Boltzmann transport equation in this regime (see Section 8.3.7). In a recent work, Myong has developed thermodynamically consistent hydrodynamic computational models for high-Knudsen-number gas flows, uniformly valid in all Mach numbers and satisfying the second law of thermodynamics [Myong, 1999].

In the free molecular flow regime ( $Kn \geq 10$ ), the molecule-wall interactions dominate the transport with significantly reduced intermolecular collisions. Hence, the collisionless Boltzmann equation is commonly used in this flow regime.

### 8.3.1 Molecular Magnitudes

Before studying the molecular-based numerical simulation algorithms, it is crucial to understand the complexity of the molecular simulation problem. In this section, we present relationships for the number density of molecules  $n$ , mean molecular spacing  $\delta$ , molecular diameter  $d_m$ , mean free path  $\lambda$ , mean collision time  $t_c$  and mean square molecular speed  $\sqrt{C^2}$ .

The number of molecules in one mole of gas is a constant known as the Avogadro's number,  $6.02252 \times 10^{23}$ /mole, and the volume occupied by one mole of gas at a given temperature and pressure is a constant, regardless of the composition of the gas [Vincenti and Kruger, 1977]. This leads to the perfect gas

relationship given by:

$$P = nk_b T \quad (8.4)$$

where  $P$  is the pressure,  $T$  is the temperature,  $n$  is the number density of the gas, and  $k_b$  is the Boltzmann constant ( $k_b = 1.3805 \times 10^{-23}$  J/K). This ideal gas law is valid for dilute gases at any pressure (above the saturation pressure). Hence, for most microscale gas flow applications we can predict the number density of the molecules at a given temperature and pressure using Eq. (8.4). At atmospheric pressure and  $0^\circ\text{C}$  (standard conditions) the number density is about  $n \cong 2.69 \times 10^{25} \text{ m}^{-3}$ . If all of these molecules are placed in a 1-m cube in an equidistant fashion, the mean molecular spacing will be

$$\delta = n^{-1/3} \quad (8.5)$$

Under standard conditions the mean molecular spacing is  $\delta \cong 3.3 \times 10^{-9}$  m.

The mean molecular diameter ( $d_m$ ) of typical gases, based on the measured coefficient of viscosity and the Chapman-Enskog theory of transport properties for hard-sphere molecules, is on the order of  $10^{-10}$  m. For air under standard conditions,  $d_m \cong 3.7 \times 10^{-10}$  m, as tabulated in Bird (1994). Comparison of the mean molecular spacing  $\delta$  and the typical molecular diameter  $d_m$  shows an order of magnitude difference. This leads to the concept of “dilute gas,” where  $\delta/d_m \gg 1$ . For dilute gases, binary intermolecular collisions are more likely than the simultaneous multiple collisions. On the other hand, dense gases and liquids go through multiple collisions at a given instant, making the treatment of the intermolecular collision process more difficult. The dilute gas approximations, along with molecular chaos and equipartition of energy principles, lead us to the well-established kinetic theory of gases and formulation of the Boltzmann transport equation starting from the Liouville equation. The assumptions and simplifications of this derivation are given in Vincenti and Kruger (1977) and Bird (1994).

Momentum and energy transport in the bulk of the fluid and settling to a thermodynamic equilibrium state happen with intermolecular collisions. Hence, the time and length scales associated with the intermolecular collisions are important parameters for many applications. The distance traveled by the molecules between the intermolecular collisions is known as the mean free path. For a simple gas of hard-sphere molecules in thermodynamic equilibrium, the mean free path is given in the following form [Bird, 1994]:

$$\lambda = (2^{1/2} \pi d_m^2 n)^{-1} \quad (8.6)$$

The gas molecules are traveling with high speeds proportional to the speed of sound. By simple considerations, the mean-square molecular speed of the gas molecules is given by [Vincenti and Kruger, 1977]:

$$\sqrt{C^2} = \sqrt{\frac{3P}{\rho}} = \sqrt{3RT} \quad (8.7)$$

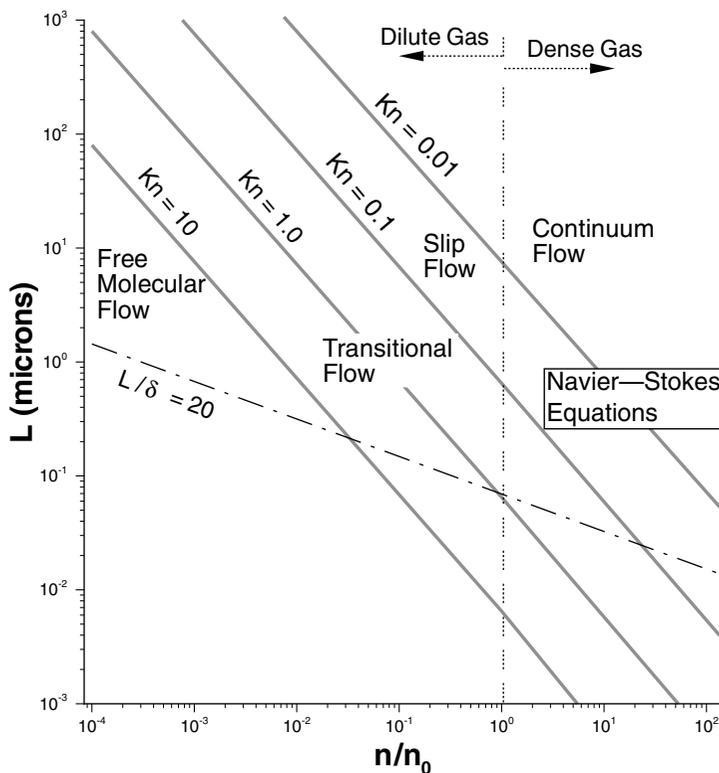

where  $R$  is the specific gas constant. For air under standard conditions, this corresponds to 486 m/s. This value is about 3 to 5 orders of magnitude larger than the typical average speeds obtained in gas microflows. (The importance of this discrepancy will be discussed in Section 8.3.3.) In regard to the time scales of intermolecular collisions, we can obtain an average value by taking the ratio of the mean free path to the mean-square molecular speed. This results in  $t_c \cong 10^{-10}$  for air under standard conditions. This time scale should be compared to a typical microscale process time scale to determine the validity of the thermodynamic equilibrium assumption.

So far we have identified the vast number of molecules and the associated time and length scales for gas flows. It is our common experience that it is possible to lump all of the microscopic quantities into time- and/or space-averaged macroscopic quantities, such as fluid density, temperature and velocity. It is crucial to determine the limitations of these continuum-based descriptions; in other words:

- How small should a sample size be so that we can still talk about the macroscopic properties and their spatial variations?
- At what length scales do the statistical fluctuations become significant?

It turns out that a sampling volume that contains 10,000 molecules typically results in 1% statistical fluctuations in the averaged quantities [Bird, 1994]. This corresponds to a volume of  $3.7 \times 10^{-22} \text{ m}^3$  for air at standard conditions. If we try to measure an “instantaneous” macroscopic quantity such as velocity in a three-dimensional space, one side of our sampling cube will typically be about 72 nm. This length scale is slightly larger than the mean free path of air ( $\lambda$ ) under standard conditions. Therefore, in complex microgeometries, where three-dimensional spatial gradients are expected, the definition of “instantaneous” macroscopic values may become problematic for  $Kn > 1$ . If we would like to subdivide this domain further to obtain an instantaneous velocity distribution, the statistical fluctuations will be increased significantly as the sample volume is decreased. Hence, we may not be able to define instantaneous velocity distribution in a  $72\text{-nm}^3$  volume. On the other hand, it is always possible to perform time or ensemble averaging of the data at such small scales. Hence, we can still talk about a velocity profile in an averaged sense.

To describe the statistical fluctuation issues further, we present in Figure 8.2 the flow regimes and the limit of the onset of statistical fluctuations as a function of the characteristic dimension  $L$  and the

**FIGURE 8.2** Limit of approximations in modeling gas microflows.  $L$  is the characteristic length,  $n/n_0$  is the number density normalized with the corresponding standard conditions. The lines that define the various Knudsen regimes are based on air at isothermal conditions ( $T = 273 \text{ K}$ ). The  $L/\delta = 20$  line corresponds to the 1% statistical scatter in the macroscopic properties. The area below this line experiences increased statistical fluctuations.

normalized number density  $n/n_o$ . The 1% statistical scatterline is defined in a cubic volume of side  $L$  which contains approximately 10,000 molecules. Using Eq. (8.5) one can find that  $L/\delta \approx 20$  satisfies this condition approximately, and the 1% fluctuation line varies as  $(n/n_o)^{-1/3}$ . Under standard conditions, 1% fluctuation is observed at  $L = 72$  nm, and the Knudsen number based on this value is  $Kn \approx 1$ . Figure 8.2 also shows the continuum, slip, transitional and free molecular flow regimes for air at 273 K and at various pressures. The mean free path varies inversely with the pressure. Hence, at isothermal conditions, the Knudsen number varies as  $(n/n_o)^{-1}$ . The fundamental question of dynamic similarity of low-pressure gas flows to gas microflows under geometrically similar and identical Knudsen, Mach and Reynolds number conditions can be answered, to some degree, by inspection of Figure 8.2. Provided that there are no unforeseen microscale-specific effects, the two flow cases should be dynamically similar. However, a distinction between the low-pressure and gas microflows is the difference in the length scales for which the statistical fluctuations become important.

It is interesting to note that for low-pressure rarefied gas flows the length scales for the onset of significant statistical scatter correspond to much larger Knudsen values compared to the gas microflows. For example,  $Kn = 1.0$  flow obtained at standard conditions in a 72-nm cube volume permits us to perform one instantaneous measurement in the entire volume with 1% scatter. However, at 100 Pascal pressure and 273 K temperature,  $Kn = 1.0$  flow corresponds to a length scale of 65  $\mu\text{m}$ . For this case, 1% statistical scatter in the macroscopic quantities is observed in a cubic volume of side 0.72  $\mu\text{m}$ , allowing about 90 pointwise instantaneous measurements. The discussion presented above is valid for instantaneous measurements of macroscopic properties in complex three-dimensional conduits. In large-aspect-ratio microdevices one can always perform spanwise averaging to define an averaged velocity profile. Also, for practical reasons one can also define averaged macroscopic properties either by time or ensemble averaging (such examples are presented in Section 8.3.4).

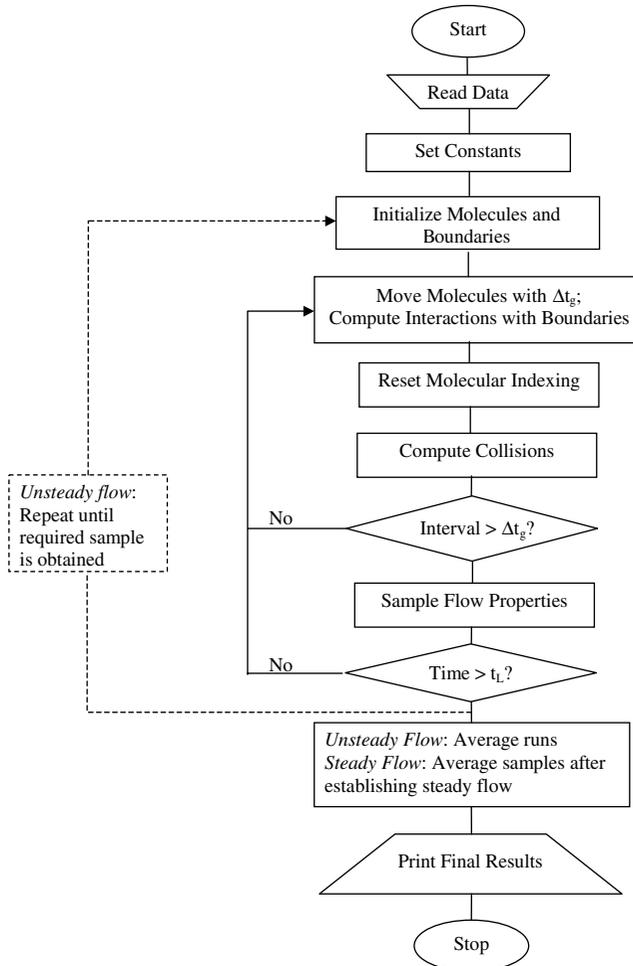

### 8.3.2 An Overview of the Direct Simulation Monte Carlo Method

In this section, we present the algorithmic details, advantages and disadvantages of using the direct simulation Monte Carlo algorithm for microfluidic applications. The DSMC method was invented by Professor Graeme A. Bird (1976, 1994). Several review articles about the DSMC method are currently available [Bird 1978; 1998; Muntz, 1989; Oran et al., 1998]. Most of these articles present an extended review of the DSMC method for low-pressure rarefied gas flow applications, with the exception of Oran et al. (1998), who also address microfluidic applications.

In the previous section, we described molecular magnitudes and associated time and length scales. Under standard conditions in a volume of 10  $\mu\text{m}^3$ , there are about  $2.69 \times 10^{10}$  molecules. A molecular-based simulation model that can compute the motion and interactions of all these molecules is not possible. The typical DSMC method uses hundreds of thousands or even millions of “simulated” molecules/particles that mimic the motion of real molecules.

The DSMC method is based on splitting the molecular motion and intermolecular collisions by choosing a time step less than the mean collision time and tracking the evolution of this molecular process in space and time. For efficient numerical implementation, the space is divided into cells similar to the finite-volume method. The DSMC cells are chosen proportional to the mean free path  $\lambda$ . In order to resolve large gradients in flow with realistic (physical) viscosity values, the average cell size should be  $\Delta x_c \equiv \lambda/3$  [Oran et al., 1998]. The time- and cell-averaged molecular quantities are obtained as the macroscopic values at the cell centers. The DSMC involves four main processes: motion of the particles, indexing and cross-referencing of particles, simulation of collisions and sampling of the flow field. The basic steps of a DSMC algorithm are given in Figure 8.3 and summarized below.

The first process involves motion of the simulated molecules during a time interval of  $\Delta t$ . Because the molecules will go through intermolecular collisions, the time step for simulation is chosen smaller than the mean collision time  $\Delta t_c$ . Once the molecules are advanced in space, some of them will have gone through wall collisions or will have left the computational domain through the inflow–outflow boundaries.

**FIGURE 8.3** Typical steps for a DSMC method. (From Oran, E.S., et al. (1998) *Ann. Rev. Fluid Mech.* **30**, 403–441. With permission.)

Hence, the boundary conditions must be enforced at this level, and the macroscopic properties along the solid surfaces must be sampled. This is done by modeling the surface molecule interactions by application of the conservation laws on individual molecules, rather than using a velocity distribution function that is commonly utilized in the Boltzmann algorithms. This approach allows inclusion of many other physical processes, such as chemical reactions, radiation effects, three-body collisions and ionized flow effects, without major modifications to the basic DSMC procedure [Oran et al., 1998]. However, *a priori* knowledge of the accommodation coefficients must be used in this process. Hence, this constitutes a weakness of the DSMC method, similar to the Navier–Stokes-based slip and even Boltzmann equation-based simulation models. This issue is discussed in detail in the following section.

The second process is the indexing and tracking of the particles. This is necessary because, during the first stage, the molecules might have moved to new cell locations. The new cell location of the molecules is indexed, thus the intermolecular collisions and flowfield sampling can be handled accurately. This is a crucial step for an efficient DSMC algorithm. The indexing, molecule tracking and data structuring algorithms should be carefully designed for the specific computing platforms, such as vector super computers and workstation architectures.

The third step is simulation of collisions via a probabilistic process. Because only a small portion of the molecules is simulated, and the motion and collision processes are decoupled, probabilistic treatment becomes necessary. A common collision model is the no-time-counter technique of Bird (1994) that is used in conjunction with the subcell technique, where the collision rates are calculated within the cells and the collision pairs are selected within the subcells. This improves the accuracy of the method by maintaining the collisions of the molecules with their closest neighbors [Oran et al., 1998].

The last process is calculation of appropriate macroscopic properties by the sampling of molecular (microscopic) properties within a cell. The macroscopic properties for unsteady flow conditions are obtained by the ensemble average of many independent calculations. For steady flows, time averaging is also used.

### 8.3.3 Limitations, Error Sources and Disadvantages of the DSMC Approach

Following the work of Oran et al., (1998), we identify several possible limitations and error sources within a DSMC method.

1. *Finite cell size*: The typical DSMC cell should be about one third of the local mean free path. Values of cell sizes larger than this may result in enhanced diffusion coefficients. In DSMC, one cannot directly specify the dynamic viscosity and thermal conductivity of the fluid. The dynamic viscosity is calculated via diffusion of linear momentum. Breuer et al. (1995), performed one-dimensional Rayleigh flow problems in the continuum flow regime and showed that, for cell sizes larger than one mean free path, the apparent viscosity of the fluid was increased. Some numerical experimentation details for this finding are also given in Beskok (1996). More recently, the viscosity and thermal conductivity dependence on cell size have been obtained more systematically by using the Green–Kubo theory [Alexander et al., 1998; Hadjiconstantinou, 2000].
2. *Finite time step*: Due to the time splitting of the molecular motion and collisions, the maximum allowable time step is smaller than the local collision time  $t_c$ . Values of time steps larger than  $t_c$  result in molecules traveling through several cells prior to a cell-based collision calculation.

The time-step and cell-size restrictions presented in items 1 and 2 are not a Courant–Friederichs–Lewy (CFL) stability condition. The DSMC method is always stable. However, overlooking the physical restrictions stated in items 1 and 2 may result in highly diffusive numerical results.

3. *Ratio of the simulated particles to the real molecules*: Due to the vast number of molecules and limited computational resources, one always has to choose a sample of molecules to simulate. If the ratio of the actual to the simulated molecules gets too high the statistical scatter of the solution is increased. The details for the statistical error sources and the corresponding remedies can be found in Oran et al. (1998), Bird (1994) and Chen and Boyd (1996). A relatively well-resolved DSMC calculation requires a minimum of 20 simulated particles per cell.
4. *Boundary condition treatment*: The inflow–outflow boundary conditions can become particularly important in a microfluidic simulation. A subsonic microchannel flow simulation may require specification of inlet and exit pressures. The flow will develop under this pressure gradient and result in a certain mass flowrate. During such simulations, specification of back pressure for subsonic flows is challenging. In the DSMC studies, one can simulate the entry problem to the channels by specifying the number density, temperature and average macroscopic velocity of the molecules at the inlet of the channel. At the outflow, the number density and temperature corresponding to the desired back pressure can be specified. By this and similar treatments it is possible to significantly reduce the spurious numerical boundary layers at inflow and outflow regions. For high Knudsen number flows (i.e.,  $Kn > 1$ ) in a channel with blockage (such as a sphere in a pipe), the location of the inflow and outflow boundaries is important. For example, the molecules reflected from the front of the body may reach the inflow region with very few intermolecular collisions, creating a diffusing flow at the front of the bluff body [Liu et al., 1998]. (The details of this case are presented in Section 8.3.4.)

5. *Uncertainties in the physical input parameters:* These typically include the input for molecular collision cross-section models, such as the hard sphere (HS), variable hard sphere (VHS) and variable soft sphere (VSS) models [Oran et al., 1998; Vijayakumar et al., 1999]. The HS model is usually sufficient for monatomic gases or for cases with negligible vibrational and rotational non-equilibrium effects, such as in the case of nearly isothermal flow conditions.

Along with these possible error sources and limitations are some particular disadvantages of the DSMC method for simulation of gas microflows:

1. *Slow convergence:* The error in the DSMC method is inversely proportional to the square root of the number of simulated molecules. Reducing the error by a factor of two requires increasing the number of simulated molecules by a factor of four! This is a very slow convergence rate compared to the continuum-based simulations with spatial accuracy of second or higher order. Therefore, continuum-based simulation models should be preferred over the DSMC method, whenever it is possible.
2. *Large statistical noise:* Gas microflows are usually low subsonic flows with typical speeds of 1 mm/s to 1 m/s (exceptions to this are the micronozzles utilized in synthetic jets and satellite thruster control applications). The macroscopic fluid velocity is obtained by time or ensemble averaging of the molecular velocities. This difference of five to two orders of magnitude between the molecular and average speeds results in large statistical noise and requires a very long time averaging for gas microflow simulations. The statistical fluctuations decrease with the square root of the sample size. Time or ensemble averages of low-speed microflows on the order of 0.1 m/s require about  $10^8$  samples in order to be able to distinguish such small macroscopic velocities. In a recent paper, Fan and Shen (1999) introduced the information preservation (IP) technique for the DSMC method, which enables efficient DSMC simulations for low-speed flows (the IP scheme is briefly covered in Section 8.3.5).
3. *Extensive number of simulated molecules:* If we discretize a rectangular domain of  $1 \text{ mm} \times 100 \text{ }\mu\text{m} \times 1 \text{ }\mu\text{m}$  under standard conditions for  $Kn = 0.065$  flow, we will need at least 20 cells per micrometer length scale. This results in a total of  $8 \times 10^8$  cells. Each of these cells should contain at least 20 simulated molecules, resulting in a total of  $1.6 \times 10^{10}$  particles. Combined with the number of time-step restrictions, simulation of low-speed microflows with DSMC easily exceeds the capabilities of current computers. An alternative treatment to overcome the extensive number of simulated molecules and long integration times is utilization of the dynamic similarity of low-pressure rarefied gas flows to gas microflows under atmospheric conditions. The key parameters for the dynamic similarity are the geometric similarity and matching of the flow Knudsen, Mach and Reynolds numbers. Performing actual experiments under dynamically similar conditions may be very difficult; however, parametric studies via numerical simulations are possible. The fundamental question to answer for such an approach is whether or not a specific, unforeseen microscale phenomenon is missed with the dynamic similarity approach. In response to this question, we must note that all numerical simulations are inherently model based. Unless microscale-specific models are implemented in the algorithm, we will not be able to obtain more physical information from a microscopic simulation than from a dynamically similar low-pressure simulation. In regard to utilization of the dynamic similarity concept, one limitation is the onset of statistical scatter in the instantaneous macroscopic flow quantities for gas microflows for  $Kn > 1$  (see Section 8.3.1 and Figure 8.2 for details). Here, we must also remember that DSMC utilizes time or ensemble averages to sample the macroscopic properties from the microscopic variables. Hence, DSMC already determines the macroscopic properties in an averaged sense.
4. *Lack of deterministic surface effects:* Molecule wall interactions are specified by the accommodation coefficients ( $\sigma_v, \sigma_T$ ). For diffuse reflection  $\sigma = 1$ , and the reflected molecules lose their incoming tangential velocity while being reflected with the tangential wall velocity. For  $\sigma = 0$ , the tangential velocity of the impinging molecules are not changed during the molecule/wall collisions. For any other value of  $\sigma$ , a combination of these procedures can be applied. The molecule–wall interaction treatment implemented in DSMC is more flexible than the slip conditions given by Eqs. (8.1) and (8.2).

However, it still requires specification of the accommodation coefficients, which are not known for any gas surface pair with a specified surface root mean square (rms) roughness. Recently, the tangential momentum accommodation coefficients for helium, nitrogen, argon and carbon dioxide on single-crystal silicon were measured by careful microchannel experiments [Arkilic, 1997].

### 8.3.4 Some DSMC-Based Gas Microflow Results

In this section, some DSMC results applied to gas microflows are presented.

#### 8.3.4.1 Microchannel Flows

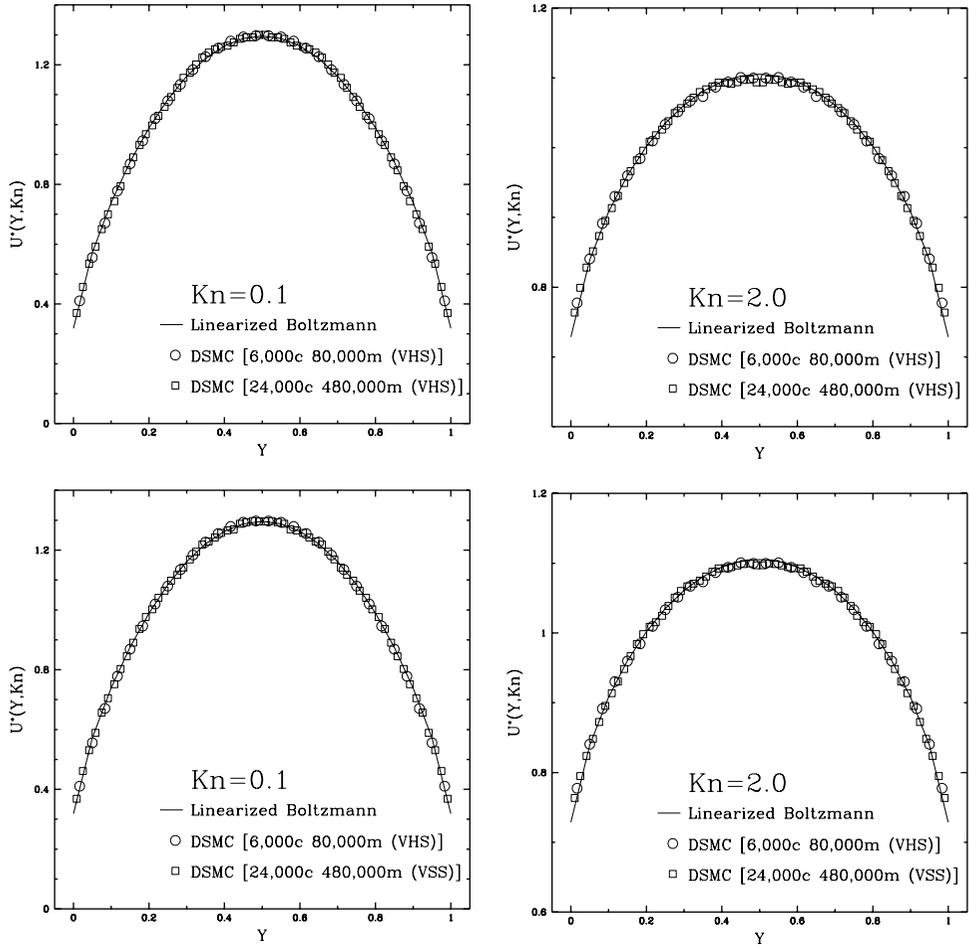

In this section, the DSMC simulation results for subsonic gas flows in microchannels are presented. Due to the computational difficulties explained in the previous sections, a low-aspect-ratio, two-dimensional channel with relatively high inlet velocities is studied. The results presented in the figures are for microchannels with a length-to-height ratio ( $L/h$ ) of 20 under various inlet-to-exit-pressure ratios. The DSMC results are performed with 24,000 cells, of which 400 cells were in the flow direction and 60 cells across the channel. A total of 480,000 molecules are simulated. The results are sampled (time averaged) for  $10^5$  times and the sampling is performed every 10 time steps.

In the following simulations, diffuse reflection ( $\sigma_V = 1.0$ ) is assumed for interaction of gas molecules with the surfaces. Because the slip amount can be affected significantly by small variations in  $\sigma_V$  (see Eq. (8.1)), the apparent value of the accommodation coefficient  $\sigma_V$  is monitored throughout the simulations by recording the tangential momentum of the impinging ( $\tau_i$ ) and reflected ( $\tau_r$ ) gas molecules. Based on these values, the apparent tangential momentum accommodation coefficient,  $\sigma_V = (\tau_i - \tau_r) / (\tau_i - \tau_w) = 0.99912$  with standard deviation of  $\sigma_{rms} = 0.01603$ , is obtained.

The velocity profiles normalized with the corresponding average speed are presented in Figure 8.4 for pressure-driven microchannel flows at  $Kn = 0.1$  and  $Kn = 2.0$ . The figure also presents the molecule/cell refinement studies as well as predictions of the VHS and VSS models. The DSMC results are compared against the linearized Boltzmann solutions [Ohwada et al., 1989], and excellent agreements of the VHS and VSS models with the linearized Boltzmann solutions are observed for these nearly isothermal flows. In regard to the molecule/cell refinement study, the number of cells and the number of simulated molecules are identified for each case. The first VHS case utilized only 6000 cells with 80,000 simulated molecules, and the results are sampled about  $5 \times 10^5$  times. Sampling is performed every 20 time steps. The refined VHS and VSS cases utilized 24,000 cells and a total of 480,000 molecules. The results for these are sampled  $10^5$  times, every 10 time steps. Although the velocity profiles for the low-resolution case (6000 cells) seem acceptable, the density and pressure profiles show large fluctuations.

The DSMC and  $\mu$ Flow (spectral-element-based, continuum computational fluid dynamics (CFD) solver) predictions of density and pressure variations along a pressure-driven microchannel flow are shown in Figure 8.5. For this case, the ratio of inlet to exit pressure is  $\Pi = 2.28$ , and the Knudsen number at the channel outlet is 0.2. Deviations of the slip flow pressure distribution from the no-slip solution are also presented in the figure. Good agreements between the DSMC and  $\mu$ Flow simulations are achieved. The curvature in the pressure distribution is due to the compressibility effect, and the rarefaction negates this curvature, as seen in Figure 8.5. The slip velocity variation on the channel wall is shown in Figure 8.6. Overall good agreements between both methods are observed. In a recent article, Pan et al. (1999) used the DSMC simulations to determine the slip distance as a function of various physical conditions such as the number density, wall temperature and the gas mass. They determined that an appropriate slip distance is  $1.125 \lambda_{gw}$ , where the subscript  $gw$  indicates the gas-wall conditions [Pan et al., 1999].

In the transitional flow regime, Beskok and Karniadakis (1999) studied the Burnett equations for low-speed isothermal flows. This analysis has shown that the velocity profiles remain parabolic even for large  $Kn$  flows. In order to verify this hypothesis, they performed several DSMC simulations; the velocity distribution nondimensionalized with the local average speed is shown in Figure 8.7. They also obtained

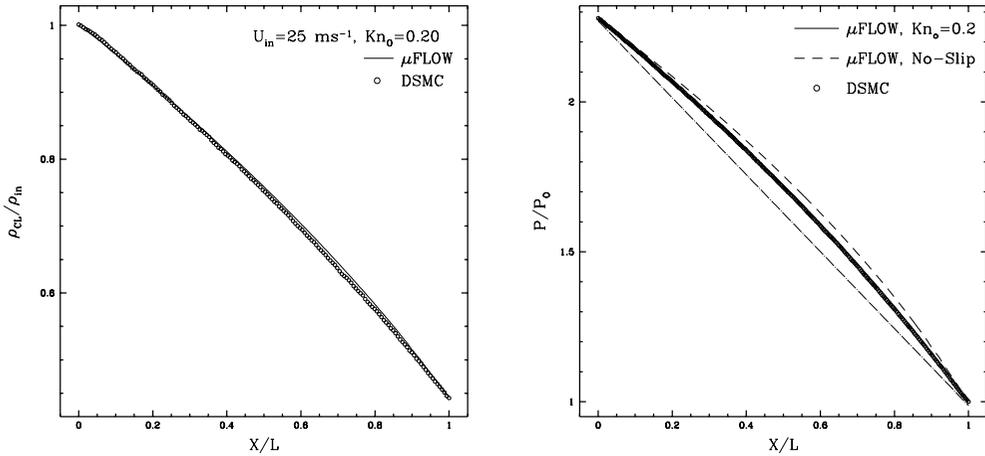

**FIGURE 8.4** Velocity profiles normalized with the local average velocity in the slip and transitional flow regimes. The DSMC predictions with the VHS and VSS models agree well with the linearized Boltzmann solutions of Ohwada et al. (1989). The number of cells and simulated molecules are identified on each figure. (Reprinted from Ohwada, T., Sone, Y., and Aoki, K. (1989) *Physics of Fluids A* 1(12), 2042–2049. With permission of the American Institute of Physics.)

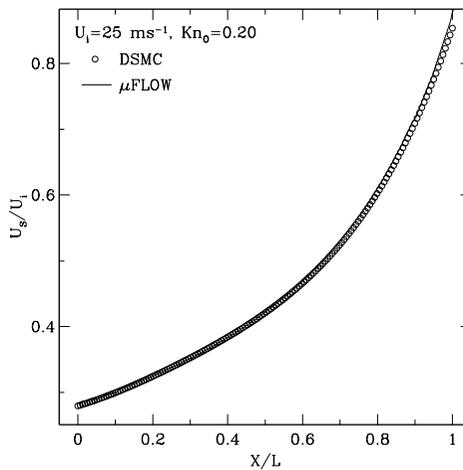

an approximation to this nondimensionalized velocity distribution in the following form:

$$U^*(y, Kn) \equiv U(x, y) / \bar{U}(x) = \left[ \frac{-\left(\frac{y}{h}\right)^2 + \frac{y}{h} + \frac{Kn}{1 - bKn}}{\frac{1}{6} + \frac{Kn}{1 - bKn}} \right] \quad (8.8)$$

where the extended slip condition given in Eq. (8.3) is used. In the above relation, the value of  $b = -1$  is determined analytically for channel and pipe flows [Beskok and Karniadakis, 1999]. In Figure 8.7, the nondimensional velocity variation obtained in a series of DSMC simulations for  $Kn = 0.1$ ,  $Kn = 1.0$ ,  $Kn = 5.0$  and  $Kn = 10.0$  flows are presented along with the corresponding linearized Boltzmann solutions [Ohwada et al., 1989]. It is seen that the DSMC velocity distribution and the linearized Boltzmann solutions agree quite well. One can use Eq. (8.8) to compare the results with the DSMC/linearized Boltzmann data by varying the parameter  $b$ . The case  $b = 0$  corresponds to Maxwell's first-order slip model and  $b = -1$  corresponds to Beskok's second-order slip boundary condition. It is clear from Figure 8.7 that Eq. (8.8) with  $b = -1$  results in a uniformly valid representation of the velocity distribution in the entire Knudsen regime.

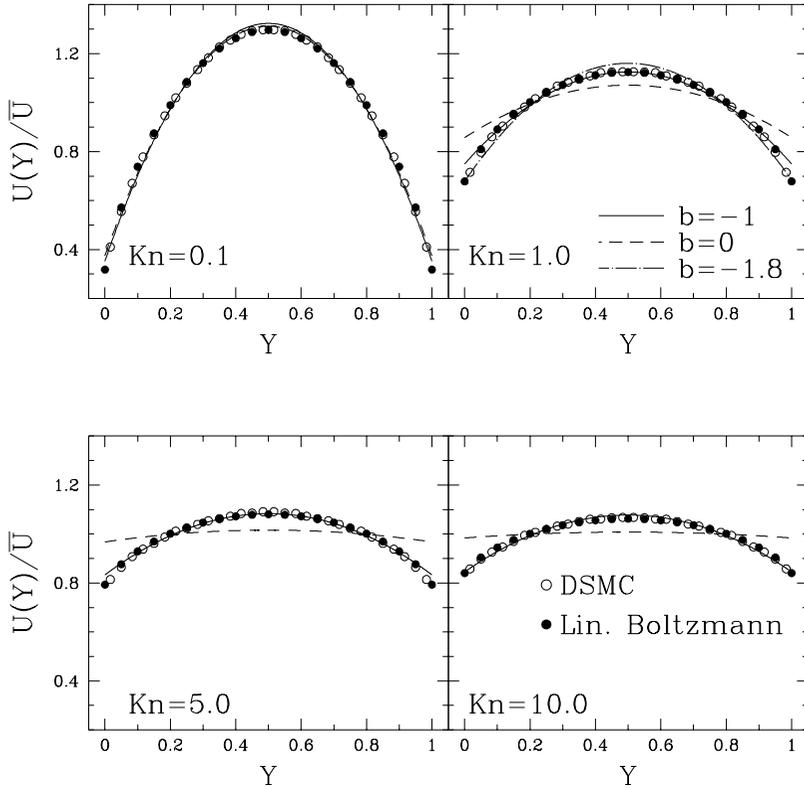

**FIGURE 8.5** Density (left) and pressure (right) variation along a microchannel. Comparisons of the Navier–Stokes and DSMC predictions for ratio of inlet to exit pressure of  $\Pi = 2.28$  and  $Kn_0 = 0.20$ . (From Beskok, A. (1996) Ph.D. thesis, Princeton University, Princeton, NJ.)

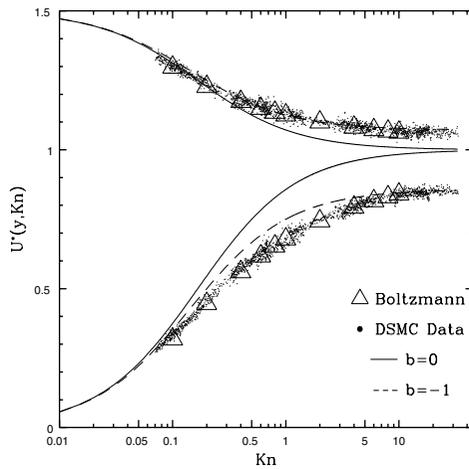

**FIGURE 8.6** Wall slip velocity variation along a microchannel predicted by Navier–Stokes and DSMC simulations. (From Beskok, A. (1996) Ph.D. thesis, Princeton University, Princeton, NJ.)

The nondimensionalized centerline and wall velocities for  $0.01 \leq Kn \leq 30$  flows are shown in [Figure 8.8](#). Included in the figure are the data for the slip velocity and centerline velocity from 20 different DSMC runs, of which 15 are for nitrogen (diatomic molecules) and 5 for helium (monatomic molecules). The differences between the nitrogen and helium simulations are negligible, thus this velocity scaling is independent of the gas type. The linearized Boltzmann solutions [Ohwada et al., 1989] for a monatomic gas are also shown in [Figure 8.8](#) by triangles. The Boltzmann solutions closely match the DSMC predictions. Maxwell’s first-order boundary condition ( $b = 0$ ) (shown by solid lines) predicts, erroneously, a uniform nondimensional velocity profile for large Knudsen numbers. The breakdown of the slip flow theory based on the first-order slip-boundary conditions is realized around  $Kn = 0.1$  and  $Kn = 0.4$  for wall and centerline velocities, respectively. This finding is consistent with the commonly accepted limits of the slip flow regime [Schaaf and Chambre, 1961]. The prediction using  $b = -1$  is shown by small dashed lines. The corresponding centerline velocity closely follows the DSMC results, while the slip velocity of the model with  $b = -1$  deviates from DSMC in the intermediate range for  $0.1 < Kn < 5$ .

**FIGURE 8.7** Comparison of the velocity profiles obtained by new slip model Eqs. (8.3) and (8.8) with DSMC and linearized Boltzmann solutions [Ohwada et al., 1989]. Maxwell’s first-order boundary condition is shown by the dashed lines ( $b=0$ ), and the general slip boundary condition ( $b=-1$ ) is shown by solid lines. (From Beskok, A., and Karniadakis, G.E. (1999) *Microscale Thermophys. Eng.* **3**, pp. 43–77. Reproduced with permission of Taylor & Francis, Inc.)

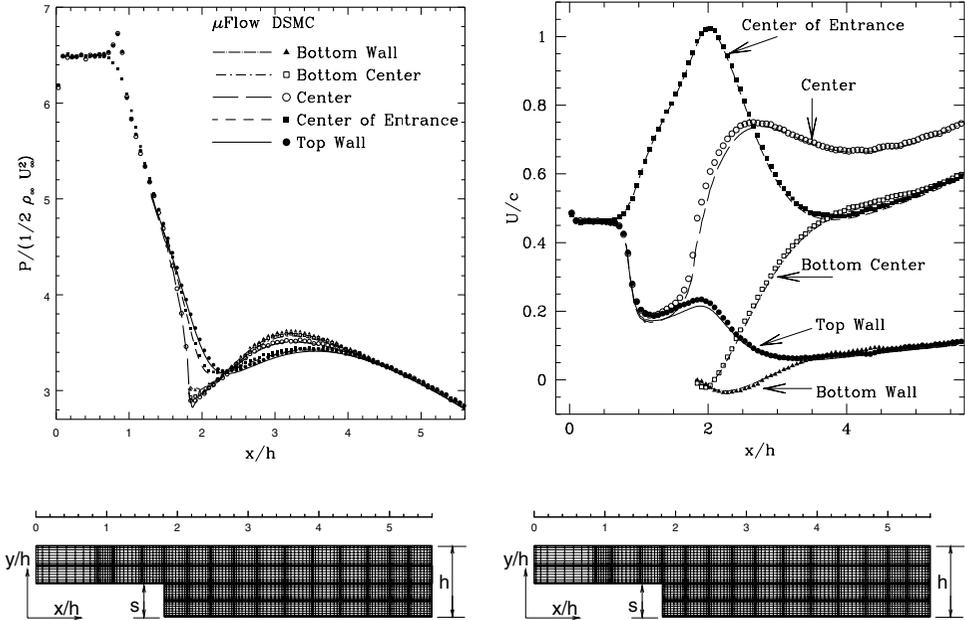

**FIGURE 8.8** Centerline and wall slip velocity variations in the entire Knudsen regime. The linearized Boltzmann solutions of Ohwada et al. (1989) are shown by triangles, and the DSMC simulations are shown by closed circles. Theoretical predictions of the velocity scaling obtained by Eq. (8.8) are shown for different values of  $b$ . The  $b=0$  case corresponds to Maxwell’s first-order boundary condition, and  $b=-1$  corresponds to the general slip-boundary condition. (Reprinted from Ohwada, T., Sone, Y., and Aoki, K. (1989) *Physics of Fluids A* **1**(12), 2042–2049. With permission of the American Institute of Physics.)

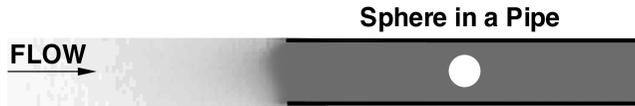

One possible reason for this is the effect of the Knudsen layer. For small  $Kn$  flows, the Knudsen layer is thin and does not affect the overall velocity distribution too much. For very large  $Kn$  flows, the Knudsen layer covers the channel entirely. However, for intermediate  $Kn$  values, both the fully developed viscous flow and the Knudsen layer co-exist in the channel. At this intermediate range, approximating the velocity profile as parabolic ignores the Knudsen layers. For this reason, the model with  $b = -1$  results in 10% error in the slip velocity at  $Kn = 1$ . However, the velocity distribution in the rest of the channel is described accurately for the entire flow regime. Based on these results, Beskok and Karniadakis (1999) developed a unified flow model that can predict the velocity profiles, pressure distribution and mass flowrate in channels, pipes and arbitrary aspect-ratio rectangular ducts in the entire Knudsen regime, including Knudsen's minimum effects [Beskok and Karniadakis, 1999; Kennard, 1938; Tison, 1993].

### 8.3.4.2 Separated Rarefied Gas Flows

Gas flow through complex microgeometries are prone to flow separation and recirculation. Most of the DSMC-based microflow analyses were performed in straight channels [Mavriplis et al., 1997; Oh et al., 1997] and for smooth microdiffusers [Piekos and Breuer, 1996]. A discussion of the Monte Carlo simulation for MEMS devices is given by Nance et al. (1997). The mainstream approach for gas flow modeling in MEMS is solution of the Navier–Stokes equations with slip models. This is more practical and numerically efficient than utilization of the DSMC method. However, rarefied separated gas flows are not studied extensively. In order to investigate the validity of slip-boundary conditions under severe adverse pressure gradients and separation, Beskok and Karniadakis (1997) performed a series of numerical simulations using the classical backwards-facing step geometry with a step-to-channel-height ratio of 0.467. The variations of pressure and streamwise velocity along a step microchannel, obtained at five different cross-flow locations ( $y/h$ ), are presented in Figure 8.9. The values of pressure and velocity are nondimensionalized with the

**FIGURE 8.9** Pressure (left) and streamwise velocity (right) distribution along a backward-facing step channel at five selected locations. Predictions of both DSMC (symbols) and continuum-based spectral element CFD code (lines) are presented. A 10th-order spectral element grid is also shown. The top wall is at  $y/h = 0.98325$ ; the center of the entrance is at  $y/h = 0.75$ ; the center is at  $y/h = 0.48$ ; the bottom center is at  $y/h = 0.25$ ; and the bottom wall is at  $y/h = 0.017$ . The simulation conditions are for  $Re = 80$ ,  $Kn_{out} = 0.04$ ,  $M_{in} = 0.45$  and  $Pr = 0.7$  (From Beskok, A., and Karniadakis, G.E. (1997) 28th AIAA Fluid Dynamics Conf., AIAA 97-1883, June 29–July 2. Copyright © 1997 by the American Institute of Aeronautics and Astronautics, Inc. Reprinted with permission.)

**FIGURE 8.10** Velocity contours for a sphere in a pipe in the transitional flow regime ( $Kn = 3.5$ ). Molecules reflected from the sphere create a diffusive layer at the entrance of the pipe [Liu et al., 1998].

corresponding freestream dynamic head and the local sound speed, respectively. The specific  $y/h$  locations are selected to coincide with the DSMC cell centers to avoid interpolations or extrapolations of the DSMC method. The results show reasonable agreements of the slip-based Navier–Stokes simulations with the DSMC data. The flow recirculation and re-attachment location at the bottom wall are predicted equally well with both methods. The DSMC simulations utilized 28,000 cells ( $700 \times 40$ ) with 420,000 simulated molecules. The solution is sampled  $10^5$  times. The continuum-based simulations are performed by 52 spectral elements with 10th-order polynomial expansions for each direction.

### 8.3.4.3 Transitional Flow Past a Sphere in a Pipe

The DSMC simulations of high  $Kn$  rarefied flows at the entry of channels or pipes show diffusion of the molecules from the entry toward the free stream region. In order to demonstrate this counterintuitive effect, Liu et al. (1998) simulated flow past a sphere in a pipe problem with diffuse reflection from the surfaces. In order to incorporate the molecules diffusing out from the entry of the pipe, the computational domain for the freestream region had to be extended more than expected. In high Knudsen number subsonic flows, the molecules reflected from the sphere can travel toward the pipe inlet with very few intermolecular collisions and then diffuse out. Figure 8.10 presents the velocity contours for  $Kn = 3.5$  flow. Diffusion of the molecules toward the inflow can easily be identified from the velocity contours. This effect was studied earlier by Kannenberg and Boyd (1996) for transitional flow entering a channel. For  $Kn = 3.5$  results presented in Figure 8.10, the length of the freestream region is equal to the length of the pipe; hence, the computational cost is increased significantly.

## 8.3.5 Recent Advances in the DSMC Method

In this section, recent developments in the application and implementation of the DSMC method are presented.

### 8.3.5.1 Information Preservation DSMC Scheme

Fan and Shen (1999) developed an information preservation (IP) DSMC scheme for low-speed rarefied gas flows. Their method uses the molecular velocities of the DSMC method as well as an information velocity that records the collective velocity of an enormous number of molecules that a simulated particle represents. The information velocity evolves with inelastic molecular collisions, and the results presented for Couette, Poiseuille and Rayleigh flows in the slip, transition and free molecular regimes show very good agreements with the corresponding analytical solutions. This approach seems to cut down the sample size and correspondingly the CPU time required by a regular DSMC method for low-speed flows by orders of magnitude. This is a tremendous gain in computational time that can lead to the effective use of IP DSMC schemes for microfluidic and MEMS simulations. Currently, the IP DSMC schemes are being validated in two-dimensional, complex-geometry flows, and extensions of the IP technique for three-dimensional flows are also being developed [Cai et al., 2000].

### 8.3.5.2 DSMC with Moving Boundaries

Some of the microflow applications require numerical simulation of moving surfaces. In continuum-based approaches, arbitrary Lagrangian Eulerian (ALE) algorithms are successfully utilized for such applications [Beskok and Warburton, 2000a; 2000b]. A similar effort to expand the DSMC method for

grid adaptation, including the moving external and internal boundaries, combined the DSMC method with a monotonic Lagrangian grid (MLG) method [Cybyk et al., 1995; Oran et al., 1998].

### 8.3.5.3 Parallel DSMC Algorithms

Because the DSMC calculations involve vast numbers of molecules, utilization of parallel algorithms with efficient interprocessor communications and load balancing can have a significant impact on the effectiveness of simulations. Recent developments in parallel DSMC algorithms are addressed by Oran et al. (1998). For example, Dietrich and Boyd (1996) were able to obtain 90% parallel efficiency with 400 processors, simulating over 100 million molecules on a 400-node IBM SP2 computer. The computing power of their code is comparable to 75 single-processor Cray C90 vector computers. Good parallel efficiencies for DSMC algorithms can be achieved with effective load-balancing methods based on the number of molecules. This is because the computational work of the DSMC method is proportional to the number of simulated molecules.

### 8.3.6 DSMC Coupling with Continuum Equations

In this section, an overview of the DSMC/Navier–Stokes and DSMC/Euler equation coupling strategies is presented. These equations are particularly important for simulation of gas flows in MEMS components. If we consider a micromotor or a microcomb drive mechanism, gas flow in most of the device can be simulated using the slip-based continuum models. The DSMC method should be utilized only when the gap between the surfaces becomes submicron, or when the local  $Kn > 0.1$ . Hence, it is necessary to implement multidomain DSMC/continuum solvers. Depending on the specific application, hybrid Euler/DSMC [Roveda et al., 1998] or DSMC/Navier–Stokes algorithms [Hash and Hassan, 1995] can be used. Such hybrid methods require compatible kinetic-split fluxes for the Navier–Stokes portion of the scheme [Chou and Baganoff, 1997; Lou et al., 1998] so that an efficient coupling can be achieved. Recently, an adaptive mesh and algorithm refinement (AMAR) procedure, which embeds a DSMC-based particle method within a continuum grid, has been developed that enables molecular-based treatments even within the continuum region [Garcia et al., 1999]. Hence, the AMAR procedure can be used to deliver microscopic and macroscopic information within the same flow region.

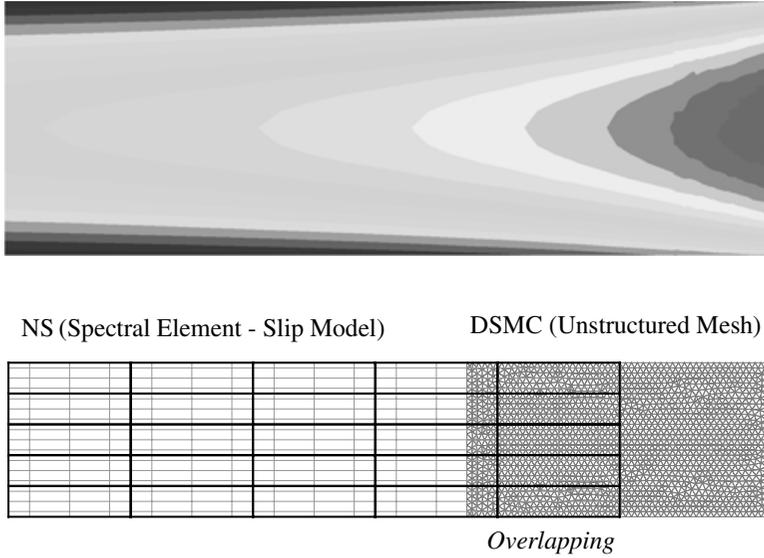

Simulation results for a Navier–Stokes/DSMC coupling procedure obtained by Liu (2001) is shown in Figure 8.11. A structured spectral element algorithm,  $\mu$ Flow [Beskok, 1996], is coupled with an unstructured DSMC method, UDSMC 2-D, with an overlapping domain. Both the grid and the streamwise velocity contours are shown in the figure; smooth transition of the velocity contours from the continuum-based slip region to the DSMC region can be observed. The details of the coupling procedure are given in Liu (2001).

### 8.3.7 Boltzmann Equation Research

Microscale thermal/fluidic transport in the entire Knudsen regime ( $0 \leq Kn < \infty$ ) is governed by the Boltzmann equation (BE). The Boltzmann equation describes the evolution of a velocity distribution function by molecular transport and binary intermolecular collisions. The assumption of binary intermolecular collisions is a key limitation in the Boltzmann formulation, making it applicable for dilute gases only. The Boltzmann equation for a simple dilute gas is given in the following form [Bird, 1994]:

$$\frac{\partial n f}{\partial t} + \vec{c} \cdot \frac{\partial n f}{\partial \vec{x}} + \vec{F} \cdot \frac{\partial n f}{\partial \vec{c}} = \int_{-\infty}^{\infty} \int_0^{4\pi} n^2 (f^* f_1^* - f f_1) c_r \sigma d\Omega d\vec{c}_1 \quad (8.9)$$

where  $f$  is the velocity distribution function,  $n$  is the number density,  $\vec{c}$  is the molecular velocity,  $\vec{F}$  is the external force per unit mass,  $c_r$  is the relative speed of class  $\vec{c}$  molecules with respect to class  $\vec{c}_1$  molecules, and  $\sigma$  is the differential collision cross section. The definition of each term in Eq. (8.9) is as follows: The first term is the rate of change of the number of class  $\vec{c}$  molecules in the phase space.

**FIGURE 8.11** Streamwise velocity contours for rarefied gas flow in mixed slip/transitional regimes, obtained by a coupled DSMC/continuum solution method. Most of the channel is in the slip flow regime, and a spectral element method  $\mu$ Flow is utilized to solve the compressible Navier–Stokes equations with slip. The rest of the channel is in the transitional flow regime, where a DSMC method with unstructured cells is utilized. (From Liu, H.F. (2001) Ph.D. thesis, Brown University, Providence, RI.)

The second term shows convection of molecules across a fluid volume by molecular velocity  $\vec{c}$ . The third term is convection of molecules across the velocity space as a result of the external force  $\vec{F}$ . The fourth term is the binary collision integral. The term  $(-ff_1)$  describes the collision of molecules of class  $\vec{c}$  with molecules of class  $\vec{c}_1$  (resulting in creation of molecules of class  $\vec{c}^*$  and  $\vec{c}_1^*$ , respectively), and it is known as the loss term. Similarly, there are inverse collisions where class  $\vec{c}^*$  molecules collide with class  $\vec{c}_1^*$  molecules, creating class  $\vec{c}$  and  $\vec{c}_1$  molecules. This is shown by  $f_1^*f^*$ , known as the gain term. Assuming binary elastic collisions enables us to determine class  $\vec{c}^*$  and  $\vec{c}_1^*$  conditions [Bird, 1994]. The difficulty of the Boltzmann equation arises due to the nonlinearity and complexity of the collision integral terms and the multidimensionality of the equation  $(x, c, t)$ .

Current numerical methods are usually very expensive, and they are applied for simple geometries, such as pipes and channels. In particular, a number of investigators have considered semi-analytical and numerical solutions of the linearized Boltzmann equation to be valid for flows with small pressure and temperature gradients [Aoki, 1989; Huang et al., 1966; Loyalka and Hamoodi, 1990; Ohwada et al., 1989; Sone, 1989]. These studies used HS and Maxwellian molecular models. Simplifications for the collision integral based on the BGK model [Bhatnagar et al., 1954] are used in the Boltzmann equation studies. The BGK model for a rarefied gas with no external forcing is given as:

$$\frac{\partial n f}{\partial t} + \vec{c} \cdot \frac{\partial n f}{\partial \vec{x}} = \nu n (f_o - f) \quad (8.10)$$

where  $\nu$  is the collision frequency and  $f_o$  is the local Maxwellian (equilibrium) distribution. The right-hand side of Eq. (8.10) becomes zero when the flow is in local equilibrium (continuum flow) or when the collision frequency goes to zero (corresponding to the free molecular flow). The BGK model captures both limits correctly. However, there are justified concerns about the validity of the BGK model in the transition flow regime. A model's ability to capture the two asymptotic limits ( $Kn \rightarrow 0$  and  $Kn \rightarrow \infty$ ) is not necessarily sufficient for its accuracy in the intermediate regimes [Bird, 1994].

Recently, Veijola et al. (1995; 1998) presented a Boltzmann equation analysis of silicon accelerometer motion and squeeze-film damping as a function of the Knudsen number and the time-periodic motion of the surfaces. Although the squeeze-film damping analysis is very challenging due to the mixed compressibility and rarefaction effects, it has many practical applications, including computer disk hard drives, micro-accelerometers and noncontact gas buffer seals [Fukui and Kaneko, 1988; 1990]. A comprehensive theory of internal rarefied gas flows, including the numerical simulation data, is given by Saripov and Seleznev (1998). The reader is referred to this article for further theoretical and numerical details on the Boltzmann equation.

The wall-boundary conditions for Boltzmann solutions typically use diffuse and mixed diffuse/specular reflections. For diffuse reflection, the molecules reflected from a solid surface are assumed to have reached thermodynamic equilibrium with the surface. Thus, they are reflected with a Maxwellian distribution corresponding to the temperature and velocity of the surface.

### 8.3.8 Hybrid Boltzmann/Continuum Simulation Methods

Solution of the Navier–Stokes equation is numerically more efficient than solution of the Boltzmann equation; therefore it is desirable to develop coupled multidomain Boltzmann/Navier–Stokes models for simulation of mixed regime flows in MEMS and microfluidic applications. Because the typical DSMC method for this coupling results in large statistical noise, as discussed before, solution of the Boltzmann equation may be preferred. The hybrid Boltzmann/Navier–Stokes simulation approach can be achieved by calculating the macroscopic fluid properties from the Boltzmann solutions by moment methods [Bird, 1994], and using the kinetic flux-vector splitting procedure of Chou and Baganoff (1997). Another continuum to Boltzmann coupling can be obtained by using local Chapman–Enskog expansions to the BGK equation [Chapman and Cowling, 1970] and evaluating the distribution function for the kinetic region [Jamamoto and Sanryo, 1990].

### 8.3.9 Lattice Boltzmann Methods

Another approach for simulating flows in microscales is the lattice Boltzmann method (LBM), which is based on the solution of the Boltzmann equation on a previously defined lattice structure with simplistic molecular collision rules. Details of the lattice Boltzmann method are given in a review article by Chen and Doolen (1998). The LBM can be viewed as a special finite differencing scheme for the kinetic equation of the discrete-velocity distribution function, and it is possible to recover the Navier–Stokes equations from the discrete lattice Boltzmann equation with sufficient lattice symmetry [Frisch et al., 1986].

The main advantages of the LBM compared to other continuum-based numerical methods include [Chen and Doolen, 1998]:

- The convection operator is linear in the phase space.
- The LBM is able to obtain both compressible and incompressible Navier–Stokes limits.
- The LBM utilizes a minimal set of velocities in the phase space compared to the continuous velocity distribution function of the Boltzmann algorithms.

With these advantages, the LBM has developed significantly within the last decade. The molecular motions for LBM are allowed on a previously defined lattice structure with restriction on molecular velocities to a few values. Particles move to a neighboring lattice location in every time step. Rules of molecular interactions conserve mass and momentum. Successful thermal and hydrodynamic analysis of multiphase flows including real gas effects can also be obtained [He, et al., 1998; Lou, 1998; Qian, 1993; Shan and Chen, 1994]. Another useful application of the LBM is for granular flows, which can be expanded to include flow-through microfiltering systems [Angelopoulos et al., 1998; Bernsdorf et al., 1999; Michael et al., 1997; Spaid and Phelan, 1997; Vangenabeek and Rothman, 1996].

Lattice Boltzmann methods have relatively simple algorithms, and they are introduced as an alternative to the solution of the Navier–Stokes equations [Frisch et al., 1986; Qian et al., 1992]. In contrast to the

continuum algorithms, which have difficulties in simulating rarefied flows with consistent slip-boundary conditions, the lattice Boltzmann method initially had difficulties in imposing the no-slip-boundary condition accurately. However, this problem has been successfully resolved [Inamuro et al., 1997; Lavallée et al., 1991; Noble et al., 1995; Zou and He, 1997].

Rapid development of the lattice Boltzmann method with relatively simpler algorithms that can handle both the rarefied and continuum gas flows from a kinetic theory point of view and the ability of the method to capture the incompressible flow limit make the LBM a great candidate for microfluidic simulations. At this time, the author is not familiar with applications of the lattice Boltzmann method specifically for microfluidic problems.

## 8.4 Liquid and Dense Gas Flows

Liquids do not have a well-advanced molecular-based theory. Similar limitations also exist for dense gases where simultaneous intermolecular collisions can exist. The stand-alone Navier–Stokes simulations cannot describe the liquid and dense gas flows in submicron-scale conduits. The effects of van der Waals forces between the fluid and the wall molecules and the presence of longer range Coulombic forces and an electrical double layer (EDL) can significantly affect the microscale transport [Ho and Tai, 1998; Gad-el-Hak, 1999]. For example, the streaming potential effect present in pressure-driven flows under the influence of EDL can explain deviations in the Poiseuille number reported in the seminal liquid microflow experiments of Pfahler et al. (1991).

In recent years, there has been increased interest in the development of micropumps and valves with nonmoving components for medical, pharmaceutical, defense and environmental-monitoring applications. Electrokinetic body forces can be used to develop microfluidic flow control and manipulation systems with nonmoving components. In this section, a brief review of continuum equations for electrokinetic phenomena and the electric double layer is presented.

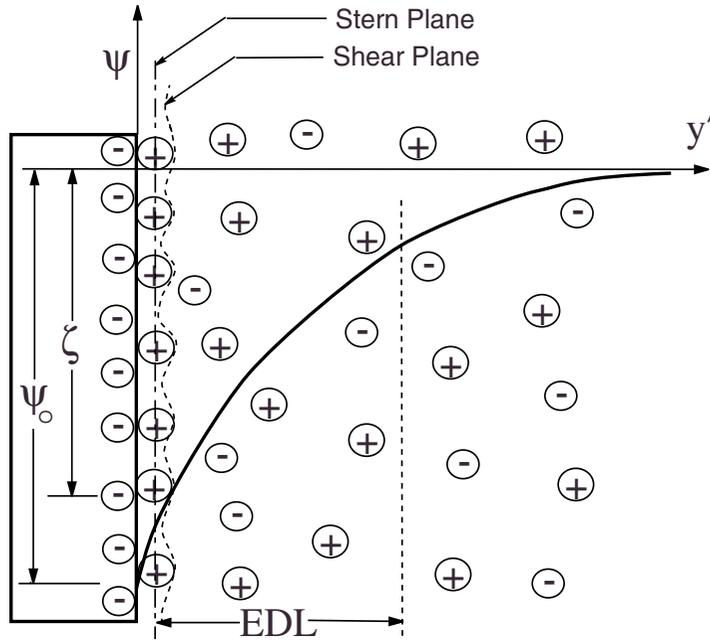

### 8.4.1 Electric Double Layer and Electrokinetic Effects

The electric double layer is formed due to the presence of static charges on the surfaces. Generally, a dielectric surface acquires charges when it is in contact with a polar medium or by chemical reaction, ionization or ion absorption. For example, when a glass surface is immersed in water, it undergoes a chemical reaction that results in a net negative surface potential [Cummings et al., 1999; Probst, 1994]. This influences the distribution of ions in the buffer solution. Figure 8.12 shows the schematic view of a solid surface in contact with a polar medium. Here, a net negative electric potential is generated on the surface. Due to this surface electric potential, positive ions in the liquid are attracted to the wall; on the other hand, the negative ions are repelled from the wall. This results in redistribution of the ions close to the wall, keeping the bulk of the liquid far away from the wall electrically neutral. The distance from the wall, where the electric potential energy is equal to the thermal energy, is known as the Debye length ( $\lambda$ ), and this zone is known as the electric double layer. The electric potential distribution within the fluid is described by the Poisson–Boltzmann equation:

$$\nabla^2(\psi/\zeta) = \frac{-4\pi h^2 \rho_e}{D\zeta} = \beta \sinh(\alpha\psi/\zeta) \quad (8.11)$$

where the  $\psi$  is the electric potential field,  $\zeta$  is the zeta potential,  $\rho_e$  is the net charge density,  $D$  is the dielectric constant, and  $\alpha$  is the ionic energy parameter given as:

$$\alpha = ez\zeta/k_b T \quad (8.12)$$

**FIGURE 8.12** Schematic diagram of the electric double layer next to a negatively charged solid surface. Here,  $\Psi$  is the electric potential,  $\Psi_s$  is the surface electric potential,  $\zeta$  is the zeta potential, and  $y'$  is the distance measured from the wall.

where  $e$  is the electron charge,  $z$  is the valence,  $k_b$  is the Boltzmann constant, and  $T$  is the temperature. In Eq. (8.11), the spatial gradients are nondimensionalized with a characteristic length  $h$ . Parameter  $\beta$  relates the ionic energy parameter  $\alpha$  and the characteristic length  $h$  to the Debye-Hückel parameter  $\omega = 1/\lambda$  as shown below:

$$\beta = (\omega h)^2 / \alpha$$

where

$$\omega = \frac{1}{\lambda} = \sqrt{\frac{2n_0 e^2 z^2}{\epsilon k_b T}}$$

The electrokinetic phenomenon can be divided into four parts [Probstein, 1994]:

1. *Electro-osmosis*: Motion of ionized liquid relative to the stationary charged surface by an applied electric field
2. *Streaming potential*: Electric field created by the motion of ionized fluid along stationary charged surfaces (opposite of electro-osmosis)
3. *Electrophoresis*: Motion of the charged surface relative to the stationary liquid, by an applied electric field
4. *Sedimentation potential*: Electric field created by the motion of charged particles relative to a stationary liquid (opposite of electrophoresis).

### 8.4.2 The Electro-Osmotic Flow

The electro-osmotic flow is created by applying an electric field in the streamwise direction, where this electric field ( $\vec{E}$ ) interacts with the electric charge distribution in the channel ( $\rho_e$ ) and creates an electrokinetic body force on the fluid. The ionized incompressible fluid flow with electro-osmotic body forces is governed by the incompressible Navier–Stokes equation:

$$\rho_f \left( \frac{\partial \vec{V}}{\partial t} + (\vec{V} \cdot \nabla) \vec{V} \right) = -\nabla P + \mu \nabla^2 \vec{V} + \rho_e \vec{E}. \quad (8.13)$$

The main simplifying assumptions and approximations are

- The fluid viscosity is independent of the shear rate; hence, the Newtonian fluid is assumed.
- The fluid viscosity is independent of the local electric field strength. This condition is an approximation. Because the ion concentration within the EDL is increased, the viscosity of the fluid may be affected; however, such effects are usually neglected for dilute solutions.
- The Poisson–Boltzmann equation, Eq. (8.11), is valid; hence, the ion convection effects are negligible.
- The solvent is continuous and its permittivity is not affected by the overall and local electric field strength.

Based on these continuum-based equations, various researchers have developed numerical models to simulate electrokinetic effects in microdevices [Yang et al., 1998; Ermakov et al., 1998; Dutta et al., 1999; 2000]. Here we must add that the EDL thickness can be as small as a few nanometers, and in such small scales the continuum description given by the Poisson–Boltzmann equation may break down [Dutta and Beskok, 2001]. Hence, the molecular dynamics method can be used to study the EDL effects in such small scales [Lyklema et al., 1998].

### 8.4.3 Molecular Dynamics Method

The molecular dynamics method requires simulation of motion and interactions of all molecules in a given volume. The intermolecular interactions are described by a potential energy function, typically the Lennard–Jones 12–6 potential given as [Allen and Tildesley, 1994]:

$$V^{LJ}(r) = 4\epsilon \left[ c_{ij} \left( \frac{\sigma}{r} \right)^{12} - d_{ij} \left( \frac{\sigma}{r} \right)^6 \right] \quad (8.14)$$

where  $r$  is the molecular separation, and  $\sigma$  and  $\epsilon$  are the length and energy parameters in the pair potential, respectively. The coefficients  $c_{ij}$  and  $d_{ij}$  are parameters chosen for particular fluid–fluid and fluid–surface combinations (see Allen and Tildesley (1994) for details). The first term on the right-hand side shows the strong repulsive force felt when the two molecules are extremely close to each other, and the second term represents the van der Waals forces. The force field is found by differentiation of this potential for each molecule pair, and the molecular motions are obtained by numerical integration of Newton’s equations of motion. Because the motion and interactions of all molecules are simulated, MD simulations are expensive. The computational work scales like the square of the number of the simulated molecules  $O(N^2)$ . Reduction in the computational intensity can be achieved by fast multipole algorithms or by implementation of a simple cutoff distance [Gad-el-Hak, 1999]. The MD simulations are usually performed for simple liquid molecules and for dense gases. Potential functions, other than the Lennard–Jones 12–6 potential, are also available. However, an intrinsic limitation of the molecular dynamics method, besides the prohibitively large number of molecules involved in the simulation, is the insight required to select the

appropriate potential functions. For example, the electrokinetic transport simulations require inclusion of electrostatic forces in the potential function.

#### 8.4.4 Treatment of Surfaces

In the molecular dynamics method, the fluid–surface interactions can be handled more realistically by including solid atoms attached to the lattice sites via a confining potential and letting them interact with gas–liquid molecules through a Lennard–Jones potential, Eq. (8.14). The solid atoms exhibit random thermal motions corresponding to the surface temperature  $T_{\text{wall}}$ . The desired temperature of the simulation is maintained by controlling the outer parts of the solid-lattice structure [Koplik and Banavar, 1995a]. Using realistic atomistic surface discretization increases the number of molecules even further, but this may become necessary to determine the surface roughness effects in microtransport. Also considering that the microfabricated surfaces can have rms surface roughness on the order of a few nanometers (depending on the fabrication process), realistic molecular-based surface treatments for liquid flows in nanoscales can be achieved using the molecular dynamics method [Tehver et al., 1998].

The molecular dynamics method is used to determine the validity range of the Newtonian fluid approximation and the no-slip-boundary conditions for simple liquids in submicron and nanoscale channels. Koplik et al. (1989) investigated dense gas and liquid Poiseuille flows with MD simulations. The molecular structure of the wall is also included in these simulations, resulting in fluid–wall interactions for smooth surfaces. Their findings for liquid flows show insignificant velocity slip effects. However, considerable slip effects with decreasing density are reported for gas molecules, consistent with Maxwell’s slip-boundary conditions given in Eq. (8.1). There are some conflicting findings in the literature in regard to the validity of the no-slip conditions, and the appropriate viscosity of liquids in nanoscale channels (see Section 2.7 in Gad-el-Hak, 1999). In a recent study by Granick (1999), the behavior of complex liquids with chain-molecule structures in nanoscales has been reported. Confined fluid behavior, solidification, melting and rapid deformation of liquid thin films can also be studied by the molecular dynamics method.

One must keep in mind that MD is restricted to very small (nanoscale) volumes, and the maximum integration time is also limited to a few thousand mean collision times. Hence, molecular simulations should be used whenever the corresponding continuum equations are suspected of failing or are expected to fail, such as in the case of fast time-scale processes, thin films or interfaces and in the presence of geometric singularities [Koplik and Banavar, 1995]. In order to apply MD to larger scale, thermal/fluidic transport problems, Hadjiconstantinou and Patera (1997) developed coupled atomistic/continuum simulation methods and recently extended this work to include multifluid interfaces [Hadjiconstantinou, 1999]. Due to the computational and practical restrictions of MD, it is crucial to develop hybrid atomistic/continuum simulation methodologies for further studies of liquid transport in micron and nanoscales.

### 8.5 Summary and Conclusions

---

In this chapter molecular-based simulation methodologies for liquid and gas flows in micron and submicron scales were presented. For simulation of gas flows, the main emphasis was given to the direct simulation Monte Carlo (DSMC) method. Its algorithmic details, limitations, advantages and disadvantages were presented. Although the DSMC is quite popular for analysis of high-speed rarefied gas flows, it is not as effective for simulation of gas microflows. It suffers from slow convergence and large statistical noise, and it requires an extensive number of simulated molecules. These disadvantages can be eliminated to some degree by using the newly developed information preservation (IP) technique. However, the IP-DSMC is still undergoing development and validation. An alternative to the DSMC method is solution of the Boltzmann transport equation, which is an integro-differential equation with seven independent variables. It is clear that the Boltzmann equation algorithms are very complicated to implement for general engineering applications, but they can be used for simple geometry cases such as in microchannels. A final alternative for simulation of gas microflows is the lattice Boltzmann method (LBM), which has

been developed extensively within the past decade. The LBM has relatively simpler algorithms that can handle both the rarefied and continuum gas flows from a kinetic theory point of view, and the ability of the LBM to capture the incompressible flow limit can make this method a great candidate for microfluidic simulations.

The molecular dynamics (MD) method was introduced for liquid flows. Because MD requires modeling of every molecule, it is computationally expensive and is usually applied to very small volumes in order to verify the onset of the continuum behavior in liquids. MD is general enough to handle the interactions of long-chain molecules with each other and the surfaces in very thin gaps. The wall surface roughness and its molecular structure can also be included in the simulations. Thus, realistic molecule/surface interactions can be obtained using the MD method. The main drawback of MD is its prohibitively large computational cost.

The DSMC, MD and Boltzmann equation models are numerically more expensive than solution of the Navier-Stokes equations. Considering that the microtransport applications cover a wide range of length scales from submillimeter to tens of nanometers, it is numerically more efficient to implement hybrid continuum/atomistic models, where the atomistic simulations take place only at a small section of the entire computational domain. References to recent developments of hybrid schemes were given for each model.

All numerical methods are inherently model based, including the constitutive laws and the boundary conditions of the Navier–Stokes equations, as well as the molecular interaction models of the MD and the DSMC methods. Although it may seem as though the molecular simulation methods are more fundamental in nature, they require assumptions and models of more fundamental levels. For example, the molecular dynamics method requires specification of the Lennard–Jones potentials and their coefficients. Physical insight about a problem is of utmost importance for any model. After all, numerical models can only deliver the physics implemented within them.

### 9.1 Introduction

---

As microengineering technology continues to advance, driven by increasingly complex and capable micro-fabrication and materials technologies, the need for greater sophistication in microelectromechanical systems (MEMS) design will increase. Fluid film lubrication has been a critical issue from the outset of MEMS development, particularly in the prediction and control of viscous damping in vibrating devices such as accelerometers and gyros. Much attention has been showered on the development of models for accurate prediction of viscous damping and of fabrication techniques for minimizing the damping (which destroys the quality, or  $Q$ -factor, of a resonant system). In addition to the development and optimization of these oscillatory devices, rotating devices—micromotors, microengines, etc.—have also captured the attention of MEMS researchers since the early days of MEMS development, and there have been several demonstrations of micromotors driven by electrostatic forces [Bart et al., 1988; Mehregany et al., 1992; Nagle and Lang, 1999; Sniegowski and Garcia, 1996]. For the most part these motors were very small,

with rotors of the order of 100  $\mu\text{m}$  in diameter, and, although they had high rotational speeds (hundreds of thousands of revolutions per minute), their tip speeds and rotational energy (which scales with tip speed) were quite small (tip speeds of 1 m/s are typical). In addition, the focus of these projects was the considerable challenge associated with the fabrication of a freely moving part and the integration of the drive electrodes. Lubrication and protection against wear were low down on the “to-do” list and the demonstrated engines relied on dry-rubbing bearings in which the rotor was held in place by a bushing, but there was no design or integration of a lubrication system. The low surface speeds of these engines meant that they could have operated for long times using this primitive bearing; however, failure was observed frequently due to rotor/bearing wear.

As MEMS devices become more sophisticated and have more stringent design and longevity requirements, the need for more accurate and extensive design tools for lubrication has increased. In addition, the energy density of MEMS is increasing. Devices for power generation, propulsion and so forth are actively under development. In such devices the temperatures and stresses are stretched to the material limits. Hence, the requirement for protection of moving surfaces becomes more than a casual interest—it is critical for the success of a “power MEMS” device (imagine, for comparison, an aircraft engine without lubrication—it would melt and fail within seconds of operation!).

### 9.1.1 Objectives and Outline

The objective of this chapter is to briefly summarize some the issues associated with lubrication in MEMS. Lubrication is a vast topic, and clearly there is no way in which these few pages can adequately introduce and treat an entire field as diverse and complex as this. For this reason, some hard choices have been made. Our focus is to review the essential features of lubrication theory and design practice and to highlight the difficulties that arise in the design of a lubrication system for MEMS devices. A key feature of MEMS is that the fabrication, material properties and mechanical and electrical design are all tightly interwoven and cannot be separated. For this reason, some attention is devoted to the important issue of how a successful lubrication system is influenced by manufacturing constraints and material properties.

Finally, one should always remember that MEMS is a rapidly developing and maturing manufacturing technology. The range of geometric options, available materials and dimensional control is continually expanding and improving. This chapter necessarily focuses on the current state of the art in MEMS fabrication, and for this reason it tends to favor silicon-based fabrication processes and the constraints that lithographic-based batch fabrication techniques place on lubrication system design and performance, but all of this may be rendered obsolete in 5 or 10 years!

Examples are drawn from several sources. In the sections on translational and squeeze-film damping examples are drawn from the extensive literature associated with accelerometer and gyro design. The rotating system lubrication discussion draws heavily on the MIT Microengine project [Epstein et al., 1997], which, to our knowledge, is the only MEMS device to date with rotating elements using a fluid-film lubrication system. This device is described in some detail further on in the chapter, and the analysis and examples of thrust bearings and journal bearings are drawn from that device.

## 9.2 Fundamental Scaling Issues

---

### 9.2.1 The Cube-Square Law

The most dominant effect that changes our intuitive appreciation of the behavior of microsystems is the so-called *cube-square law*, which simply reflects the fact that volumes scale with the cube of the typical length scale, while areas (including surface areas) scale with the square of the length scale. Thus, as a device shrinks, surface phenomena become relatively more important than volumetric phenomena. The most important consequence of this is the observation that the device mass (and inertia) becomes negligibly small at the micro- and nanoscales. For lubrication, the implication of this is that the volumetric loads that require support (such as the weight of a rotor) quickly become negligible. As an

example, consider the ratio of the weight of a microfabricated rotor (a cylinder of density  $\rho$ , diameter  $D$  and length  $L$ ) compared to the pressure  $p$  acting on its projected surface area. This can be expressed as a nondimensional load parameter:

$$\zeta = \frac{\rho\pi LD^2/4}{pLD} \propto \frac{D}{p}$$

from which it can clearly be seen that the load parameter decreases linearly as the device shrinks. For example, the load parameter (due to the rotor mass) for the MIT Microengine (which is a relatively large MEMS device, measuring 4 mm in diameter and 300  $\mu\text{m}$  deep) is approximately  $10^{-3}$ . The benefits of this scaling are that orientation of the freely suspended part becomes effectively irrelevant and that unloaded operation is easy to accomplish, should one desire to do so. In addition, because the gravity loading is negligible, the primary forces to be supported are pressure-induced loads and (in a rotating device) loads due to rotational imbalance. This last load is, in fact, *very* important and will be discussed in more detail in connection to rotating lubrication requirements. The chief disadvantage of the low natural loading is that unloaded operation is often undesirable (in hydrodynamic lubrication, where a minimum eccentricity is required for journal bearing stability); in practice, gravity loading is often used to advantage. Thus, a scheme for applying an artificial load must be developed. This is discussed in more detail later in the chapter.

## 9.2.2 Applicability of the Continuum Hypothesis

A common concern in microfluidic devices is the appropriateness of the continuum hypothesis as the device scale continues to fall. At some scale, the typical intermolecular distances will be comparable to the device scales, and the use of continuum fluid equations becomes suspect. For gases, the Knudsen number ( $Kn$ ) is the ratio of the mean free path to the typical device scale. Numerous experiments (e.g., see Arkilic et al., 1993; 1997; Arkilic et al., 2001) have determined that noncontinuum effects become observable when  $Kn$  reaches approximately 0.1, and continuum equations become meaningless (the “transition flow regime”) at  $Kn$  of approximately 0.3. For atmospheric temperature and pressure, the mean free path (of air) is approximately 70 nm. Thus, atmospheric devices with features smaller than approximately 0.2  $\mu\text{m}$  will be subject to nonnegligible, noncontinuum effects. In many cases, such small dimensions are not present, thus the fluidic analysis can safely use the standard Navier–Stokes equations (as is the case for the microengine).

Nevertheless, in applications where viscous damping is to be avoided (for example, in high- $Q$  resonating devices, such as accelerometers or gyroscopes) the operating gaps are typically quite small (perhaps a few microns) and the gaps serve double duty as both a physical standoff and a sense gap where capacitive sensing is accomplished. In such examples, one is “stuck” with the small dimension, so, in order to minimize viscous effects, the device is packaged at low pressures where noncontinuum effects are clearly evident. For small Knudsen numbers, the Navier–Stokes equations can be used with a single modification—the boundary condition is relaxed from the standard non-slip condition to that of a slip-flow condition, where the velocity at the wall is related to the Knudsen number and the gradient of velocity at the wall:

$$u_w = \lambda \frac{2 - \sigma}{\sigma} \frac{\partial u}{\partial y} \Big|_w$$

where  $\sigma$  is the tangential momentum accommodation coefficient (TMAC) which varies between 0 and 1. Experimental measurements [Arkilic et al., 2001] indicate that smooth native silicon has a TMAC of approximately 0.7 in contact with several commonly used gases.

Despite the fact that the slip-flow theory is only valid for low  $Kn$ , it is often used (incorrectly) with great success at much higher Knudsen numbers. Its adoption beyond its range of applicability stems primarily from the lack of any better approach (short of solving the Boltzmann equation or using direct simulation Monte Carlo [DSMC] computations [Beskok and Karniadakis, 1994; Cai et al., 2000]).

However, for many simple geometries, the “extended” slip-flow theory works much better than it should and provides quite adequate results. This is demonstrated in the sections on Couette and squeeze-film damping later in the chapter.

### 9.2.3 Surface Roughness

Another peculiar feature of MEMS devices is that the surface roughness of the material used can become a significant factor in the overall device geometry. MEMS surface finishes are quite varied, ranging from atomically smooth surfaces found on polished single-crystal silicon substrates to the rough surfaces left by various etching processes. The effects of these topologies can be important in several areas for microdevice performance. Probably the most important effect is the way in which the roughness can affect structural characteristics (crack initiation, yield strength, etc.), although this will not be explored in this chapter. Second, the surface finish can affect fluidic phenomena such as the energy and momentum accommodation coefficient, as described above, and consequently the momentum and heat transfer. Finally, the surface characteristics (although not only the roughness, but also the surface chemistry and affinity) can strongly affect its adhesive force. This again is not treated in any detail in this discussion, although it is mentioned briefly at the end of the chapter in connection with tribology issues in MEMS.

## 9.3 Governing Equations for Lubrication

With the proviso that the continuum hypothesis holds for micron-scale devices (perhaps with a modified boundary condition), the equations for microlubrication are identical to those used in conventional lubrication analysis and can be found in any standard lubrication textbook (for example, see Hamrock, 1984). We present the essential results here for convenience and completeness, but the reader is referred to more complete treatments for full derivations and a detailed discussion of the appropriate limitations.

Starting with the Navier–Stokes equations, we can make a number of simplifying assumptions appropriate for lubrication problems:

1. *Inertia*: The terms representing transfer of momentum due to inertia may be neglected. This arises due to the small dimensions that characterize lubrication geometries and MEMS, in particular. In very high-speed devices (such as the MIT Microengine) inertial terms may not be as small as one might like, and corrections for inertia may be applied. However, preliminary studies suggest that these corrections are small [Piekos, 2000].
2. *Curvature*: Lubrication geometries are typically characterized by a thin fluid film with a slowly varying film thickness. The critical dimension in such systems is the film thickness, which is assumed to be much smaller than any radius of curvature associated with the overall system. This assumption is particularly important in a rotating system where a circular journal bearing is used. However, assuming that the radius of the bearing,  $R$ , is much larger than the typical film thickness  $c$  (i.e.,  $c/R \ll 1$ ) greatly simplifies the governing equations.
3. *Isothermal*: Because volumes are small and surface areas are large, thermal contact between the fluid and the surrounding solid is very good in a MEMS device. In addition, common MEMS materials are good thermal conductors. For both these reasons, it is very safe to assume that the lubrication film is isothermal.

With these restrictions, the Navier–Stokes equations, the equation for the conservation of mass and the equation of state for a perfect gas may be combined to yield the Reynolds equation (named after Osborne Reynolds, 1886, who first derived it), written here for two-dimensional films:

$$0 = \frac{\partial}{\partial x} \left( -\frac{\rho h^3}{12\mu} \frac{\partial p}{\partial x} \right) + \frac{\partial}{\partial y} \left( -\frac{\rho h^3}{12\mu} \frac{\partial p}{\partial y} \right) + \frac{\partial}{\partial x} \left( \frac{\rho h(u_a + u_b)}{2} \right) + \frac{\partial}{\partial y} \left( \frac{\rho h(v_a + v_b)}{2} \right) + \rho(w_a - w_b) - \rho u_a \frac{\partial h}{\partial x} - \rho v_a \frac{\partial h}{\partial y} + h \frac{\partial \rho}{\partial t}$$

where  $x$  and  $y$  are the coordinates in the lubrication plane, and  $u_a$  etc. are the velocities of the upper and lower surfaces. An alternate (and more general) version may be derived [Burgdorfer, 1959] by non-dimensionalization with the film length and width  $l$  and  $b$ , the minimum clearance  $h_{\min}$ , characteristic shearing velocity  $u_b$  and characteristic unsteady frequency  $\omega$ . In addition, gas rarefaction can be incorporated for low Knudsen numbers by assuming a slip-flow wall boundary condition:

$$\frac{\partial}{\partial X} \left[ (1 + 6K)PH^3 \frac{\partial P}{\partial X} \right] + A^2 \frac{\partial}{\partial Y} \left[ (1 + 6K)PH^3 \frac{\partial P}{\partial Y} \right] = \Lambda \frac{\partial(PH)}{\partial X} + \sigma \frac{\partial(PH)}{\partial T}$$

where

$$A = \frac{l}{b}; \quad \Lambda = \frac{6\mu u_b l^2}{p_a h_{\min}^2}; \quad \sigma = \frac{12\mu\omega l^2}{p_a h_{\min}^2}$$

Here,  $A$  is the film aspect ratio,  $\Lambda$  is the bearing number and  $\sigma$  is the squeeze number, representing unsteady effects.

Solution of the Reynolds equation is straightforward but not trivial. A chief difficulty comes from the fact that gas films are notoriously unstable if they operate in the wrong parameter space. In order to determine the stability or instability of the numerically generated solution, both the steady Reynolds equation and its unsteady counterpart need to be addressed and with some accuracy. These issues are discussed more by Piekos and Breuer (1998), as well as others.

## 9.4 Couette-Flow Damping

The viscous damping of a plate oscillating in parallel motion to a substrate has been a problem of tremendous importance in MEMS devices, particularly in the development of resonating structures such as accelerometers and gyros. The problem arises due to the fact that the proof mass, which may be hundreds of microns in the lateral dimension, is typically suspended above the substrate with a separation of only a few microns. A simple analysis of Couette-flow damping for rarefied flows is easy to demonstrate by choosing a model problem of a one-dimensional proof mass (i.e., ignoring the dimension perpendicular to the plate motion). This is shown schematically in Figure 9.1.

The Navier–Stokes equations for this simple geometry reduce simply to:

$$\frac{\partial u}{\partial t} = \mu \frac{\partial^2 u}{\partial y^2}$$

in which only viscous stresses due to the velocity gradient and the unsteady terms survive. This can be solved using separation of variables and employing a slip-flow boundary condition [Arkilic and Breuer, 1993],

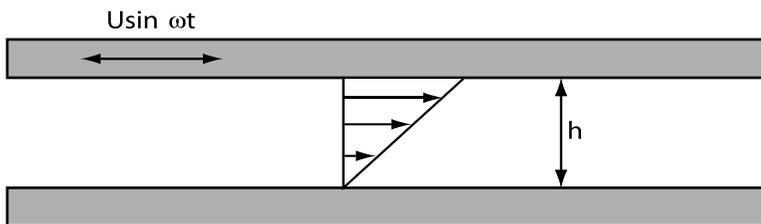

FIGURE 9.1 Schematic of Couette-flow damping geometry. The upper plate vibrates with a proscribed amplitude and frequency; however, for most MEMS geometries and frequencies, the unsteadiness can usually be neglected.

yielding the solution the drag force experienced by the moving plate:

$$D = \frac{4\pi U^2}{\beta} \left[ \frac{\sinh \beta + \sin \beta}{(\cosh \beta - \cos \beta) + D_R} \right]$$

where

$$\beta = \sqrt{\frac{\omega h^2}{\mu}}$$

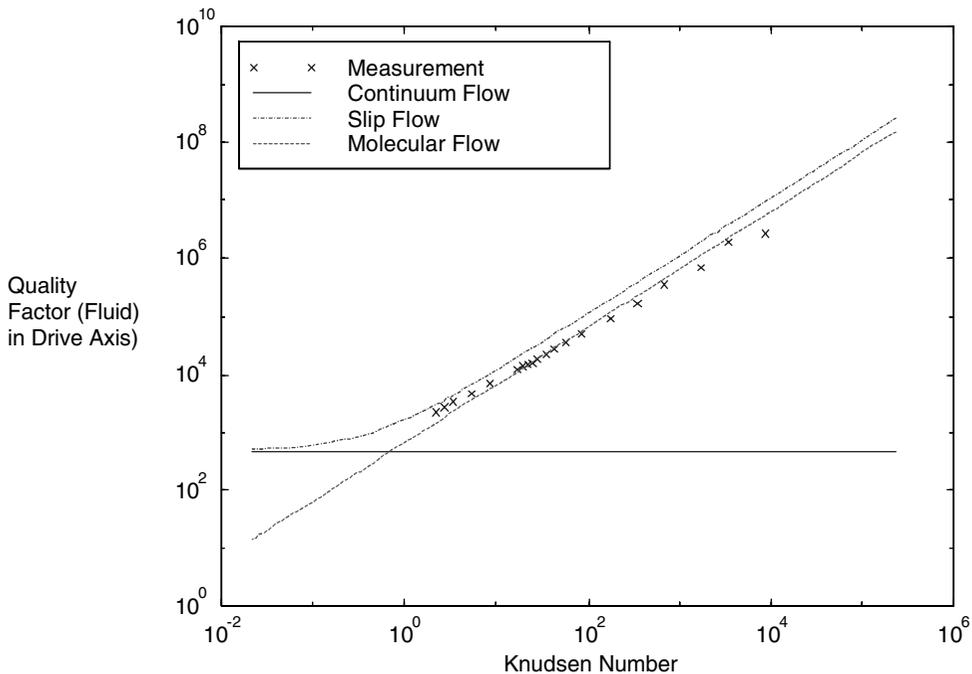

is a Stokes number, representing the balance between unsteady and viscous effects, and  $D_R$  is a correction due to slip-flow at the wall:

$$D_R = 2Kn\beta(\sinh \beta + \sin \beta) + 2Kn^2\beta^2(\cosh \beta + \cos \beta)$$

A typical MEMS geometry might have a plate separation of 1  $\mu\text{m}$  and an operating frequency of 10 kHz. With these parameters, we see that the Stokes number, as defined, is very small (approximately 0.1), so that the flow may be considered quasi-steady to a high degree of approximation. In addition, the rarefaction effects indicated by  $D_R$  are also vanishingly small at atmospheric conditions.

### 9.4.1 Limit of Molecular Flow

Although the slip-flow solution is limited to low Knudsen numbers, the damping due to a gas at high degrees of rarefaction can be easily computed using a free molecular-flow approximation. In such cases,

**FIGURE 9.2** Theory and measurements of Couette damping in a tuning fork gyro [Kwok et al., 2001]. Note that in the high Knudsen number limit, the free molecular approximation predicts the damping more closely, but that the slip-flow model, though totally inappropriate at this high  $Kn$  level, is not too far from the experimental measurements.

the friction factor on a flat plate is given by Rohsenow and Choi (1961):

$$C_f = \sqrt{\frac{2}{\pi\gamma M}}$$

where  $\gamma$  is the ratio of specific heats and  $M$  is the Mach number. It is important to recognize that the damping (and  $Q$ ) in this case is provided not only by the flow in the gap, but also by the flow above the vibrating plate. However, it is unlikely that the fluid damping provides the dominant source of damping at such extremely low pressures. More likely, damping derived from the structure (for example, flexing of the support tethers, nonelastic strain at material interfaces etc.) will take over as the dominant energy-loss mechanism. Kwok et al. (2001) compared the continuum, slip-flow and free molecular-flow models for Couette damping with data obtained by measuring the “ring down” of a tuning fork gyroscope fabricated by Draper Laboratories. The measurements and theory are shown in Figure 9.2, confirming the functional behavior of the damping as the pressure drops ( $Kn$  increases) and the unexpected accuracy of these rather simple models. Although the trends are well predicted, the absolute value of the  $Q$ -factor is still in error by a factor of two, suggesting that more detailed computations are still of interest.

## 9.5 Squeeze-Film Damping

Squeeze-film damping arises when the gap size changes in an oscillatory manner, squeezing the trapped fluid (Figure 9.3). Fluid (usually air) is trapped between the vibrating proof mass and the substrate, resulting in a squeeze film that can significantly reduce the quality factor of the resonator. In some cases, this damping is desirable, but, as with the case of Couette-flow damping, it is often parasitic, and the MEMS designer tries to minimize its effects and thus maximize the resonant  $Q$ -factor of the device. Common methods for alleviating squeeze-film effects are to fabricate breathing holes (“chimneys”) throughout the proof mass which relieve the buildup of pressure and/or by packaging the device at low pressure. Both of these solutions have drawbacks. The introduction of vent holes reduces the vibrating mass, necessitating an even larger structure, while the low-pressure packaging adds considerable complexity to the overall device development and cost. An example of this is shown in Figure 9.4, which illustrates a high-performance tuning fork gyroscope fabricated by Draper Laboratories.

### 9.5.1 Derivation of Governing Equations

An analysis of squeeze-film damping is presented in the following section. The Reynolds equations may be used as the starting point. However, a particularly elegant and complete solution was published by Blech (1983) for the case of the continuum flow and extended by Kwok et al. (2001) to the case of slip-flow and flows films with vent holes. This analysis is summarized here.

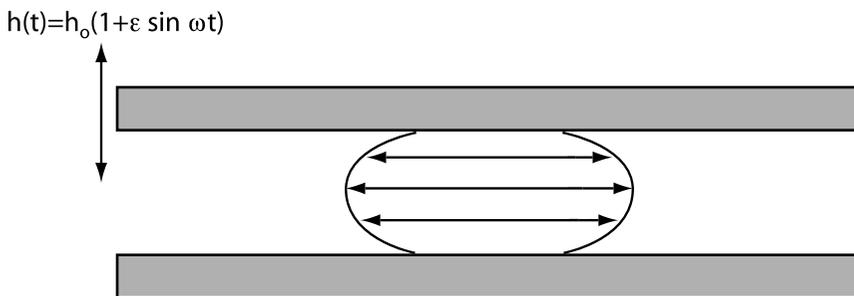

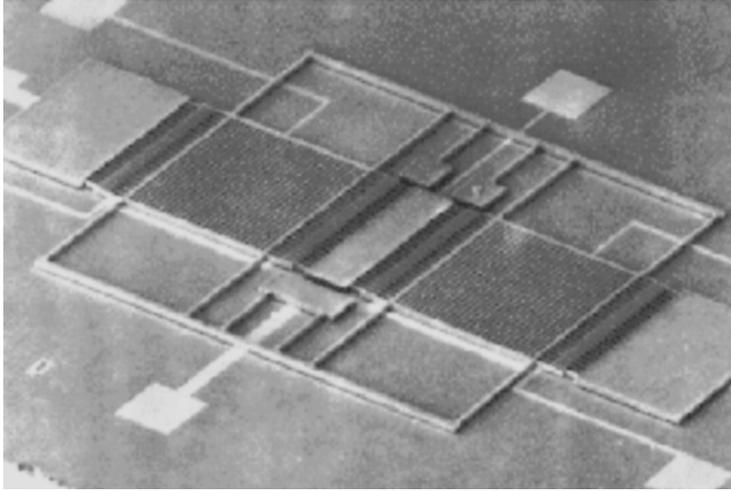

FIGURE 9.3 Schematic of squeeze-film damping between parallel plates. As with Couette damping, for most practical embodiments of MEMS, the damping is quasi-steady.

**FIGURE 9.4** Photograph of a typical microfabricated vibrating proof mass used in a high-performance tuning fork gyroscope. (Courtesy of M. Weinberg, Draper Laboratories, Cambridge, MA.)

The Navier–Stokes equations are written for the case of a parallel plate, vibrating sinusoidally in a proscribed manner in the vertical direction. If we assume that the motion and subsequent pressure and velocity perturbations are small, a perturbation analysis yields the classical squeeze-film equation derived by Blech, with an additional term due to the rarefaction:

$$\frac{\partial}{\partial X} \left( \Psi H^3 \frac{\partial \Psi}{\partial X} \right) + \frac{\partial}{\partial X} \left( 6KH^2 \frac{\partial \Psi}{\partial X} \right) = \sigma \frac{\partial(\Psi H)}{\partial T}$$

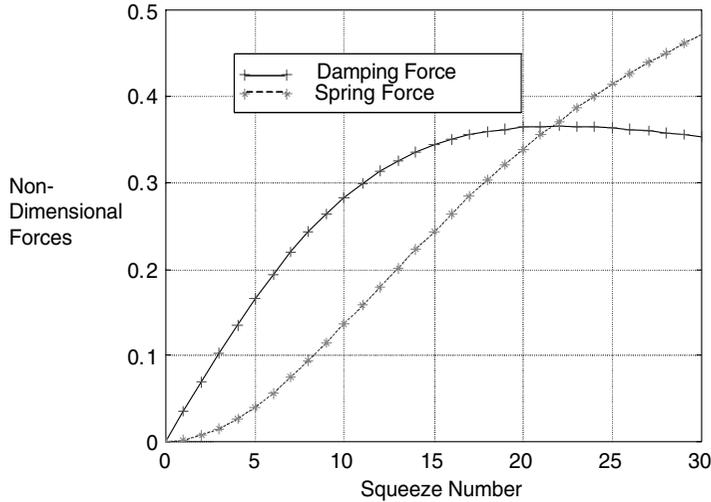

where the variables have been nondimensionalized, so that  $H$  represents the film gap, normalized by the nominal film gap:  $H = h(x, y, t)/h_0$ ;  $\Psi$  is the pressure, normalized by ambient pressure:  $\Psi = P(x, y, t)/P_0$ ;  $X$  and  $Y$  are the coordinates, normalized by the characteristic plate geometry:  $X = x/L_x$ ,  $Y = y/L_y$ ;  $T$  is time, normalized by the vibration frequency:  $T = \omega t$ ; and, finally, the squeeze number  $\sigma$  is defined as before:

$$\sigma = \frac{12\mu\omega L_x^2}{P_0 h_0^2}$$

Assuming small-amplitude, harmonic forcing of the gap,  $H = 1 + \epsilon \sin T$ , and by assuming a harmonic response of the pressure we can derive a pair of coupled equations describing the in-phase ( $\Psi_0$ ) and out-of-phase ( $\Psi_1$ ) pressure distributions in the gap (representing stiffness and damping coefficients, respectively):

$$\begin{aligned} \frac{\partial^2 \Psi_0}{\partial x^2} + \frac{\sigma}{1+6K} \Psi_1 + \frac{\sigma}{1+6K} &= 0 \\ \frac{\partial^2 \Psi_1}{\partial x^2} + \frac{\sigma}{1+6K} \Psi_0 &= 0 \end{aligned}$$

Note that these equations represent the standard conditions with the adoption of a modified squeeze number,  $\sigma_m \equiv \sigma/(1+6K)$ . The solutions are easy to achieve, either by manual substitution of Fourier sine and cosine series or by direct numerical solution. The results, for rectangular plates (with no vent holes) are shown in [Figure 9.5](#).

**FIGURE 9.5** Solutions to the squeeze-film equation for a rectangular plate. The stiffness and damping coefficients are presented as functions of the modified squeeze number, which includes a correction due to first-order rarefaction effects. (Adapted from Blech, 1983; Kwok et al., 2001.)

### 9.5.2 Effects of Vent Holes

The equations as derived above can be made more useful by extending them to account for the presence of vent holes in the vibrating proof mass. In such cases, the boundary condition at each vent hole is no longer atmospheric pressure ( $\Psi_0 = \Psi_1 = 0$ ), but rather an elevated pressure proscribed by the pressure drop through the “chimney” that vents the squeeze film to the ambient. Kwok et al. (2001) demonstrate that this can be incorporated into the above model (in the limit of low squeeze number) by a modified boundary condition for the squeeze film equations for  $\Psi_0$ :

$$\Psi = \left[ \frac{32 \frac{t}{L_x} \left( \frac{h_0}{L_x} \right)^3 \left( 1 - \left( \frac{L_h}{L_x} \right)^2 \right)}{12 \left( \frac{L_h}{L_x} \right)^4} \right] \left[ \frac{1}{1 + 8 \frac{\lambda}{L_h}} \right] \sigma$$

This boundary condition has three components: The first is a geometric component dependent on the plate thickness  $t$ , length  $L_x$ , hole size  $L_h$  and nominal gap size  $h_0$ . The second component is a rarefaction component (here based on the hole size), and the third is a time-dependent component—the squeeze number  $\sigma$ . Note that as the thickness of the plate decreases and the chimney pressure drop falls, the boundary condition approaches zero. Similarly, as the open area fraction of the plate increases (more venting), the boundary condition approaches that of the ambient (as one would expect). This boundary condition can be applied at the chimney locations and can thus accurately simulate the squeeze-film damping of perforated micromachined plates.

### 9.5.3 Reduced-Order Models for Complex Geometries

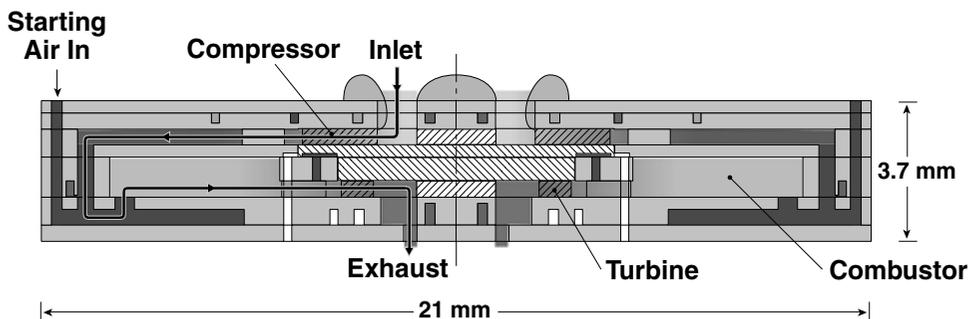

Unfortunately, most devices of practical interest have geometries that are usually too complex to enable full numerical simulation of the kind described above. Reduced-order models are of great value in such cases. Many such models have been developed, including those based on acousto-electric models (see, for example, Veijola et al. [1995]). In the case of squeeze-film damping in the limit of low squeeze numbers, such models reduce to solution of a resistor network that models the pressure drops associated with each

segment of the squeeze film. This is effectively a finite-element approach to the problem; however, instead of modeling a large number of elements, as is generally the case in a “brute-force” numerical solution, a relatively small number of discrete elements can be used if higher order solutions can be employed to connect each element together. Kwok et al. (2001) demonstrate this approach and model the damping associated with an inclined plate with vent holes—in this case, the pressure at the center of each vent hole. More complex numerical solution techniques based on boundary integral techniques have also been presented [Aluru and White, 1998; Ye et al., 1999], providing a good balance between solution fidelity and required computing power.

## 9.6 Lubrication in Rotating Devices

Rotating MEMS devices bring a new level of complexity to both MEMS fabrication as well as the lubrication considerations. As discussed in the introduction, many rotors and motors have been demonstrated with dry-rubbing bearings, and the success of these devices is due to the low surface speeds of the rotors. However, as the surface speed increases (in order to get high power densities), the dry-rubbing bearings are no longer an option and true lubrication systems need to be considered. An example of such “power-MEMS” development is provided by a project initiated at MIT in 1995 to demonstrate a fully functional microfabricated gas turbine engine [Epstein et al., 1997]. The baseline engine, illustrated in Figure 9.6, consists of a centrifugal compressor, fuel injectors (hydrogen is the initial fuel, although hydrocarbons are planned for later configurations), a combustor operating at 1600 K and a radial inflow turbine. The device is constructed from single-crystal silicon and is fabricated by extensive and complex fabrication of multiple silicon wafers fusion-bonded in a stack to form the complete device. An electrostatic induction generator may also be mounted on a shroud above the compressor to produce electric power instead of thrust [Nagle and Lang, 1999]. The baseline MIT Microengine has at its core a “stepped” rotor consisting of a compressor with an 8-mm diameter and a journal bearing and turbine with a diameter of 6 mm. The rotor spins at 1.2 million rpm.

Key to the successful realization of such a device is clearly the ability to spin a silicon rotor at high speed in a controlled and sustained manner, and the key to spinning a rotor at such high speeds is the demonstration of efficient lubrication between the rotating and stationary structures. The lubrication system needs to be simple enough to be fabricated and yet have sufficient performance and robustness to be of practical use both in the development program and in future devices. To develop this technology, a microbearing rig was fabricated and is illustrated in Figure 9.7. Here, the core of the rotating machinery has been implemented, but without the substantial complications of the thermal environment that the full engine brings. The rig consists of a radial inflow turbine mounted on a rotor and embedded inside two thrust bearings, which provide axial support. A journal bearing located around the disk periphery provides radial support for the disk as it rotates.

**FIGURE 9.6** Schematic of the MIT Microengine, showing the air path through the compressor, combustor and turbine. Forward and aft thrust bearings located on the centerline hold the rotor in axial equilibrium, while a journal bearing around the rotor periphery holds the rotor in radial equilibrium [Protz, 2000].

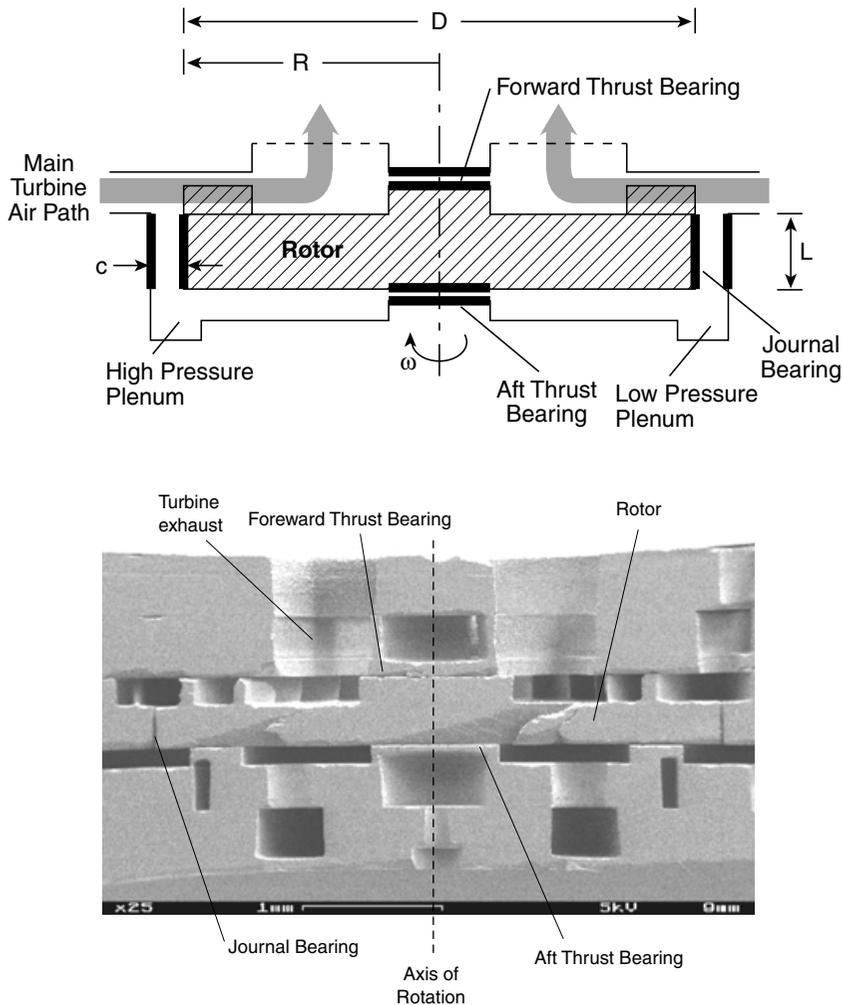

FIGURE 9.7 Illustrating schematic and corresponding SEM of a typical microfabricated rotor, supported by axial thrust bearings and a radial journal bearing.

## 9.7 Constraints on MEMS Bearing Geometries

### 9.7.1 Device Aspect Ratio

Perhaps the most restrictive aspect of microbearing design is the fact that MEMS devices are limited to rather shallow etches, resulting in devices with a low aspect ratio. Even with the advent of deep reactive ion etchers (DRIE), in which the ion etching cycle is interleaved with a polymer passivation step, the maximum practical etch depth that can be achieved while maintaining dimensional control is about  $500\ \mu\text{m}$  (even this has an etch time of about 9 hours which makes its adoption a very costly decision). This is in comparison with typical rotor dimensions of a few millimeters. The result is that microbearings are characterized by very low aspect ratios (length/depth, or  $L/D$ ). In the case of the MIT microturbine test rig, the journal bearing is nominally  $300\ \mu\text{m}$  deep, while the rotor is 4 mm in diameter, yielding an aspect ratio of 0.075. To put this in perspective, commonly available design charts [Wilcox, 1972] present data for values of  $L/D$  as low as 0.5 or perhaps 0.25. Prior to this work, there were no data for lower  $L/D$ . The implications of the low-aspect-ratio bearings are that the task becomes one of supporting a *disk* rather than a *shaft*.

In fact, the low-aspect-ratio bearings do not have terrible performance by any standard. The key features of the low  $L/D$  bearings are

- The load capacity is reduced compared to “conventional” designs. This is because the fluid leaking out of the ends relieves any tendency for the bearing to build up a pressure distribution. Thus, for a given geometry and speed, a short bearing supports a lower load (per unit length) than its longer counterpart.
- The bearing acts as an incompressible bearing over a wide range of operation. The reason for this is as above—pressure rises, which might lead to gas compressibility, are minimized by the flow leaking out of the short bearing. The implication of this is that incompressible behavior (without, of course, the usual fluid cavitation commonly assumed in incompressible liquid bearings) can be observed to relatively high speeds and eccentricities.

### 9.7.2 Minimum Etchable Clearance

It is reasonable to question why one could not fabricate a 300- $\mu\text{m}$ -long “shaft” but with a much smaller diameter and thus greatly enhance the  $L/D$ . For example, a shaft with a diameter of 300  $\mu\text{m}$  would result in a reasonable value for  $L/D$ ; however, this leads us to the second major constraint on bearing design with current microfabrication technologies—that of minimum etchable clearance.

In the current microengine manufacturing process, the bearing/rotor combination is defined by a single deep and narrow etch, currently 300  $\mu\text{m}$  deep and about 12  $\mu\text{m}$  in width. No foreseeable advance in fabrication technology will make it possible to significantly reduce the minimum etchable clearance, which has considerable implications for bearing design. In particular, if one were to fabricate a bearing with a diameter of 300  $\mu\text{m}$  (in an attempt to improve the  $L/D$  ratio), it would result in a bearing with a ratio of clearance to radius ( $c/R$ ) of 12/300, or 0.04. For a fluid bearing, this is *huge* (two orders of magnitude above conventional bearings) and has several detrimental implications. The most severe of these is the impact on the dynamic stability of the bearing. The nondimensional mass of the rotor depends on  $c/R$  raised to the *fifth* power [Piekos, 2000]. Thus, bringing the bearing into the center of the disk and raising the  $c/R$  by a factor of 10 result in a mass parameter increasing by a factor of  $10^5$ . This increase in effective mass has severe implications for the stability of the bearing that are difficult to accommodate.

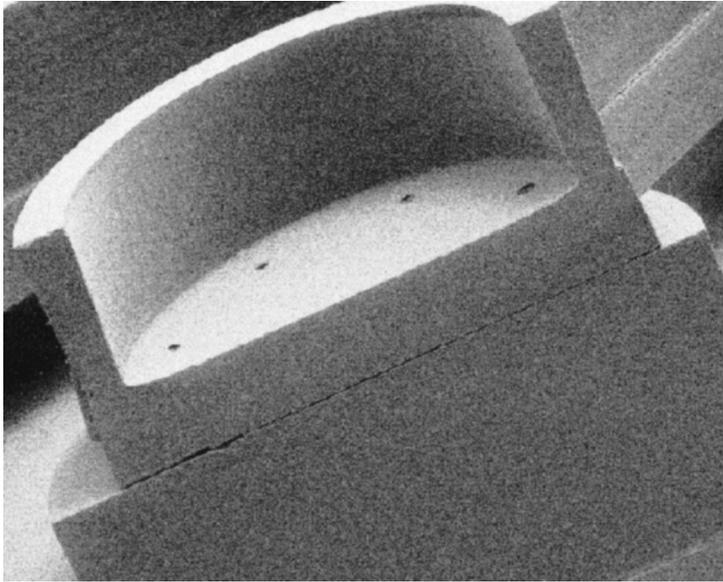

All of these factors, and others not enumerated here (such as the issue of where to locate the thrust bearings), make the implementation of an inner-radius bearing less attractive; thus, the constraint of small  $L/D$  is, in our opinion, unassailable as long as one requires that the microdevice be fabricated *in situ*. If one were to imagine a change in the fabrication process such that the rotor and bearing could be fabricated separately and subsequently assembled (*reliably*), this situation would be quite different. In such an event, the bearing gap is not constrained by the minimum etch dimension of the fabrication process, and almost any “conventional” bearing geometry could be considered and would probably be superior in performance to the bearings discussed here. Such fabrication could be considered for a “one-off” device but does not appear feasible for mass production, which relies on the monolithic fabrication of the parts. Finally, the risk of contamination during assembly—a common concern for all precision-machined MEMS—effectively rules out piece-by-piece manufacture and assembly and again constrains the bearing geometry as described.

## 9.8 Thrust Bearings

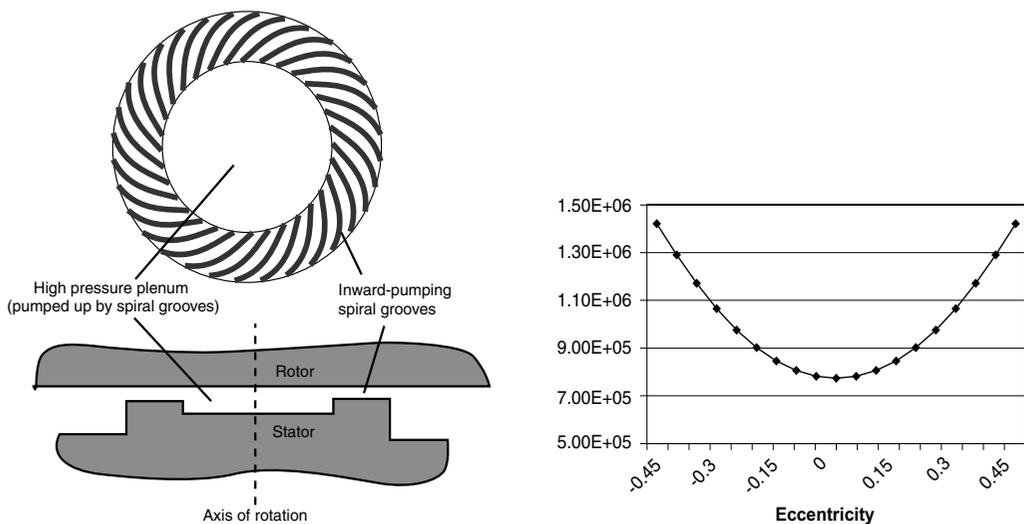

---

Thrust bearings are required to support any axial loads generated by rotating devices, such as turbines, engines or motors. Current fabrication techniques require that the axis of rotation in MEMS devices lie normal to the lithographic plane. This immediately lends a significant advantage to the design and operation of thrust bearings, as the area available for the thrust bearing is relatively large (defined by lithography), while the weight of the rotating elements will be typically small (due to the cube-square law and the low thicknesses of microfabricated parts). For these reasons, thrust bearings are one (rare) area of microlubrication where solutions abound and problems are dealt with relatively easily.

Two options exist: (1) hydrostatic (externally pressured) thrust bearings, in which the fluid is fed from a high-pressure source to a lubrication film, and (2) hydrodynamic, where the supporting pressure is generated by a viscous pump fabricated on the surface of the thrust bearing itself (see Figure 9.9). Hydrostatic bearings are easy to operate and relatively easy to fabricate. These have been successfully demonstrated in the MIT Microengine program [Fr chet te et al., 2000]; the thrust bearing is shown in Figure 9.8, which shows an SEM of the fabricated device cut through the middle to reveal the plenum, restrictor holes and bearing lubrication gap, which is approximately 1  $\mu\text{m}$  wide. Key to the successful operation of hydrostatic

**FIGURE 9.8** Close-up cutaway view of microthrust bearing showing the pressure plenum (on top), feed holes and bearing gap (faintly visible). (SEM courtesy of C.-C. Lin.)

**FIGURE 9.9** Schematic of hydrodynamic thrust bearings and predicted performance (stiffness, in N/m, vs. axial eccentricity) for a typical spiral-groove thrust bearing for use in a high-speed MEMS rotor.

thrust bearings is the accurate manufacture of the restrictor holes, maintenance of sharp edges at the restrictor exit and carefully controlling the dimension of the lubrication film. In an initial fabrication run, the restrictor holes were fabricated  $2\ \mu\text{m}$  larger than specified. While the bearing operated, its performance was well below its design peak, due to the off-design restrictor size. Current specifications of the fabrication protocols control the restrictor size carefully, ensuring close to optimal operation.

Hydrodynamic, or spiral groove, bearings (SGB; illustrated in [Figure 9.9](#)) were first analyzed in some detail some 40 years ago [Muijderman, 1966] but have not received much attention due to their low load capacity (compared to hydrostatic thrust bearings) and complex manufacturing requirements.

Spiral groove bearings operate by using the rotor motion against a series of spiral grooves (etched in the bearing) to viscously pump fluid into the lubrication gap and thus create a high-pressure cushion on which the rotor can ride. The devices typically have relatively low load capacity, which has limited their use in macroscopic applications. However, the load capacity becomes more than adequate at microscales due to favorable cube-square scaling. Thus, they gain considerable advantage when compared with conventional hydrostatic thrust bearings as the scale (and Reynolds number) decreases. In addition, the fabrication of the multitude of shallow spiral features (which is an expensive task for a traditional SGB) is ideally suited for lithographic fabrication technologies such as MEMS. [Figure 9.9](#) illustrates the bearing stiffness for a single-point design for the MIT microrotor rotating at design speed (2.4 million rpm) and supported by matched forward and aft spiral groove bearings. The stiffness at full speed is quite impressive (superior to comparable hydrostatic bearings), but the SGB do suffer at lower speeds as the bearing stiffness is roughly proportional to rotational speed. However, for this design, the lift-off speed (the speed at which the film can support the weight of the rotor and the pressure distribution associated with the turbine flow) is only a few thousand rpm, so the dry rubbing endured during startup will be minimal. They also have the strong advantage that the two matched spiral groove bearings (forward and aft) naturally balance each other (no supply pressures to maintain or adjust). Also, and most importantly, removal of the thrust bearing plena and restrictor holes considerably simplifies the overall device fabrication and can allow for the use of two fewer wafers in the wafer-bonded stack—a considerable advantage from the perspective of manufacturing process cost and yield.

## 9.9 Journal Bearings

---

Journal bearings, which are used to support radial loads in a rotating machine, have somewhat unusual requirements in MEMS deriving from the extremely shallow structures that are currently fabricated. Thus, rotating devices tend to be disk shaped, and their corresponding journal bearings are characterized by very low aspect ratios, defined as the ratio of the bearing height to its radius. In addition, the minimum etchable gap allowed by current (and foreseeable) fabrication techniques results in a paradoxically large bearing clearance—a  $10\text{-}\mu\text{m}$  gap over a  $2\text{-mm}$ -radius rotor, or a  $c/R$  of  $1/200$ , which is large in comparison to conventional journal bearings, which typically have  $c/R$  ratios lower by a factor of 10. Journal bearings can operate in two distinct modes: hydrodynamic and hydrostatic, although typically any operating condition will contain aspects of both modes. Each of these modes is discussed in the following sections.

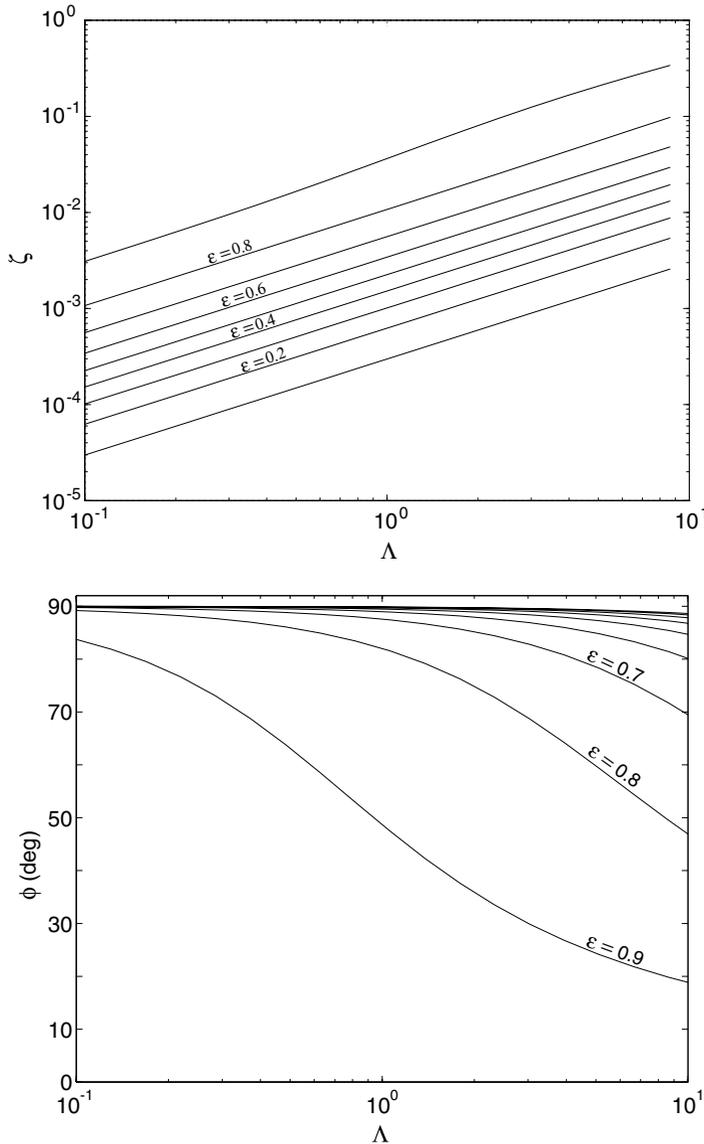

### 9.9.1 Hydrodynamic Operation

Hydrodynamic operation occurs when the rotor is forced to operate at an eccentric position in the bearing housing. As a consequence of this, a pressure distribution develops in the gap to balance the viscous stresses that arise due to the rotor motion. This pressure distribution is used to support the rotor both statically (against the applied force) and dynamically (to suppress random excursions of the rotor due to vibration etc.). Hydrodynamic operation has the advantage that it requires no external supply of lubrication fluid; however, it has two distinct drawbacks: First, it requires a means to load the rotor to an eccentric position, and, second, insufficient eccentricity results in instability (the so-called “fractional speed whirl”) and likely failure. Both of these issues are particularly difficult to resolve in the case of MEMS bearings.

### 9.9.2 Static Journal Bearing Behavior

The static behavior of a MEMS journal bearing is shown in Figure 9.10, which presents the load capacity  $\zeta$  and the accompanying attitude angle (the angle between the applied load and the eccentricity vector) as functions of the bearing number and the operating eccentricity. The geometry considered here is for a low-aspect-ratio bearing ( $L/D = 0.075$ ) typical of a deep reactive ion-etched rotor such as the MIT Microengine. The bearing number is defined as:

$$\Lambda = \frac{6\mu\omega}{p} \left[ \frac{R}{c} \right]^2$$

**FIGURE 9.10** Static performance (eccentricity and attitude angle vs. bearing number) for a journal bearing with  $L/D = 0.075$ . Notice that the load lines are almost constant (linear), indicating the absence of compressibility effects. This is also indicated by the attitude angle, which remains close to  $90^\circ$  except at very high eccentricities. (From Piekos, E.S., and Breuer, K.S. (1999) *J. Tribol.* **121**, pp. 604–609, ASME, New York. With permission.)

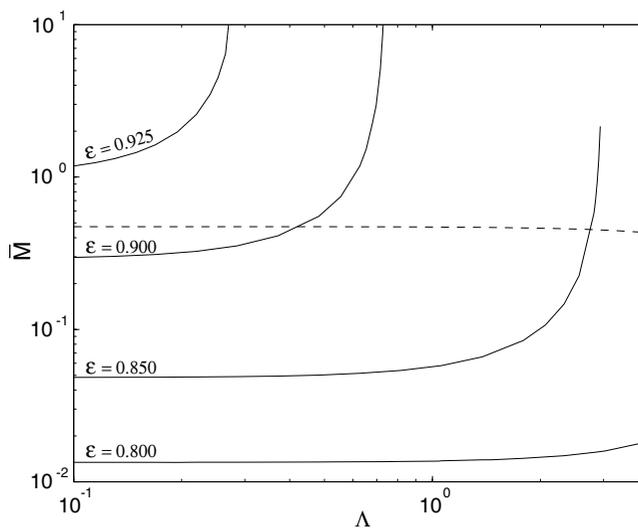

where  $\mu$  is the fluid viscosity,  $\omega$  the rotation rate,  $p$  the ambient pressure and  $R/c$  the ratio of the radius to clearance. For a given bearing geometry,  $\Lambda$  can be interpreted as operating speed.

Several aspects of these results should be noted. First, the load capacity is quite small when compared with bearings of higher  $L/D$ . As mentioned before, this is due to the fact that, for very short bearings, the applied load simply squeezes the fluid out of the bearing ends, which has difficulty developing significant restoring force. The same mechanism is responsible for the fact that the load lines are straight, indicating that little compressibility of the fluid is taking place (which usually results in a “saturation” of the load parameter at higher values of the bearing number). Again, this is because any tendency to compress the gas is alleviated by the fluid venting at the bearing edge. This point is driven home by the behavior of the attitude angle, which maintains a high angle (close to  $\pi/2$ ) over a wide range of bearing numbers and eccentricities. This value of the attitude angle corresponds to the analytic behavior of a Full-Sommerfeld incompressible short bearing [Orr, 1999], which clearly is a good approximation for such short bearings at low to moderate eccentricities, so long as the eccentricity remains below approximately 0.6, at which point compressibility finally becomes important. This incompressible behavior is much more extensive than “conventional” gas bearings of higher aspect ratio and has profound ramifications, particularly with respect to the dynamic properties of the system.

### 9.9.3 Journal Bearing Stability

The stability of a hydrodynamic journal bearing has long been recognized as troublesome and is foreshadowed by the static behavior shown in Figure 9.10. The high attitude angle suggests that the bearing spring stiffness is dominated by cross stiffness as opposed to direct stiffness. Thus, any perturbation to the rotor will result in its motion perpendicular to the applied force. If this reaction is not damped, the rotor will enter a whirling motion. This is precisely what is observed, and gas bearings are notorious for their susceptibility to fractional-speed whirl. The instability is suppressed by the generation of more damping and/or increased direct stiffness, both of which are obtained by increasing the loading and the static eccentricity of the rotor.

Figure 9.11 shows a somewhat unusual presentation of the stability boundaries for a low-aspect-ratio MEMS journal bearing. The vertical axis shows the nondimensional mass of the rotor,  $\bar{M}$ , which is

**FIGURE 9.11** Stability boundaries for a typical microbearing, plotted vs. bearing number (speed for a fixed geometry). The dotted line represents an operating line for a microbearing that has almost constant  $\bar{M}$  (varying only due to centrifugal expansion of the rotor at high speeds) [Piekos, 2000].

defined as:

$$\bar{M} = \frac{mp}{72L\mu^2} \left[ \frac{c}{R} \right]^5$$

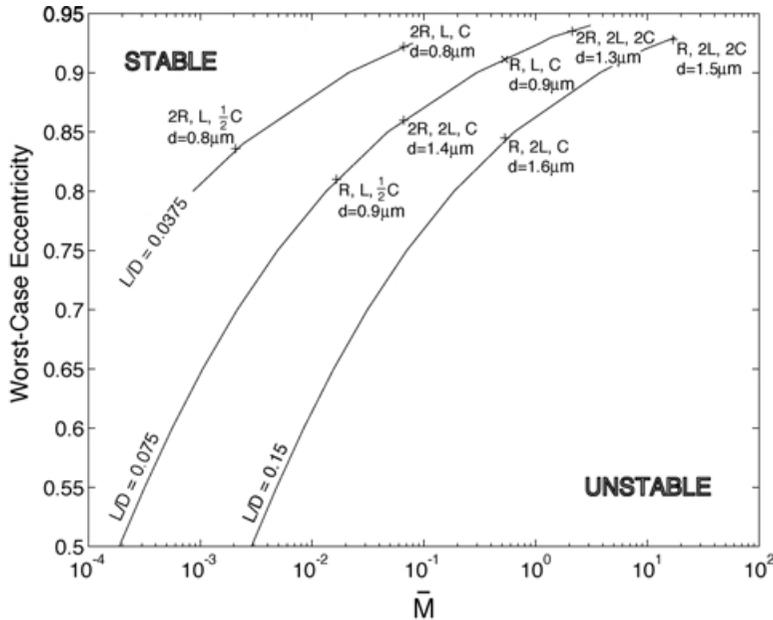

This is the “mass” that appears in the nondimensionalized equations of motion for the rotor, and it is fixed for a given geometry (close inspection of Figure 9.11 indicates that  $\bar{M}$  does change very slightly with speed due to elastic expansion of the rotor due to centrifugal forces, the variation in the ambient pressure at different speeds and temperature effects on viscosity). The horizontal axis of Figure 9.11 shows the bearing number, which can be interpreted as speed, for a fixed-bearing geometry. The contours on the graph represent the stability boundary at fixed eccentricity. Stable operation lies above each line. Thus, for a fixed  $\bar{M}$  at low bearing number (i.e., speed), a minimum eccentricity must be obtained to ensure stability. As the speed increases, this minimum eccentricity remains almost constant (the lines are horizontal) until a particular speed, at which point the lines break upward and the minimum eccentricity required for stability starts to drop (note that as  $\Lambda$  increases the load required to maintain a fixed eccentricity increases linearly due to the stiffening of the hydrodynamic bearing, as indicated by Figure 9.10). The key feature of this chart is that the minimum eccentricities are *very* high and suggest that stable operation requires running very close to the wall, which is troublesome. The high eccentricities are driven by high values of the mass parameter  $\bar{M}$ , which is due to the relatively high value of the clearance-to-radius ratio ( $c/R$ ) and the short length  $L$ . The low aspect ratio ( $L/D$ ) also contributes to high minimum eccentricities. At high speeds, the problem becomes less severe, as the high speed has allowed the bearing to generate sufficient direct stiffness. However, even at these points, the eccentricity is very high and may not be manageable in practical operation.

Orr (1999) has demonstrated, on a scaled-up experimental rig that matches the microengine geometry, that stable high-eccentricity operation is possible for extended periods of time. His experiments achieved 46,000 rpm, which when translated to the equivalent speed at the microscale corresponds to approximately 1.6 million rpm. However, in order to accomplish this high eccentricity operation, he noted that the rotor system must (1) have very good axial thrust bearings to control axial and tipping modes of the rotor system, and (2) be well balanced—a rotor with imbalance of more than a few percent could not be started from rest. Piekos (2000) also explored the tolerance of the microbearing system to imbalance and found that it was surprisingly robust to imbalance of several percent. However, his computations were achieved assuming that the rotor was at full speed and then carefully subjected to imbalance. In practice, the imbalance will exist at rest and so it might well be the case that the rotor is stable at full speed but unable to accelerate to that point. This “operating line” issue is discussed in some more detail by Savoulides et al. (2001), who explored several options for accelerating microbearings from rest under both hydrodynamic and hydrostatic modes of operation.

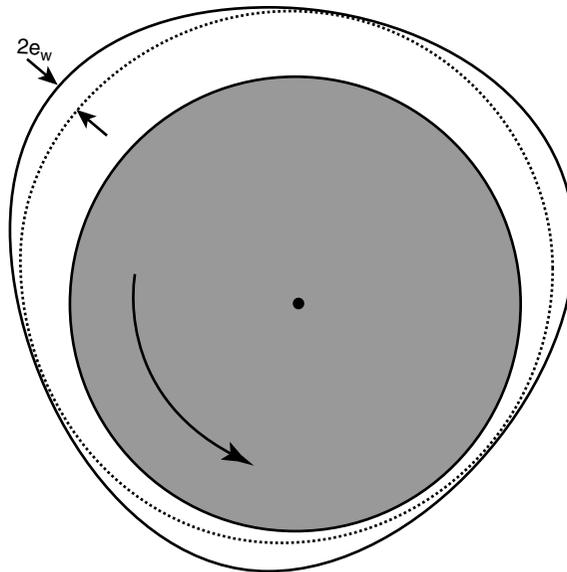

A convenient summary of the trade-offs for design of a hydrodynamic MEMS bearing is shown in Figure 9.12. This presents the variation of the low-speed minimum eccentricity asymptote (or worst-case eccentricity, as demonstrated in Figure 9.11) as functions of the mass parameter  $\bar{M}$  and other geometric factors ( $L/D$ , clearance  $c$  etc.). Notice that the worst-case eccentricity improves as the  $L/D$  increases and the  $\bar{M}$  decreases. However, it is interesting to note that the physical running distance from the wall is actually increased (slightly) by running at a higher eccentricity, but with a larger bearing gap. In all cases, however, the stable eccentricity is alarmingly high and other alternatives must be sought for simpler stable operation.

### 9.9.4 Advanced Journal Bearing Designs

One prospect for further improvement in the journal bearing performance is the incorporation of “wave bearings” [Dimofte, 1995], as illustrated in Figure 9.13. These bearing geometries have been demonstrated to suppress the subsynchronous whirl due to the excitation of multisynchronous pressure perturbations imposed by the bearing geometry. As an added attraction, the geometric complexity of the wave bearing is no problem for lithographic manufacturing processes such as are used for MEMS, thus alleviating many of the reservations and cost that might inhibit their adoption. However, because the MEMS constraint is the minimum gap dimension, the wave bearing in a MEMS machine can only be implemented by

**FIGURE 9.12** Trade-off chart for microbearing design. For a given length-to-diameter ratio ( $L/D$ ) and a given  $\bar{M}$ , the worst-case (i.e., low-speed) eccentricity is shown for a variety of geometric perturbations. In general, lower eccentricities are preferred [Piekos, 2000].

**FIGURE 9.13** Geometry of a wave bearing, with the clearance greatly exaggerated for clarity [Piekos, 2000].

selectively enlarging the bearing gap. Piekos (2000) has analyzed the performance of the wave bearing for the microengine geometry and has found (Figure 9.14) that, while the load capacity is diminished, the stability is enhanced (as expected) and the load required to maintain stable operation (i.e., to achieve the minimum stable eccentricity) is reduced considerably with the introduction of a wave geometry. In microbearings, the load capacity is usually quite sufficient (the cube-square law to our rescue!), thus the wave bearing looks very attractive as a stabilizing mechanism.

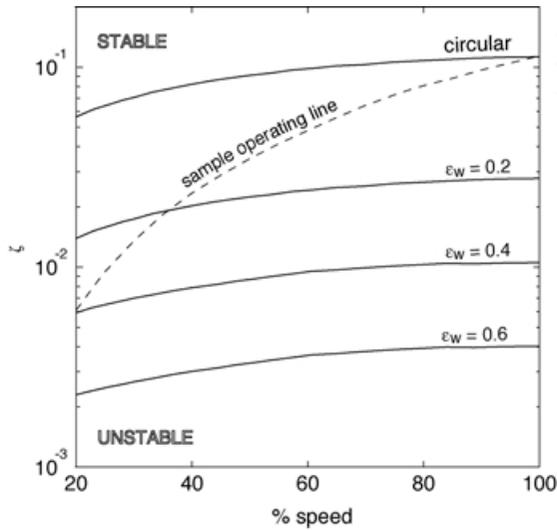

FIGURE 9.14 Effect of wave-bearing amplitude on journal-bearing stability as a function of rotor speed. The dotted line shows a typical operating line for a microengine [Piekos, 2000].

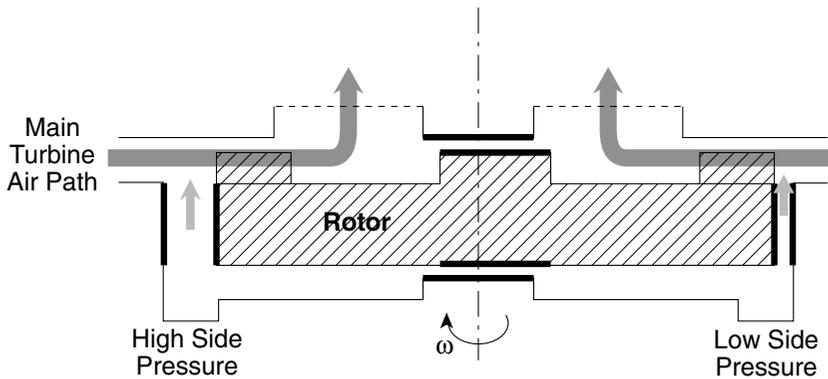

FIGURE 9.15 Schematic of the pressure-loading scheme used in the microengine to provide a side load to the rotor during hydrodynamic operation. The side load is developed by applying a differential pressure to the two plena located on the aft side of the rotor.

Having said that, rotor imbalance, which is increasingly becoming a first-order issue, can only be contained with excess load capacity, so this trade-off is by no means clear. The adoption and testing of wave-bearing geometries are scheduled to be explored in the near future as part of our development program.

### 9.9.5 Side Pressurization

Due to the small mass of the rotor in a MEMS device, any eccentricity required to enable stable hydrodynamic operation *must* be applied using some other means. Typically, this requires the use of a pressure distribution introduced around the circumference of the bearing, which serves to load the bearing preferentially to one side. Such a scheme is illustrated in Figure 9.15 for the MIT Microengine. Here, the aft side of the rotor is divided into two plena, isolated by seals. Each plenum can be separately pressurized. The pressure in each plenum forces an axial flow through the journal bearing to the forward side (which is assumed to be at a uniform pressure) and establishes two differing pressure distributions on the

high- and low-pressure sides of the rotor. Of course, nothing comes without its consequences, and the axial flow through the bearing has consequences of its own—the generation of a hydrostatic stiffness mechanism and an associated hydrostatic critical frequency, discussed in the following section.

### 9.9.6 Hydrostatic Operation

Although hydrodynamically lubricated bearings with low aspect ratio are predicted to operate successfully and have now been demonstrated on a scaled-up level [Orr, 1999], a number of issues make them undesirable in a practical MEMS rotor system. The primary difficulty is that in order to satisfy the requirements of subsynchronous stability, the rotor needs to operate at very high eccentricity (made unavoidable due to the low aspect ratio of the journal). For a MEMS device, this means operating 1 to 2  $\mu\text{m}$  from the wall. This is hard to control, particularly with the limited available instrumentation that plagues MEMS devices. An alternative mode of operation is to use a hydrostatic lubrication system. In this mode, fluid is forced from a high-pressure source through a series of restrictors, each of which imparts a fixed resistance. The fluid then flows through the lubrication passage (the bearing gap). If the rotor moves to one side, the restrictor/lubrication film acts as a pressure divider such that the pressure in the lubrication film rises, forcing the rotor back toward the center of the bearing. The advantages of using hydrostatic lubrication in MEMS devices include:

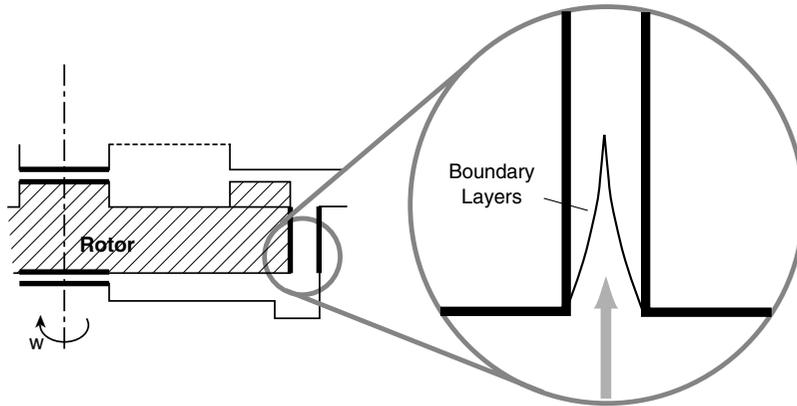

- The rotor tends to operate near the center of the housing, thus small clearances are avoided. This is “safer,” being far more tolerant of any motion induced by rotor imbalance, and results in lower viscous resistance.
- Because the hydrostatic system is a zero-eccentricity-based system, no position information about the rotor is needed. This greatly simplifies instrumentation requirements.

Significant disadvantages to a hydrostatic system include:

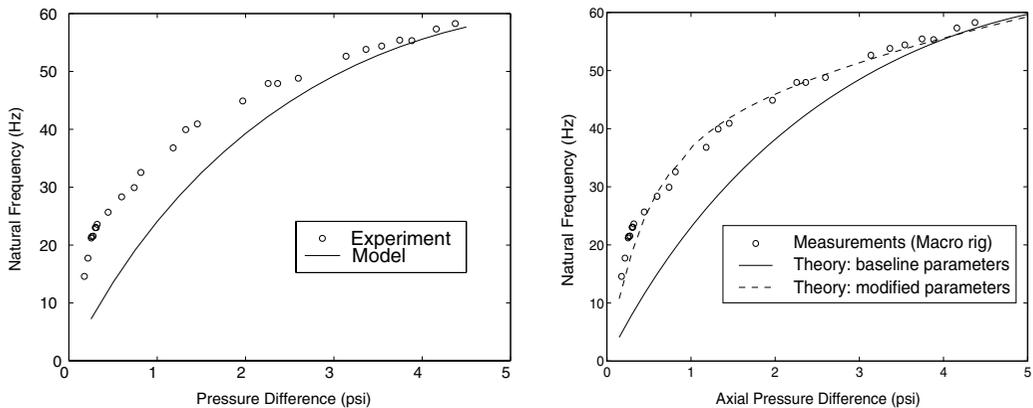

- Pressurized air must be supplied to the bearing. This requires supply channels, which complicate the fabrication process. This requirement also comes with a system cost—the high-pressure air must come from somewhere (in a turbomachinery application, bleed air from the compressor could be used).
- Because the bearing gaps are relatively large (due to minimum etchable dimensions discussed above), the mass flow through hydrostatic systems can be substantial and might be impractical in anything but demonstration experiments.
- Fabrication constraints make the manufacture of effective flow restrictors very difficult. Flow restrictors must have very well-controlled dimensions and sharp edges, as well as other specific geometric features. Only the simplest restrictors can be implemented without undue cost and effort, severely limiting the hydrostatic design.

For journal bearings with low aspect ratio, a novel method for achieving hydrostatic lubrication was demonstrated by Orr et al. (2000). The mechanism relies on the fact that small pressure differences will inevitably exist between the forward and aft sides of the rotor and that, for a short bearing of the kind seen in MEMS devices, the flow resistance to that pressure differences is small enough that an axial flow will ensue.

As the flow enters the bearing channel, boundary layers develop along the wall, eventually merging to form the fully developed lubrication film. This boundary layer development (Figure 9.16) acts as an inherent restrictor so that if the rotor moves off the centerline and disturbs the axisymmetric symmetry of the flow, a restoring force is generated. This source of hydrostatic stiffness acts to support the bearing at zero eccentricity and is effective even when the rotor is not moving. The stiffness is also enhanced by the conventional inherent restriction of the flow entering the lubrication channel. The stiffness coupled with the rotor mass defines a natural frequency which was measured by Orr (1999) (indeed the presence of this frequency led to the discovery of the axial-through-flow mechanism). Simple theory [Orr et al., 2000]

**FIGURE 9.16** Schematic illustrating the origin of the axial-through-flow hydrostatic mechanism.

**FIGURE 9.17** Prediction and measurement of natural frequency associated with axial through-flow in a low-aspect-ratio microbearing. The left-hand figure shows the measurements (from a 26:1 scaled-up experimental rig) along with the theoretical predictions based on the assumed geometry, while the right-hand figure shows the same measurements compared with the same model but using slightly modified geometric parameters [Orr et al., 2000].

was also able to predict the frequency (in a scaled-up experimental facility) with reasonable accuracy (Figure 9.17). However, at this writing, there is a severe gap between our ability to accurately predict and account for all the hydrostatic lubrication phenomena in a real microrotor. Nevertheless, experiments conducted at the microscale [Fr chet te et al., 2000] demonstrate successful operation at high speeds (1.4 million rpm at the time of writing), despite theoretical predictions of failure! Indeed, experimental measurements suggest that both the natural frequency is higher than predicted by the simple axial-through-flow theory of Piekos (2000) and that the damping is sufficient to operate at critical speed ratios (rotor frequency, scaled by the natural frequency of the hydrostatic system) greater than 10. Conventional analysis [Savoulides, 2001] suggests that the instability occurs at critical speed ratios of 2, and this discrepancy suggests that the real bearing exhibits significantly higher damping than is accounted for by the theory, perhaps deriving from the turbine which drives the rotor or some other source of fluid damping, not yet considered. Resolution of these discrepancies clearly requires more attention and will be aided greatly by improved models as well as more detailed measurements of the microrotor in operation.

## 9.10 Fabrication Issues

---

A key challenge to the successful operation of a high-speed microbearing is the accurate fabrication of bearing geometries. Two aspects of this need to be considered: the need to hold design tolerances in any given fabrication process and the ability to manufacture multiple devices with good uniformity in a single fabrication run.

The first issue, that of achieving design tolerances, is a matter of process maturity, and the attention paid to the maintenance of tight tolerances and small details is the hallmark of a well-established fabrication process. The microengine process is *very* complex and continually advances the state of the art in micro-machining complexity. Almost any fabrication run that results in a freely rotating turbine should deservedly be considered a manufacturing triumph. However from the standpoint of the success of the *system*, we must have much more stringent manufacturing requirements. The bearing designs are very sensitive to critical dimensions such as the bearing-rotor gap and the size of restrictor holes for hydrostatic injectors, and the failure to hold these dimensions within a specified tolerance can make the difference between a device that operates with a lubricated film and one that grinds the rotor and stator surface until failure. The very first version of the microbearing rig ran in just this mode, with very occasional demonstrations of lubricated operation. However, subsequent designs and builds have paid extreme attention to dimensional accuracy, and the fabrication protocols at this stage are quite mature so that this precision is ensured from one build to the next.

### 9.10.1 Cross-Wafer Uniformity

Typically, multiple microengines are fabricated in parallel on a single silicon wafer. Thus, in addition to the accurate manufacture of critical dimensions on a single microengine die, manufacturing uniformity from one die to the next on a single wafer is vital and has revealed itself to be a major obstacle to device yield. It is very common for a given process to exhibit cross-wafer variations. For example, a shallow plasma etch into a silicon substrate might show a variance of as much as 10% from one side of the wafer to the other due to variations in the plasma that are intrinsic to the fabrication tool. All fabrication processes will exhibit such variations to one degree or another, and any microfabrication process should identify and accommodate these variations. Should they be unacceptably large, either the fabrication tool must be improved or a different processing path needs to be considered. This need is a common driver throughout both the MEMS and microelectronics industry (which also desires greater process uniformity as feature size diminishes and processing moves to larger and larger wafers).

As discussed above, for microbearing design several critical etches must be controlled to a high degree of precision. The difficulty in maintaining cross-wafer uniformity thus results in some operational devices on the wafer (typically from the center of the wafer, where the process was initially honed to precision), while many devices (from the wafer edge) are out of spec and will not operate satisfactorily. At this stage, most of the uniformity issues have been addressed; however, two items are still troublesome. First, the DRIE, being a relatively new tool (perhaps 5 years in maturity), exhibits a fairly significant variation in etch rate between the center and edge of a wafer. This variation results in a gradient in etch depth that is particularly severe on devices lying on the wafer periphery (perhaps 3- $\mu\text{m}$  variation across a 4-mm rotor wheel). This gradient may not seem important, but it contributes to a mass imbalance of as much as 25% of the bearing gap, rendering the bearing inoperable at high speed (the imbalance force increases with the square of the rotational speed).

The second continuing difficulty is that of front-to-back mask alignment during fabrication. It is common during the fabrication process for a single silicon wafer to be patterned on both the front and back surfaces. For example, the rotor has the turbine blades patterned from one side and the bearing gap patterned from the other side. Any slight misalignment between the lithography on the front and back surfaces of the wafer will result in an offset of front and back features which, as with the etch-depth gradient, leads to a rotor imbalance. At the present, mask alignment of critical features (primarily the rotor blades and the bearing gap) must be maintained to within 0.5  $\mu\text{m}$  or better in order to ensure

operable rotors from every die on the wafer. This is an extremely tight, but achievable, tolerance and work continues to improve the alignment even further and to improve process design to minimize imbalance.

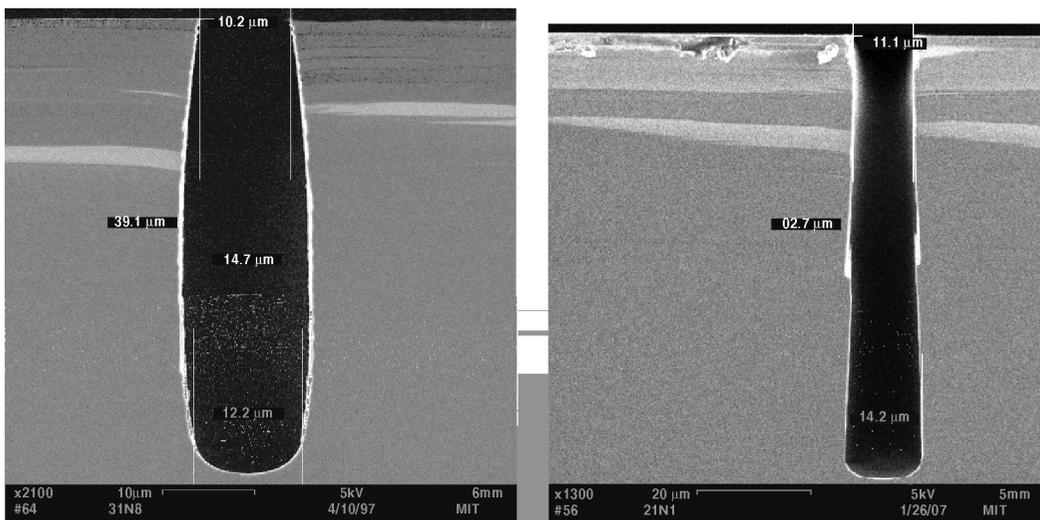

### 9.10.2 Deep Etch Uniformity

The last issue for fabrication precision is that of deep-etch uniformity. Any high-speed bearing depends critically on the straightness and parallelism of the sidewalls that constitute the bearing and rotor surfaces. This is particularly true for hydrodynamic operation at high eccentricity. Unfortunately, in the drive to generate deep trenches so that the bearing aspect ratio is minimized, the quality of the bearing etch is often compromised. These two issues—the etch depth and the etch quality—constantly pull against each other, and their relative advantages need to be weighed against each other in any final design.

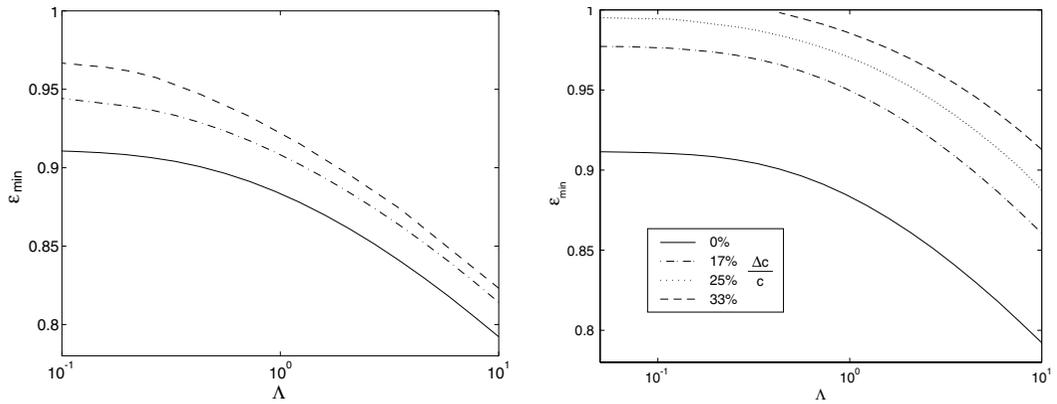

For DRIE, typical nonuniform etch profiles shown in [Figure 9.18](#) illustrate two common phenomena—etch bow (where the trench widens in the middle) and etch taper (where the trench widens, usually at the bottom). The effects of these nonuniformities have been analyzed computationally [Piekos, 2000]. As one might expect, the static performance of the bearing (load capacity) is degraded by the blow-out, particularly in the case of the tapered bearing where fluid pressure cannot accumulate in the gap but rather leaks out the enlarged end. The bowed bearing, due to its concave curvature, tends to “hold” the pressure a bit more successfully, and the loss in load capacity is typically less severe. However, as mentioned earlier, load capacity is less of an issue in microbearings, and it is the effect on hydrodynamic stability that is of most interest. The effects of bow and taper on hydrodynamic operation are summarized in [Figure 9.19](#), which shows the minimum stable eccentricity as a function of bearing number (i.e., speed, for a fixed bearing geometry) for different levels of both bow and taper. Clearly, the effects of taper are most severe, and considerable effort has been spent in the fabrication process design to minimize bearing taper.

### 9.10.3 Material Properties

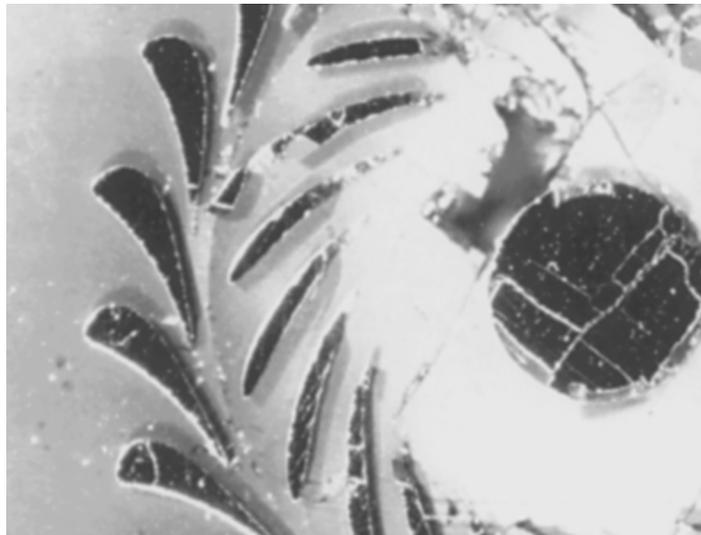

One of the key benefits that can be realized at the microscale is the improvement in strength-related material properties. This is particularly true in silicon-based MEMS where the baseline structural material is single-crystal silicon, which can be fabricated to have very good mechanical properties. The strength of brittle materials is controlled primarily by flaws and to some extent by grain boundaries, both of which

**FIGURE 9.18** SEMS of bearing etches, illustrating typical manufacturing nonuniformities. The left-hand SEM shows an etch with a bow in the center, while the right-hand SEM shows an etch with a taper. (SEMs courtesy of A. Ayon.)

**FIGURE 9.19** Degradation of hydrodynamic stability due to bow (left) and taper (right), as indicated by the minimum eccentricity required for hydrodynamic stability at a given bearing number (speed) [Piekos, 2001].

**FIGURE 9.20** Photograph of the remains of a silicon rotor after experiencing a high-speed crash. The instant fracture of the rotor (largely along crystallographic planes) is clearly visible.

become smaller or nonexistent in a single-crystal material with surfaces defined by microfabrication processes. In addition, the device size becomes comparable with the flaw distribution, such that the incidence of “super-strong” devices increases in microscale systems. Finally, silicon is a light material with a density ( $2330 \text{ kg/m}^3$ ) lower than that of aluminum ( $2700 \text{ kg/m}^3$ ). For these reasons, the strength-to-weight ratio of silicon micromachined structures is unparalleled, which is a key for high-speed rotating machinery. However, notwithstanding its high specific strength, silicon is still a very brittle material. For a high-speed rotating system, such as a turbine, this can be problematic, as an impact or touchdown at any appreciable speed is likely to result in a catastrophic failure rather than an elastic rebound or more benign plastic deformation. This is illustrated in [Figure 9.20](#), which shows a photograph of a microturbine rotor that crashed during a high-speed test run. The importance of robust bearings is emphasized, as the material is extremely unforgiving.

## 9.11 Tribology and Wear

---

When lubrication fails, tribology and wear become important as our focus shifts from the prevention of contact to mitigation of its effects. Clearly, tribology has been a subject of technical and industrial importance since the industrial revolution, and a certain level of accomplishment has allowed the design and operation of complex machinery in difficult environments. With the advent of microengineering (and the development of the atomic force microscope), the field has defined a new set of problems and has witnessed a rebirth with a focus on the micro- and nanoscale processes associated with friction and wear. This chapter will not address in any complete manner the progress in micro- and nanotribology. However, a few general comments can be made that are of value in practical MEMS devices.

### 9.11.1 Stiction

A common problem associated with the failure of MEMS devices is that of stiction, in which two surfaces touch and stick together due to the high surface energies, high areas in close contact and small separating gaps. The problem is exacerbated by the use of wet etching during fabrication and by the relatively smooth surfaces (and thus high contact areas) associated with MEMS materials. Many lubricants have been used to mitigate the problem. Self-assembling monolayers (SAMs), such as perfluoro-decyl-trichlorosilane, coat the surface with a monolayer of a long molecule, which adheres to the surface at one end and is hydrophobic at the other end (thus preventing stiction). Other lubricants are also under investigation, such as Fomblin-Zdol, which is used in the hard-disk industry to protect the disk surface during head crashes and can be vapor deposited during manufacture. Other remedies include the intentional design of textured surfaces or standoffs to prevent large areas from coming into direct contact.

### 9.11.2 The Tribology of Silicon

Because most MEMS devices are silicon based, the tribology of silicon has received considerable attention in the past several years. By itself, silicon is not a very desirable bearing material (see, for example, Gardos, 2001) and exhibits high wear rates, high coefficients of friction and poor stiction characteristics. Surface treatments (e.g., silicon carbide, fluorocarbon or Teflon<sup>TM</sup>-like materials) have been demonstrated to improve matters considerably, as well as appropriate design. However, most MEMS have not *yet* been designed with significant surface motions that require either supporting lubrication films or protective coatings. This is likely to change as fabrication processes enable more complex devices with higher power densities and more challenging lubrication and wear requirements. In addition, the lifetime and reliability requirements of MEMS are becoming more stringent as devices are being developed for space, medical and national defense applications. Each of these has unique requirements for predicting lifetime, wear and failure, so this oft-neglected corner of the industry will receive the attention it deserves.

## 9.12 Conclusions

---

In this chapter, we have tried to focus on some of the key issues that face us in the design, manufacture and operation of microdevices that must operate with minimal friction or wear. Many of the issues in Couette and squeeze-film lubrication have been successfully addressed, although fundamental surface models (such as gas accommodation coefficients) are still unknown and reliable prediction methods are only just becoming available. Stiction issues remain problematic, although they are dealt with in an engineering manner. As before, increased understanding of surface science is again needed to solve this problem.

Rotating MEMS devices still require much more development before they can be reliably manufactured and used. Even with dramatic advances in lubricant and surface treatment technologies, high-speed operation will likely require gas bearings, which have always offered high-speed, low-wear operation with the attendant cost of a narrow and treacherous window of stable operation. Many of the commonly held

assumptions and design rules that have guided previous fluid-film bearings in conventional machinery have had to be revisited due to the consequences of scaling and the current (and foreseeable) limitations in microfabrication technology.

Future research will focus on many areas. On the manufacturing side, the single largest obstacle to trouble-free production of gas bearings for high-speed rotors and shafts is the issue of precision microfabrication. Macroscopic systems, with typical scale of 1 m, require precision manufacturing, in some places with submillimeter tolerances. So, too, microdevices with typical dimensions of 1 mm will require tolerances of 1  $\mu\text{m}$  or less. The ability to manufacture with such precision will require much improved understanding of micromachining technologies such as etching and deposition so that cross-device and cross-wafer uniformities can be improved.

At the level of lubrication technologies, the new parameter regimes that are exposed by microfabricated systems (very low aspect ratios, relatively large clearances, insignificant inertial properties etc.) must be further explored and understood. Despite the low Reynolds numbers, inertial losses are critically important for hydrostatic lubrication mechanisms and must be better understood and predicted. Similarly, the coupled fluid–structure interactions at high eccentricities and the interactions between hydrodynamic and hydrostatic mechanisms should be more fully explored. Finally, fundamental issues of fluid and solid physics need to be addressed as the scale continues to shrink. Gas surface interactions, momentum and energy accommodation phenomena and the effects of surface contamination (whether deliberate or accidental) all must be rigorously studied so that the macroscopic behavior can be predicted with some certainty. These issues are only going to become more important as manufacturing scales decrease further and as continuum assumptions become more and more problematic.

## Acknowledgments

---

I am indebted to my several friends and collaborators over the years with whom I have been fortunate to work in this exciting area. In particular, the contributions of Errol Arkilic, Stu Jacobson, Fred Ehrlich, Alan Epstein, Luc Fréchette, Peter Kwok, C.-C. Lin, D.J. Orr, Ed Piekos, Nick Savoulides, Marc Weinberg and C.-W. Wong are gratefully acknowledged. Some of the contents of this paper are drawn from a similar chapter, presented at a NIST-sponsored workshop [Hsu, 2001].

### 10.1 Introduction

---

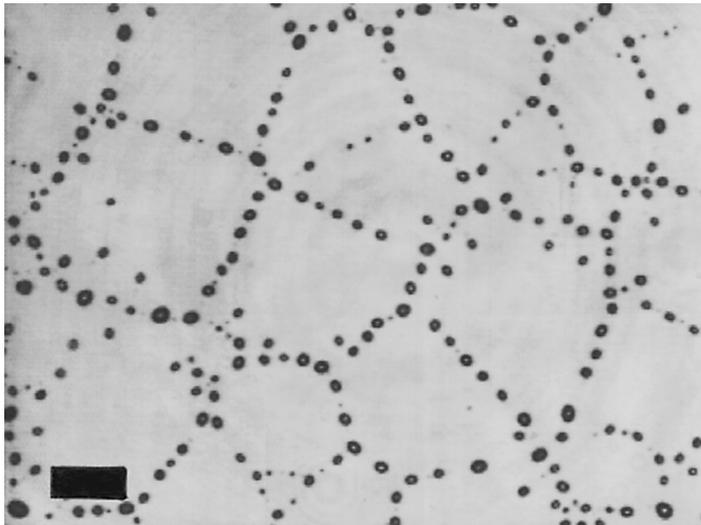

Various aspects of fluid mechanics in microelectromechanical systems (MEMS), such as flows in micro-configurations, flow transducers and flow control by microsystems, were reviewed by Ho and Tai (1998). However, the issue of thin liquid films and their dynamics in the context of microelectromechanical systems was left out of the scope of that important work. This chapter is intended to fill this gap.

Thin liquid films are encountered in a variety of phenomena and technological applications [Myers, 1998]. On a large scale, they emerge in geophysics as gravity currents under water or as lava flows [Huppert and Simpson, 1980; Huppert, 1982]. On the engineering scale, liquid films serve in heat and mass transfer processes to control fluxes and protect surfaces, and their various applications arise in paints, coatings and adhesives. They also occur in foams [Schramm, 1994; Prud'homme and Khan, 1996], emulsions [Ivanov, 1988; Edwards et al., 1991] and detergents [Adamson, 1990]. In biological applications, they appear as membranes, as linings of mammalian lungs [Grotberg, 1994] or as tear films in the eye [Sharma and Ruckenstein, 1986]. On the microscale in MEMS, thin liquid films are used to produce an insulating coating of solid surfaces, to form stable liquid bridges at specified locations, to create networks of microchannels on patterned microchips [Herminghaus et al., 1999; 2000] and to design fluid microreactors [Ichimura et al., 2000].

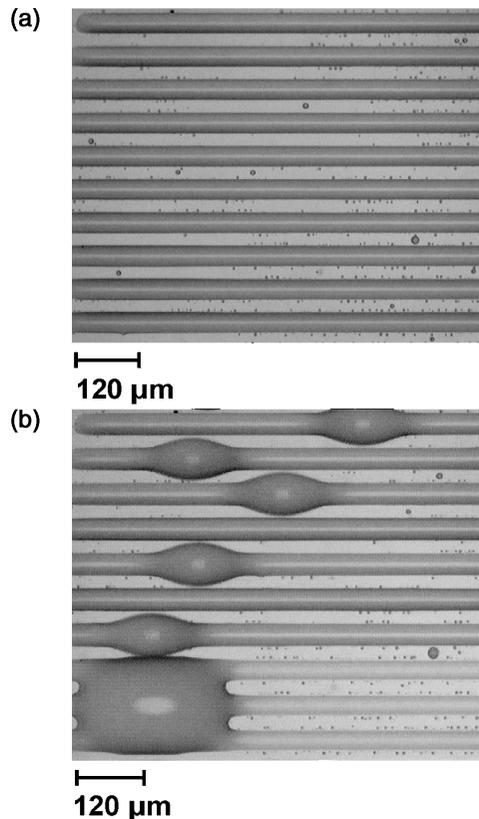

The presence of the deformable interface between the liquid and the ambient (normally gaseous, but possibly also another liquid) phases engenders various kinds of dynamics driven by one or usually several physical factors simultaneously. Liquid films may spontaneously or under the influence of external factors

undergo diverse profound changes in their shapes. These changes are related to different kinds of instability, which may interact. Such interactions may lead either to a mutual enhancement or quenching of each other, so that the overall film dynamics may be rather complex. The film can rupture when its local depth vanishes and dewet the solid leading to holes in the liquid that expose the substrate to the ambient gas. The continuous character of the film changes in this case, if droplets of liquid are detached from the film. Changes in structure may occur in flows with contact lines leading to wavy fronts, fingered patterns or rivulets. Liquid films may be isothermal or subjected to the influence of the temperature field, which normally alters their dynamics. Liquid films may also undergo phase changes, such as mass loss by evaporation, mass gain by condensation or solidification. Liquid films exhibit many fascinating examples of behavior, some of which are presented below.

Sharma and Reiter (1996) studied the process of spontaneous dewetting of thin (less than 60 nm thick) polystyrene films on various coated silicon wafers and found a wealth of types of pattern formation. Different stages of dewetting identified in their experiments were (1) rupture of the film and emergence of holes; (2) expansion of the holes, their coalescence and formation of polygonal cellular pattern, where most of the liquid gathers in the ridges (see also Reiter [1998]); and (3) disintegration of liquid ridges into isolated, ultimately spherical drops. Also, fingering instability of the hole rim during hole expansion was observed on low wettability coatings, which resulted in the emergence of separate drops (see Elbaum and Lipson [1994]). It was found that the growth rate of the initial disturbance, the time of rupture, the number density of holes and the size of the polygons depend *only* on the solid substrate and is independent of the coating. The contact angle, which strongly depends on the choice of the coating layer, was found to affect the generation of droplets via the fingering instability, which is faster for larger contact angles. Also, the size of spherical drops forming as a result of the breakup of the liquid ridges was found to depend on the contact angle. Figure 10.1 displays the final pattern established by a 45-nm-thick liquid polysterene film on a coated silicon wafer, where the average contact angle for this combination of solid and liquid was about 22°. The pattern presented in Figure 10.1 consists of spherical droplets of various sizes aligned along the polygonal structure obtained as a result of the evolution of an initially uniform film that went through all the stages mentioned above. Problems associated with dewetting of solid surfaces by liquid films are discussed below in Section 10.3.

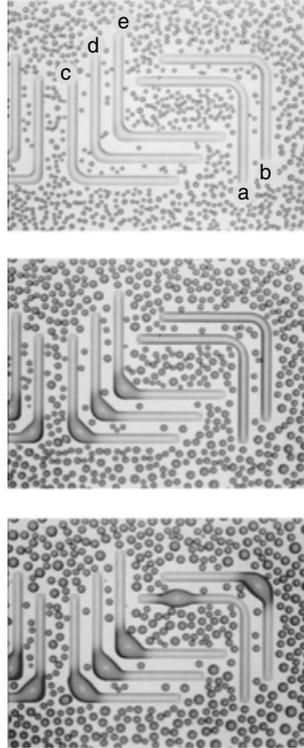

**FIGURE 10.1** Photograph of the final polygonal pattern of spherical droplets for an initially flat polysterene film of mean thickness 45 nm on a coated silicon wafer. For reference, the length of the bar is 70  $\mu\text{m}$ . (From Sharma, A., and Reiter, G. (1996) *J. Coll. Interface Sci.* **178**, 383–399. With permission.)

**FIGURE 10.2** Water condensation on hydrophilic (magnesium fluoride) stripes of an elsewhere hydrophobic (silicone rubber) substrate. (a) Low-condensate-volume regime: The parallel channels of condensed water have a constant cross section and small contact angle; several droplets are also seen on the hydrophobic domains of the substrate. (b) High-condensate-volume regime: Some of the liquid channels develop a single drop when the contact angle exceeds a certain critical value; if two drops are in a close proximity, they merge to form a microbridge between the two neighboring microchannels. (From Herminghaus, S. et al. (2000) *J. Phys. Condens. Matter* **12**, A57–A74. With permission.)

Thiele et al. (1998) carried out experiments with thin (around 10 nm thick) volatile films consisting of collagen solution in acetic acid in various conditions of ambient humidity. For low ambient humidity, and thus a high evaporation rate, the pattern of very small holes along with several large ones was observed, suggesting that the small holes emerged due to polar interactions with the short residence time, while the large holes nucleated because of defects, such as dust particles or imperfections of the substrate. However, when the humidity was high and therefore the evaporation rate was low, the pattern of homogeneous polygonal network with large spacing was found. The large size of the polygons was explained by the long residence time, during which holes created by nucleation were able to open up. The effects associated with evaporation are discussed below in the section dedicated to phase changes.

Figure 10.2 displays the patterns generated by condensation of water on a spatially heterogeneous, solid, poorly wetted (hydrophobic) silicon rubber substrate with well-wetted (hydrophilic) magnesium fluoride stripes. Figure 10.2a shows the intermediate stage of water condensation, in which the liquid phase forms parallel microchannels with a certain contact angle  $\theta$  at the edges of the stripes where the liquid appears to be pinned. The cross section of these microchannels is position independent and represents a circular cap. Several drops of the condensate between the hydrophilic stripes are also observed on Figure 10.2a. When the process of water condensation proceeds further, the contact angle  $\theta$  increases beyond a certain value, and the microchannels undergo morphological change. As a result of this, droplets

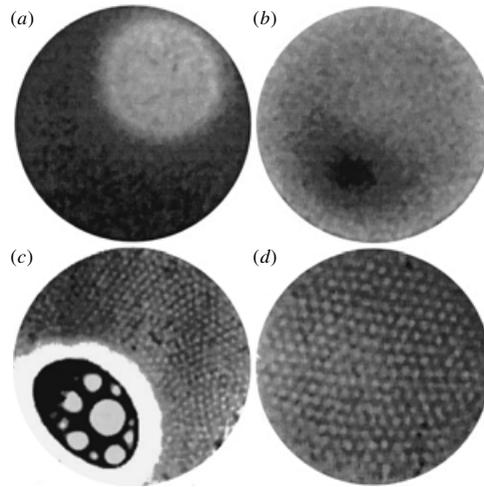

**FIGURE 10.3** Deposition of water onto a patterned surface with hydrophilic microchannels with corners. The width of the channel in the corner region increases from channel (a) to channel (e). Time and the volume of the condensate increase from top to bottom. When a microchannel undergoes a morphological change of its shape, the drop moves to the corner to maximize the contact area with the hydrophilic part of the substrate. (From Herminghaus, S. et al. (2000) *J. Phys. Condens. Matter* 12, A57–A74. With permission.)

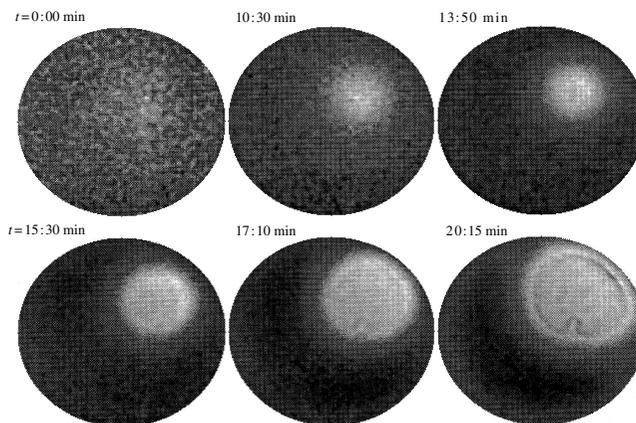

emerge on some of the microchannels, one per channel, as seen in [Figure 10.2b](#). When such droplets develop near each other, they merge to create a bridge, as shown in the left corner in the bottom of [Figure 10.2b](#). These fundamental phenomena can be used to guide the liquid into the desired location(s) on the substrate with a specially designed wettability pattern [Herminghaus et al., 2000].

[Figure 10.3](#) shows the time evolution (from top to bottom) of deposition of water condensing onto curved wettable patches of different width in the corners. This width increases from channel (a) to channel (e). When water condenses and gradually fills the channels, the behavior of the liquid depends solely on the width of the corner. If the latter is large, as for case (e), the drop develops in the corner. However, if it is small, as for case (a), the uniform channel configuration becomes unstable and a droplet develops in the straight part before it occurs in the corner. In the intermediate range of (b) to (d), the corner first develops a structure similar to case (a), but then it suddenly and discontinuously moves into the corner when a critical value of capillary pressure is attained. In such a configuration, the contact area of the liquid with the hydrophilic patch of the substrate is maximized. If the corners are sufficiently close each to another, two droplets will merge to produce a microbridge between the two neighboring microchannels, similar to what is shown in [Figure 10.2](#).

Van Hook et al. (1997) carried out experiments aiming to study the thermocapillary convection produced by variations of surface tension in bilayer systems containing silicon oil films 0.007 to 0.027 cm thick and an overlying gas gap. [Figure 10.4](#) shows some of their representative results. The dominant feature for thinner films was found to be the emergence of a drained spot, [Figure 10.4a](#), or of a localized elevated structure with a peak touching the upper lid, [Figure 10.4b](#). The drained spot may contain in certain circumstances isolated droplets trapped inside it. All these are manifestations of the long-wave instability of the film. These and other effects will be discussed below in the section dedicated to thermal effects. However, along with long-wave features of the system, other phenomena were observed for generally thicker films. These short-wave phenomena (whose length scale is comparable with the mean thickness of the layer) displayed the formation of hexagons or a combination of hexagons with the emergence of a dry spot, as shown in [Figures 10.4c,d](#). Mathematical treatment of such short-wave phenomena will not

**FIGURE 10.4** Infrared images of various states as seen in the experiments. The temperature increases with increasing brightness, so warm depression regions are white, except in (c), and cool elevated regions are dark. Each image has its own brightness, so temperatures in different images cannot be compared. (a) A localized depression (dry spot) with a helium gas layer and  $d = 0.025$  cm; (b) a localized elevation (high spot) with an air gas layer and  $d = 0.037$  cm; (c) a dry spot with hexagons in the surrounding region and  $d = 0.025$  cm; (d) hexagons with an air gas layer and  $d = 0.045$  cm. For further details, the reader is referred to Van Hook et al. (1997). (From Van Hook, S.J. et al. (1997) *J. Fluid Mech.* **345**, 45–78. Reprinted with permission of Cambridge University Press.)

**FIGURE 10.5** Evolution of a localized depression and formation of a dry spot in silicon oil of depth  $d = 0.0267 \pm 0.0008$  cm and helium in the gas layer. At  $t = 0$  (an arbitrary starting point), deformation of the interface is negligible. The liquid layer begins to form a localized depression (the white circle) and in 15 minutes the interface has ruptured ( $h_{\min} \rightarrow 0$ ) and formed a dry spot. The dry spot continues to grow for several more minutes before saturating. Bright (dark) regions are hot (cool) because they are closer (farther) to (from) the heater. All images have the same intensity scaling. (From Van Hook, S.J. et al. (1997) *J. Fluid Mech.* **345**, 45–78. Reprinted with permission of Cambridge University Press.)

be considered here. It turns out that rupture of thin liquid films and, following that, growth of the dry spot are frequent features associated with various physical mechanisms. Such an evolution of a local depression to the stage of film rupture and further to the growth and saturation of the dry spot driven by the thermocapillary effect (see Section 10.4) is shown in [Figure 10.5](#).

A low-cost, high-yield passive alignment method known as controlled collapse chip connection (C4) process was designed [Goldmann, 1969] and used in opto-electronic packaging, where alignment

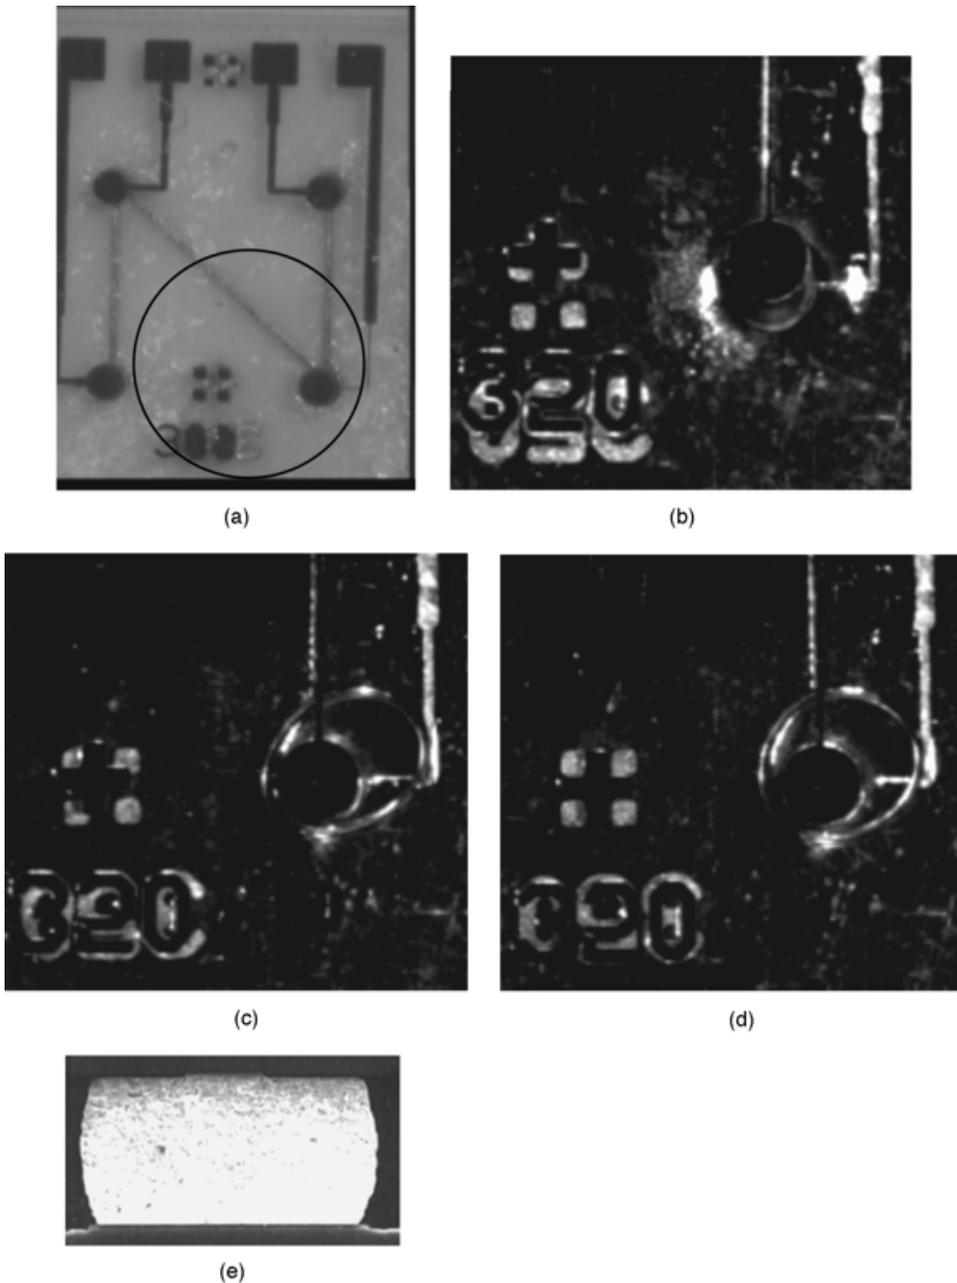

accuracies at the submicron level are required [Wale and Edge, 1990; Lin et al., 1995]. Such precision alignment techniques, as illustrated in Figure 10.6, are employed for coupling fibers and waveguides to devices such as lasers and photo detectors and are being actively developed and improved. They use molten solder and are based on the restoring force arising from surface tension that drives the misaligned solder joint to become well aligned and to minimize by this the total interfacial energy of the system. The final well-aligned configuration is then fixed by cooling down and further solidifying the solder. Figure 10.6a presents such a misaligned layout of the two chips with four solder joints seen as dark circles. The misalignment is illustrated by the position of the center of the cross with respect to the point between the four squares. Figure 10.6b is a zoom of the area designated by the large circle on Figure 10.6a and presents the initial position of the misaligned system, which moves through the intermediate state, Figure 10.6c, to its final well-aligned position, Figure 10.6d. Figure 10.6e displays the final cross section of the solder between the two chips. It is interesting to note that the alignment process presented here takes place in the time range of a second. A similar mechanism, by which a hard contact lens centers itself over the cornea in a human eye, was discussed by Moriarty and Terrill (1996).

The centrifugal spinning of volatile solutions has been found to be a convenient and efficient means of coating planar solids with thin films. This process, known as spin coating, has been widely used in many technological processes, such as deposition of dielectric layers onto silicon wafers in the micro-electronic industry, formation of ultrathin antireflective coatings for deep ultraviolet lithography and others. Two important stages of the process are usually considered. The first one occurs shortly after the liquid volume is delivered to the disk surface, rotating usually at the speed of 1000 to 10,000 rpm. At the beginning of this stage, the liquid film is relatively thick (usually greater than 500  $\mu\text{m}$ ). The film thins mainly due to radial drainage under the influence of centrifugal forces. Inertial forces are important and may lead to the appearance of instabilities of the spinning film. The second stage occurs when the film has thinned to the point where inertia is no longer important (film thickness usually less than 100  $\mu\text{m}$ ), and the flow slows down considerably, but deformations of the fluid interface may still be present due to the instabilities that appeared during the first stage. The film continues to thin mainly due to solvent evaporation until the solvent becomes depleted and the film solidifies and ceases to flow. Such problems will be discussed further below.

Numerous applications relevant for MEMS involve the dynamics of liquid films or drops. This area is experiencing constant progress, and new, exciting developments are often reported in the literature. Knight et al. (1998) described a new method of enhancement and control of nanoscale fluid jets. They demonstrated their method with the design of a continuous-flow mixer capable of mixing flowrates of nanoliters per second within the time scale of 10  $\mu\text{s}$ . Such a mixer can be useful in nanofabrication techniques and serve as an essential part of a microreactor built on a chip.

Spatially controlled changes in the chemical structure of a solid substrate can guide a deposited liquid along the substrate. Ichimura et al. (2000) reported their experimental results showing the possibility of reversible guidance of liquid motion by light irradiation of a photoresponsive solid substrate. Asymmetric irradiation of the solid surface with blue light led to movement of a 2- $\mu\text{l}$  olive oil droplet with a typical speed of 35  $\mu\text{m/s}$ . Similar irradiation with a homogeneous blue light stopped the movement of the droplet completely. The speed of the droplet and the direction of its movement were found adjustable to the conditions of such irradiation. The phenomenon described has potential applicability in the design of microreactors and microchips.

A new technique of creation and replication of lateral structures in films of submicron-length scales was proposed by Schaeffer et al. (2000). It is based on the fact that lateral gradients of the electric field applied in the vicinity of the film interface induce variations of surface tension and thus lead to the electrocapillary effect. The latter is similar to the thermocapillary effect already mentioned above and is addressed more thoroughly in Section 10.4. The electrocapillary effect triggering the electrocapillary instability of the film results in formation of ordered patterns on the film interface and focusing of the interfacial troughs and peaks in the desired locations following the master pattern of the electrodes. Schaeffer et al. (2000) reported the replication of patterns of lateral dimensions on the order of 140 nm while employing this technique. A complete investigation of the electrocapillary instability of thin liquid

**FIGURE 10.6** Photographs of C4 bonding based on self-alignment mechanism. (a) Layout of the chip ( $4\text{ mm} \times 4\text{ mm}$ ) which consists of four solder joints made of 63Sn37Pb. The upper chip is not aligned with the lower one, as can be seen from the position of the upper cross relative to the four squares at the lower chip. Initial misalignment is  $150\text{ }\mu\text{m}$ . (b) Enlarged picture of one of the solder joints at the initial moment. (c) Intermediate stage. (d) Final position. (2000) "Prediction of Yield for Flip-Chip Packaging," presented at International CIRP Design Seminar, Haifa, Israel. With permission.)

films has not yet appeared in the literature. Lee and Kim (2000) presented a liquid micromotor and liquid-metal droplets rotating along a microchannel loop being driven by a continuous electrowetting (CEW) phenomenon based on the electrocapillary effect. They identified and developed key technologies to design, manufacture and test the first MEMS devices employing CEW.

An attempt to provide a mathematical treatment of such phenomena must confront the fact that the interface of the film lying or flowing on a solid surface is partially or entirely a free boundary whose configuration evolving both temporally and spatially must be determined as an integral part of the solution of the governing equations. This renders the problem too difficult and very often almost intractable analytically, which may lead researchers to rely on computing only. The latter also becomes very complicated due to the free-boundary character of the problem which requires a careful design of adequate numerical methods.

Another property of such mathematical problems is their strong inherent nonlinearity, which is present in both governing equations and boundary conditions. Such nonlinearity of the problem presents another complexity that has to be faced. Consideration of coupled phenomena, such as those mentioned above, requires compact description of simultaneous instabilities that interact in intricate ways. This compact form must be tractable and at the same time still complex enough to retain the main features of the problem at hand.

The most appropriate analytical method of dealing with the above complexities is to analyze long-scale phenomena only, in which the characteristic lateral length scales are much larger than the average film thickness, the flowfield and temperature variations along the film are much more gradual than those normal to it, and the time variations are slow. Similar theories arise in a variety of areas of classical physics: shallow-water theory for water waves, lubrication theory in viscous flows and slender-body theory in aerodynamics and in dynamics of jets [e.g., Yarin, 1993]. In all these, a geometrical disparity is utilized in order to practically separate the variables and simplify the analysis. In thin viscous films, it turns out that most rupture and instability phenomena do occur on long scales, and a long-wave approach explained below is, in fact, very useful.

The long-wave theory approach is based on the asymptotic reduction of the governing equations and boundary conditions of a simplified system, which consists often, but not always, of a single, nonlinear, partial differential equation formulated in terms of the local thickness of the film varying in time and space. The rest of the unknowns (i.e., the fluid velocity, pressure, temperature etc.) are then determined via functionals of the solution of this differential equation, usually called an *evolution* equation. The notorious complexity of a free-boundary problem is thus removed. The corresponding penalty is, however, the presence of strong nonlinearity in the evolution equation(s) and the higher order spatial derivatives (usually up to the fourth) appearing there. A simplified linear stability analysis of the problem can be carried out based on the resulting evolution equation. A weakly nonlinear analysis of the problem is also possible through that equation. However, the fully nonlinear analysis that allows one to study finite-amplitude deformations of the film interface must be performed numerically. Still, numerical solution of the evolution equation is incomparably less difficult than that of the original, free-boundary problem.

Several encouraging verifications of the long-wave theory vs. the experimental results have appeared in the literature. Burelbach et al. (1990) carried out a series of experiments attempting to check the long-wave theory of Tan et al. (1990) for steady thermocapillary flows induced by nonuniform heating of the solid substrate. The measured steady shapes were favorably tested against theoretical predictions for layers less than 1 mm thick under moderate heating conditions. However, the relative error was large for conditions near rupture, where the long-wave theory is *formally* invalid [Burelbach et al., 1988], but in all other cases the predicted and measured values of the minimal film thickness agreed to within 20%. The theory also predicts rupture when the parameter  $L$  (see Eq. (3.6) in Tan et al. [1990]) exceeds a certain critical value, but steady patterns otherwise. Experimental results [Burelbach et al., 1990, Figure 1] showed that  $L$  is an excellent qualitative indicator of whether or not the film ruptures.

Van Hook et al. (1995; 1997) performed experiments on the onset of the long-wavelength instability in thin layers of silicon oil of varying thickness, aspect ratios and transverse temperature gradients across the layer. Formation of “dry spots” at randomly varying locations was found above the critical temperature

difference across the layer, in qualitative agreement with corresponding numerical simulations. More about the experimental support for theoretical results can be found below in various sections of this chapter.

Another test for the validity of an asymptotic theory, such as the long-wave theory presented here, is achieved via comparison between the numerical solutions for the *full* free-boundary problem in its original form and the solutions obtained for the corresponding long-wave evolution equations. Due to the difficulty of carrying out the direct numerical simulations already discussed above, the number of such comparative studies is quite limited. Krishnamoorthy et al. (1995) performed a full-scale direct numerical simulation of the governing equations to study the rupture of thin liquid films due to thermocapillarity and found very good qualitative agreement with the results arising from solution of the corresponding evolution equation, except for times prior to rupture. Oron (2000b) found even better agreement at rupture between his results and direct simulations of the Navier–Stokes equations of Krishnamoorthy et al. (1995). There has been a long debate in the literature about the validity of fingered structures of the film interface arising from solution of the evolution equations and whether they are artifacts of the asymptotic reduction applied. Direct solution of the Navier–Stokes equations [Krishnamoorthy et al., 1995] provides convincing evidence supporting the validity of the evolution equations even in the domain where some assumptions leading to their derivation are violated.

There has been major progress in the analysis of thin liquid films in recent years. In the review article by Oron et al. (1997), such analyses were unified into a simple framework in which the special cases naturally emerged. In this chapter, the physics of thin liquid films is reviewed with an emphasis on the phenomena of considerable interest for MEMS. The theory of drop spreading, in spite of its importance, is not included here and the reader is referred to other reviews [de Gennes, 1985; Leger and Joanny, 1992; Oron et al., 1997] and the references therein.

The general evolution equation describing the general dynamics of thin liquid films will be derived following Oron et al. (1997) and discussed in Section 10.2. The topic to be addressed in Section 10.3 is isothermal films, for which the physical effects discussed are viscous, surface tension, gravity and centrifugal forces along with van der Waals interactions. Section 10.4 examines the influence of thermal effects on the dynamics of liquid films. Section 10.5 considers the dynamics of liquid films undergoing phase changes, such as evaporation and condensation.

## 10.2 The Evolution Equation for a Liquid Film on a Solid Surface

We now describe the long-wave approach and apply it to a flow of a viscous liquid in a film supported below by a solid horizontal plate and bounded above by an interface separating the liquid and a passive gas, slowly evolving in space and time, as given by its equation  $z = h(x, y, t)$ . We assume the possibility of the existence of external interfacial forces  $\Pi$  with the components  $\{\Pi_3, \Pi_1, \Pi_2\}$  in the normal and both of the tangential to the film surface directions, respectively, determined by the vectors:

$$\mathbf{n} = \frac{\{-h_x, -h_y, 1\}}{\sqrt{1 + h_x^2 + h_y^2}}, \quad \mathbf{t}_1 = \frac{\{1, 0, h_x\}}{\sqrt{1 + h_x^2}}, \quad \mathbf{t}_2 = \frac{\{0, 1, h_y\}}{\sqrt{1 + h_y^2}}. \quad (10.1)$$

The components of the vectors  $\mathbf{n}$ ,  $\mathbf{t}_1$ ,  $\mathbf{t}_2$  in Eq. (10.1) are specified in the order of the  $x$ ,  $y$  and  $z$  directions, where  $x$  and  $y$  are the spatial coordinates in the given solid plane, while  $z$  is normal to the latter and directed across the film. The presence of a conservative body force determined by the potential  $\phi$  acting on the liquid phase, such as gravity, centrifugal or van der Waals force, is accounted for as well. We note that the vectors  $\mathbf{t}_1$ ,  $\mathbf{t}_2$  are not orthogonal, but it is sufficient for our application below that  $(\mathbf{n}, \mathbf{t}_1)$  and  $(\mathbf{n}, \mathbf{t}_2)$  constitute pairs of orthogonal vectors. From here on, the letter subscripts denote the partial derivatives with respect to the corresponding variable.

The liquid considered in this work is assumed to be a simple Newtonian incompressible viscous fluid whose dynamics are well described by the Navier–Stokes and mass conservation equations, provided that the length scales characteristic for the flow domain are within the continuum range exceeding several molecular spacings. The mass conservation and Navier–Stokes equations for such a liquid in three dimensions have the form:

$$u_x + v_y + w_z = 0 \quad (10.2a)$$

$$\rho(u_t + uu_x + vu_y + wu_z) = -p_x + \mu(u_{xx} + u_{yy} + u_{zz}) - \phi_x \quad (10.2b)$$

$$\rho(v_t + uv_x + vv_y + wv_z) = -p_y + \mu(v_{xx} + v_{yy} + v_{zz}) - \phi_y \quad (10.2c)$$

$$\rho(w_t + uw_x + vw_y + ww_z) = -p_z + \mu(w_{xx} + w_{yy} + w_{zz}) - \phi_z \quad (10.2d)$$

where  $\rho$  and  $\mu$  are, respectively, the density and kinematic viscosity of the liquid;  $u, v, w$  are the respective components of the fluid velocity vector  $\mathbf{v}$  in the directions  $x, y, z$ ;  $t$  is time; and  $p$  is pressure.

The classical boundary conditions between the liquid and the solid surface supporting it are no penetration,  $w = 0$ , and no slip,  $u = 0, v = 0$ . These conditions are appropriate for the continuous films to be considered here. Problems related to the case where a contact line is a junction of the three phases (solid, liquid, gas) exist, and the liquid on a solid surface spreading or receding will not be examined in this chapter. The reader interested in this topic is referred to the review papers by de Gennes (1985), Leger and Joanny (1992), Oron et al. (1997) and references therein.

The boundary conditions at the solid surface are, therefore:

$$w = 0, u = 0, v = 0 \quad \text{at } z = 0 \quad (10.3)$$

At the film surface  $z = h(x, y, t)$ , the boundary conditions are formulated in the vector form [e.g., Wehausen and Laitone, 1960]:

$$h_t + \mathbf{v} \cdot \nabla^* h - w = 0 \quad (10.4a)$$

$$\mathbf{T} \cdot \mathbf{n} = -2\tilde{H}\boldsymbol{\sigma}\mathbf{n} + \nabla_s \boldsymbol{\sigma} + \Pi \quad (10.4b)$$

where  $\mathbf{T}$  is the stress tensor of the liquid,  $\Pi$  is the prescribed forcing at the interface,  $\tilde{H}$  is the mean curvature of the interface determined from:

$$2\tilde{H} = \nabla^* \cdot \mathbf{n} = -\frac{h_{xx}(1+h_y^2) + h_{yy}(1+h_x^2) - 2h_x h_y h_{xy}}{(1+h_x^2+h_y^2)^{3/2}} \quad (10.5)$$

$\nabla^* = (\partial/\partial x, \partial/\partial y, \partial/\partial z)$  is the gradient operator, and  $\nabla_s$  is the surface gradient with respect to the interface  $z = h(x, y, t)$ . Note that in Eq. (10.4) the dot represents both the inner product of two vectors and the product of a tensor and a vector, respectively.

Equation (10.4a) is the kinematic boundary condition formulated in the absence of interfacial mass transfer that represents the balance between the normal component of the liquid velocity at the interface and the velocity of the interface itself. An appropriate change should be made in Eq. (10.4a) to accommodate the phenomena of evaporation or condensation (see Section 10.5). Equation (10.4b), which constitutes the balance of interfacial stresses in the absence of interfacial mass transfer, has three components. The physical meaning of its two tangential components is that the shear stress at the interface is balanced by the sum of the respective  $\Pi_i, i = 1, 2$ , and the surface gradient of surface tension  $\boldsymbol{\sigma}$ , whereas

the normal component of Eq. (10.4b) states that the difference between the normal interfacial stress and  $\Pi_3$  exhibits a jump equal to the product of twice the mean curvature of the film interface and surface tension. This jump is known in the literature as the capillary pressure. When the external force  $\Pi$  is zero, and the fluid has zero viscosity or the fluid is static,  $\mathbf{v} = 0$ , then  $\mathbf{T} \cdot \mathbf{n} \cdot \mathbf{n} = -p$ , and Eq. (10.4b) reduces to the well-known Young–Laplace equation which describes, for instance, the excess pressure in an air bubble gauged to the external pressure as twice the surface tension divided by the bubble radius (see, e.g., Landau and Lifshitz [1987]). The derivations below closely follow those made by Oron et al. (1997), being explicitly extended into three dimensions.

Projecting Eq. (10.4b) onto the directions  $\mathbf{n}$ ,  $\mathbf{t}_1$ ,  $\mathbf{t}_2$ , respectively, yields:

$$-p + \frac{2\mu[u_x(h_x^2 - 1) + v_y(h_y^2 - 1) + h_x h_y(u_y + v_x) - h_x(u_z + w_x) - h_y(v_z + w_y)]}{1 + h_x^2 + h_y^2} = 2H\sigma + \Pi_3$$

$$\mu[(u_z + w_x)(1 - h_x^2) - (v_z + w_y)h_x h_y - (u_y + v_x)h_y - 2(u_x - w_z)h_x] = \left(\Pi_1 + \frac{\partial\sigma}{\partial x}\right)(1 + h_x^2 + h_y^2)^{1/2}$$

$$\mu[-(u_z + w_x)h_x h_y + (v_z + w_y)(1 - h_y^2) - (u_y + v_x)h_x - 2(v_y - w_z)h_y] = \left(\Pi_2 + \frac{\partial\sigma}{\partial y}\right)(1 + h_x^2 + h_y^2)^{1/2} \quad (10.6)$$

Let us now introduce scales appropriate for thin films where the transverse length scale is much smaller than the lateral scales. Assume length scales in the lateral directions  $x$  and  $y$  to be defined by wavelength  $\lambda$  of the interfacial disturbance on a film of mean thickness  $d$ . The film is referred to as a *thin* film if the interfacial distortions are much longer than the mean film thickness; that is,

$$\varepsilon = \frac{d}{\lambda} \ll 1 \quad (10.7)$$

The  $z$  coordinate (normal to the solid substrate) is normalized with respect to  $d$ , while the coordinates  $x$  and  $y$  are scaled with  $\lambda$  or equivalently  $d/\varepsilon$ . Thus, the dimensionless  $z$  coordinate is defined as:

$$\zeta = \frac{z}{d} \quad (10.8a)$$

while the dimensionless  $x$ - and  $y$  coordinates are given by:

$$\xi = \frac{\varepsilon x}{d}, \quad \eta = \frac{\varepsilon y}{d} \quad (10.8b)$$

It is assumed that in the new spatial variables no rapid variations occur as  $\varepsilon \rightarrow 0$ ; then,

$$\frac{\partial}{\partial \xi}, \frac{\partial}{\partial \eta}, \frac{\partial}{\partial \zeta} = O(1) \quad (10.8c)$$

If the lateral components of the velocity field  $u$  and  $v$  are assumed to be of order one and  $U_0$  denotes the characteristic velocity of the problem, the dimensionless fluid velocities in the  $x$  and  $y$  directions are

defined as:

$$U = \frac{u}{U_0}, \quad V = \frac{v}{U_0} \quad (10.8d)$$

Then, the continuity equation, Eq. (10.2a), requires that the  $z$  component of the velocity field  $w$  be small, and the dimensionless fluid velocity in the  $z$  direction is defined as:

$$W = \frac{w}{\varepsilon U_0} \quad (10.8e)$$

We stress that the characteristic velocity  $U_0$  is not specified here for the sake of generality. The freedom of choosing this value is thus given to the user. We just note one of the possible choices but not the unique one,  $U_0 = \mu/\rho d$ , which is known in the literature as a viscous velocity.

Time is scaled in the units of  $\lambda/U_0$ , so the asymptotically long-time behavior of the film is to be considered. The dimensionless time is therefore defined via:

$$\tau = \frac{\varepsilon U_0 t}{d} \quad (10.8f)$$

Finally, because of the assumed slow lateral variation of the film interface, one expects locally parallel flow in the liquid so that the pressure gradient is balanced with the viscous stress  $p_x \propto \mu u_{zz}$ , and the dimensionless interfacial stresses, body-force potential and pressure are defined, respectively, as:

$$(\Pi_1, \Pi_2, \Pi_3) = \frac{d}{\mu U_0} (\hat{\Pi}_1, \hat{\Pi}_2, \varepsilon \hat{\Pi}_3), \quad (\Phi, P) = \frac{\varepsilon d}{\mu U_0} (\phi, p) \quad (10.8g)$$

Notice that pressure is asymptotically large similar to the situation arising in the lubrication effect [Schlichting, 1968].

If all these dimensionless variables are substituted into the governing system, Eqs. (10.2) to (10.5), the following scaled system is obtained:

$$U_\xi + V_\eta + W_\varsigma = 0 \quad (10.9a)$$

$$\varepsilon R(U_\tau + UU_\xi + VU_\eta + WU_\varsigma) = -P_\xi + U_{\varsigma\varsigma} + \varepsilon^2(U_{\xi\xi} + U_{\eta\eta}) - \Phi_\xi \quad (10.9b)$$

$$\varepsilon R(V_\tau + UV_\xi + VV_\eta + WV_\varsigma) = -P_\eta + V_{\varsigma\varsigma} + \varepsilon^2(V_{\xi\xi} + V_{\eta\eta}) - \Phi_\eta \quad (10.9c)$$

$$\varepsilon^3 R(W_\tau + UW_\xi + VW_\eta + WW_\varsigma) = -P_\varsigma + \varepsilon^2 W_{\varsigma\varsigma} + \varepsilon^4(W_{\xi\xi} + W_{\eta\eta}) - \Phi_\varsigma \quad (10.9d)$$

At  $\varsigma = 0$ :

$$W = 0, \quad U = 0, \quad V = 0 \quad (10.10)$$

At  $\varsigma = H$ :

$$W = H_\tau + UH_\xi + VH_\eta \quad (10.11a)$$

$$\begin{aligned} & \frac{2\varepsilon^2[U_\xi(\varepsilon^2 H_\xi^2 - 1) + V_\eta(\varepsilon^2 H_\eta^2 - 1) + \varepsilon^2 H_\xi H_\eta(U_\eta + V_\xi) - H_\xi(U_\varsigma + W_\xi) - H_\eta(V_\varsigma + W_\eta)]}{1 + \varepsilon^2(H_\xi^2 + H_\eta^2)} \\ &= P + \hat{\Pi}_3 + \frac{\bar{S}\varepsilon^3[H_{\xi\xi}(1 + \varepsilon^2 H_\eta^2) + H_{\eta\eta}(1 + \varepsilon^2 H_\xi^2) - 2\varepsilon^2 H_\xi H_\eta H_{\xi\eta}]}{[1 + \varepsilon^2(H_\xi^2 + H_\eta^2)]^{3/2}} \end{aligned} \quad (10.11b)$$

$$\begin{aligned}
& (U_\zeta + \varepsilon^2 W_\xi)(1 - \varepsilon^2 H_\xi^2) - \varepsilon^2 (V_\zeta + \varepsilon^2 W_\eta) H_\xi H_\eta - \varepsilon^2 (U_\eta + V_\xi) H_\eta - 2\varepsilon^2 (U_\xi - W_\zeta) H_\xi \\
& = (\hat{\Pi}_1 + \Sigma_\xi) [1 + \varepsilon^2 (H_\xi^2 + H_\eta^2)]^{1/2}
\end{aligned} \tag{10.11c}$$

$$\begin{aligned}
& (V_\zeta + \varepsilon^2 W_\eta)(1 - \varepsilon^2 H_\eta^2) - \varepsilon^2 (U_\zeta + \varepsilon^2 W_\xi) H_\xi H_\eta - \varepsilon^2 (U_\eta + V_\xi) H_\xi - 2\varepsilon^2 (V_\eta - W_\zeta) H_\eta \\
& = (\hat{\Pi}_2 + \Sigma_\eta) [1 + \varepsilon^2 (H_\xi^2 + H_\eta^2)]^{1/2}
\end{aligned} \tag{10.11d}$$

Here,  $H = h/d$  is the dimensionless thickness of the film and  $\Sigma = \varepsilon\sigma/\mu U_0$  is the dimensionless surface tension normalized with respect to its characteristic value. The Reynolds number  $R$  and the inverse capillary number  $\bar{S}$  are defined by:

$$R = \frac{U_0 d \rho}{\mu}, \quad \bar{S} = \frac{\sigma}{U_0 \mu} \tag{10.12}$$

The continuity equation, Eq. (10.9a), is now integrated in  $\zeta$  across the film from 0 to  $H$  ( $\xi, \eta, \tau$ ), and Eqs. (10.10) and (10.11a) are used along with integration by parts to obtain:

$$H_\tau + \frac{\partial}{\partial \xi} \int_0^H U d\zeta + \frac{\partial}{\partial \eta} \int_0^H V d\zeta = 0 \tag{10.13}$$

Equation (10.13) is a more convenient form of the kinematic condition in the sense that only two of three components of the fluid velocity field appear there explicitly. It also warrants conservation of mass in a domain with a deflecting upper boundary.

The solution of the governing equations, Eqs. (10.2) to (10.5), is sought in the form of expansion of the dependent variables into asymptotic series in powers of the small parameter  $\varepsilon$ :

$$\begin{aligned}
U &= U^{(0)} + \varepsilon U^{(1)} + \varepsilon^2 U^{(2)} + \dots, & V &= V^{(0)} + \varepsilon V^{(1)} + \varepsilon^2 V^{(2)} + \dots \\
W &= W^{(0)} + \varepsilon W^{(1)} + \varepsilon^2 W^{(2)} + \dots, & P &= P^{(0)} + \varepsilon P^{(1)} + \varepsilon^2 P^{(2)} + \dots
\end{aligned} \tag{10.14}$$

One way to approximate the solution of the governing system is to assume that  $R, \bar{S} = O(1)$  as  $\varepsilon \rightarrow 0$ . Under this assumption, the inertial terms measured by  $\varepsilon R$  are one order of magnitude smaller than the dominant viscous terms, consistent with the local-parallel-flow assumption, while the surface tension terms measured by  $\bar{S}\varepsilon^3$  are two orders of magnitude smaller and would be lost. However, it is essential to retain surface-tension effects at the leading order, so it is assumed that capillary effects are strong relative to those of viscosity and

$$\bar{S} = S\varepsilon^{-3} \tag{10.15}$$

It is then assumed that  $R, S = O(1)$ , as  $\varepsilon \rightarrow 0$ .

Equations (10.14) and (10.15) are substituted into Eqs. (10.9) to (10.11) and (10.13), and the resulting equations are sorted with respect to the powers of  $\varepsilon$ . At the leading order in  $\varepsilon$  the governing system becomes, after omitting the superscript zero in  $U^{(0)}, V^{(0)}, W^{(0)}$  and  $P^{(0)}$ :

$$\begin{aligned}
U_{\zeta\zeta} &= (P + \Phi)_\xi \\
V_{\zeta\zeta} &= (P + \Phi)_\eta \\
(P + \Phi)_\zeta &= 0 \\
H_\tau + UH_\xi + VH_\eta - W &= 0 \\
U_\xi + V_\eta + W_\zeta &= 0
\end{aligned} \tag{10.16}$$

with the boundary conditions at  $\zeta = 0$ :

$$W = 0, \quad U = 0, \quad V = 0 \quad (10.17)$$

and at  $\zeta = H$ :

$$\begin{aligned} P &= -\hat{\Pi}_3 - S(H_{\xi\xi} + H_{\eta\eta}) \\ U_\zeta &= \hat{\Pi}_1 + \Sigma_\xi \\ V_\zeta &= \hat{\Pi}_2 + \Sigma_\eta \end{aligned} \quad (10.18)$$

We note here that Eqs. (10.16) to (10.18) are linear with respect to the variables  $U, V, W, P$ , and the only nonlinearity of this problem is associated, as seen from Eq. (10.19) in conjunction with the kinematic condition Eq. (10.16d), with the local film thickness  $H(\xi, \eta, \tau)$ . Solving Eqs. (10.16) to (10.18) yields:

$$\begin{aligned} U &= \left[ \frac{1}{2}\zeta^2 - H\zeta \right] (\Phi - \hat{\Pi}_3|_{\zeta=H} - S\nabla^2 H)_\xi + \zeta(\hat{\Pi}_1 + \Sigma_\xi) \\ V &= \left[ \frac{1}{2}\zeta^2 - H\zeta \right] (\Phi - \hat{\Pi}_3|_{\zeta=H} - S\nabla^2 H)_\eta + \zeta(\hat{\Pi}_2 + \Sigma_\eta) \\ W &= -\int_0^\zeta (U_\xi + V_\eta) d\zeta, \quad P = -\hat{\Pi}_3|_{\zeta=H} - S\nabla^2 H \end{aligned} \quad (10.19)$$

If Eq. (10.19) is substituted into the mass conservation Eq. (10.13), one obtains the appropriate evolution equation for the interface,

$$H_\tau + \frac{1}{2}\nabla \cdot [H^2(\hat{\Pi}^* + \nabla\Sigma)] + \frac{1}{3}\nabla \cdot \{H^3[\nabla(\hat{\Pi}_3 - \Phi|_{\zeta=H}) + S\nabla\nabla^2 H]\} = 0 \quad (10.20)$$

where  $\hat{\Pi}^* = (\hat{\Pi}_1, \hat{\Pi}_2)$  is the tangential projection of the dimensionless vector  $\hat{\Pi}$ ,  $\nabla \equiv (\partial/\partial\xi, \partial/\partial\eta)$  and  $\nabla^2 \equiv \partial^2/\partial\xi^2 + \partial^2/\partial\eta^2$ .

In two dimensions ( $\partial/\partial\eta = 0$ ), this evolution equation reduces to:

$$H_\tau + \frac{1}{2}[H^2(\hat{\Pi}_1 + \Sigma_\xi)]_\xi + \frac{1}{3}\{H^3[(\hat{\Pi}_3 - \Phi|_{\zeta=H})_\xi + SH_{\xi\xi\xi}]\}_\xi = 0 \quad (10.21)$$

In these equations, the location of the film interface  $H = H(\xi, \eta, \tau)$  is unknown and has to be determined from the solution of the corresponding partial differential equation. When such a solution is obtained, the components of the velocity and the pressure fields can be determined from Eq. (10.19).

The physical significance of the terms becomes apparent when Eqs. (10.20) and (10.21) are written in the original dimensional variables:

$$\mu h_t + \frac{1}{2}\bar{\nabla} \cdot [h^2(\Pi^* + \bar{\nabla}\sigma)] + \frac{1}{3}\bar{\nabla} \cdot \{h^3[\bar{\nabla}(\Pi_3 - \phi|_{z=h}) + \sigma\bar{\nabla}\bar{\nabla}^2 h]\} = 0 \quad (10.22)$$

with  $\bar{\nabla} \equiv (\partial/\partial x, \partial/\partial y)$ ,  $\bar{\nabla}^2 \equiv (\partial^2/\partial x^2 + \partial^2/\partial y^2)$  and

$$\mu h_t + \frac{1}{2}[h^2(\Pi_1 + \sigma_x)]_x + \frac{1}{3}\{h^3[(\Pi_3 - \phi|_{z=h})_x + \sigma h_{xxx}]\}_x = 0 \quad (10.23)$$

The first terms in Eqs. (10.22) and (10.23) represent the effect of viscous damping, while the next ones account, respectively, for the effects of the imposed tangential interfacial stress, nonuniformity of surface tension, imposed normal interfacial stress, body forces and surface tension on the dynamics of the film.

In the examples discussed below, both two- and three-dimensional cases are examined. Further, unless specified, only disturbances periodic in  $x$  and  $y$  are discussed. Thus,  $\lambda$  is the wavelength of these disturbances and  $2\pi d/\lambda$  is the corresponding dimensionless wave number. In accordance with this, Eqs. (10.20) to (10.23) are normally solved with periodic boundary conditions. These equations, whether in two or three dimensions, are of fourth order in each of the spatial variables; therefore, four boundary conditions are needed to define a well-posed mathematical problem. These four boundary conditions imply periodicity of the solution  $H$  and its first, second and third derivatives with respect to the corresponding spatial variable. On the other hand, Eqs. (10.20) to (10.23) are of first order in time, thus one initial condition is needed to complete the well-posed statement of the problem. Such an initial condition representing the location of the film interface at  $t = 0$  or  $\tau = 0$  is usually taken as a small-amplitude random or sinusoidal disturbance on top of the uniform state given by  $H = 1$ . In two dimensions it can be written by:

$$H(\tau = 0, \xi) = 1 + \delta \sin(\xi + \varphi) \quad \text{or} \quad H(\tau = 0, \xi) = 1 + \delta \text{rand}(\xi) \quad (10.24)$$

where  $\delta \ll 1$ ,  $\varphi$  is a phase, and  $\text{rand}(\xi)$  is a random function uniformly distributed in the interval  $(-1, 1)$ . An obvious extension of Eq. (10.24) can be obtained in the three-dimensional case.

## 10.3 Isothermal Films

We now examine the dynamics of films whose temperature remains unchanged and phase changes do not occur.

### 10.3.1 Constant Surface Tension and Gravity

Consider the simplest case in which the film is supported from below by a solid surface and subjected to the influence of gravity and constant surface tension. In this case, one has  $\Sigma_\xi = \Sigma_\eta = \hat{\Pi}_1 = \hat{\Pi}_2 = \hat{\Pi}_3 = 0$  and  $\Phi = Gg$ , so that in two dimensions Eq. (10.21) becomes:

$$H_\tau - \frac{1}{3}G(H^3 H_\xi)_\xi + \frac{1}{3}S(H^3 H_{\xi\xi\xi})_\xi = 0 \quad (10.25a)$$

where  $G$  is the unit-order positive gravity number,

$$G = \frac{\rho g d^2}{\mu U_0}$$

The second term of Eq. (10.25a) accounts for the influence of gravity, while the third one describes the effect of the capillary forces. The dimensional version of Eq. (10.25a) is obtained from Eq. (10.23) as:

$$\mu h_t - \frac{1}{3}\rho g(h^3 h_x)_x + \frac{1}{3}\sigma(h^3 h_{xxx})_x = 0 \quad (10.25b)$$

In the absence of surface tension, Eq. (10.25b) is a nonlinear (forward) diffusion equation so that one can envision that no disturbance to  $h = d$  experiences growth in time. Surface tension acts through a fourth-order (forward) dissipation term only, enhancing stabilization of the interface, so that no instabilities would occur in the case described by Eq. (10.25b) for  $G > 0$ .

To formally assess these intuitive observations one can investigate the stability properties of the uniform film,  $h = d$ , perturbing it by a small disturbance,  $h'$ , periodic in  $x$  (i.e.,  $h = d + h'$ , with  $h' \ll d$ ). Substituting this into Eq. (10.25b) and linearizing it with respect to  $h'$ , one obtains the linear-stability equation for the uniform state  $h = d$ . Since this equation has coefficients independent of  $t$  and  $x$ , one can seek separable solutions of the form:

$$h' = h'_0 \exp(ikx + \omega t), \quad h'_0 = \text{const}$$

which constitute a complete set of “normal modes” and can be used to represent any disturbance by means of the Fourier series. Here,  $k$  is the wave number of the disturbance in the  $x$  direction. If these normal modes are substituted into the linear-stability equation, one obtains the following characteristic equation for  $\omega$ :

$$\mu\omega = -\frac{1}{3d}(\rho g d^2 + \sigma a^2)a^2 \quad (10.26)$$

where  $a = kd$  is the nondimensional wave number and  $\omega$  is the growth rate of the perturbation. In general, the amplitude of the perturbation will decay if the real part of the growth rate,  $Re(\omega)$ , is negative and will grow if  $Re(\omega)$  is positive. Purely imaginary values of  $\omega$  will correspond to translation along the  $x$ -axis and give rise to traveling-wave solutions. Finally, zero values of  $Re(\omega)$  will correspond to neutral, stationary-in-time perturbations.

Two remarks are now in order. First, the linear stability analysis is carried out here in the dimensional form, but it could be done also in the same way in the dimensionless form when its starting point would be Eq. (10.25a). Second, the linear stability analysis is carried out here in the two-dimensional case. The same can be done in the three-dimensional case with respect to the normal modes:

$$h' = h'_0 \exp(ik_x x + ik_y y + \omega t), \quad h'_0 = \text{const}$$

where  $k_x$  and  $k_y$  are, respectively, the wave numbers in the  $x$  and  $y$  directions. As in the physical problem at hand, the symmetry is such that the spatial variables  $x$  and  $y$  are interchangeable; the characteristic equation for  $\omega$  will be identical to Eq. (10.26), but now  $k = (k_x^2 + k_y^2)^{1/2}$  is the total wave number of the disturbance.

Equation (10.26) describes the rate of film leveling, as  $\omega < 0$  for any value of the dimensionless wave number  $a$  and the rest of parameters. This implies that if at time  $t = 0$  a small bump is imposed on the interface, Eq. (10.26) describes how it will relax to zero and the interface will return to  $h = d$ .

The overall rate of film leveling can be estimated by the maximal value of the growth (decay, in the case at hand) rate  $\omega$ , as given by Eq. (10.26). If the lateral size of the film is  $L$ , the fastest decaying mode is the longest available one, so that its wave number is  $k = 2\pi/L$ . Thus, the rate of disturbance decay is given by:

$$\omega_m = -\frac{4\pi^2 d^3}{3\mu L^2} \left( \rho g + \frac{4\pi^2 \sigma}{L^2} \right)$$

so the amplitude of the disturbance will reach the value of, say a thousandth of the initial amplitude at the time of  $t = (\ln 0.001)/\omega_m$ . However, this is only an estimate based on the linear stability analysis, and the effect of nonlinearities on the rate of film leveling can be found only from the solution of Eq. (10.25).

Equations (10.25a,b), with the obvious change in the sign of the gravity term in each of these, also apply to the case of a film on the underside of a plate. This case is known in the literature as the Rayleigh–Taylor instability [Chandrasekhar, 1961] of a thin viscous layer. To study the stability properties of such a system, one replaces  $g$  by  $-g$  in Eq. (10.26) and finds that:

$$\mu\omega = \frac{1}{3d}(\rho|g|d^2 - \sigma a^2)a^2 \quad (10.27)$$

The film is linearly unstable if

$$a^2 < a_c^2 \equiv \frac{\rho |g| d^2}{\sigma} \equiv Bo$$

That is, if the perturbations are so long that the nondimensional wave number is smaller than the square root of the Bond number  $Bo$ , which measures the relative importance of gravity and capillary effects. The value of  $a_c$  is often called the (dimensionless) *cutoff wave number* for neutral stability. The cutoff wave number is defined in a way that all perturbations with the wave number larger than  $a_c$  are damped, while those with the wave number smaller than  $a_c$  are amplified.

We should point out that Eq. (10.25) constitutes the valid limit to the governing set of equations and boundary conditions when the Bond number  $Bo$  is asymptotically small. This follows from the relationships  $G = Bo\bar{S}$  and  $G = O(1)$  and the large value of  $\bar{S}$ , as assumed in Eq. (10.15).

The case of Rayleigh–Taylor instability was studied by Yiantsios and Higgins (1989; 1991) for a thin film of a light fluid atop the plate, overlain by a large body of a heavy fluid, and by Oron and Rosenau (1992) for a thin liquid film on the underside of a plane. It was found that evolution of an interfacial disturbance of small amplitude leads to rupture of the film; that is, at certain location(s) the local thickness of the film is driven to zero.

The dimensionless wave number of the fastest growing mode is determined for a film of an infinite lateral extent from Eq. (10.27) as  $a = \sqrt{Bo}/2$ , and its growth rate is determined from Eq. (10.27) as:

$$\omega_m = \frac{\rho^2 g^2 d^3}{12\mu\sigma}$$

Thus, the time of film rupture can be estimated by  $t = \ln(d/h'_0)/\omega_m$ .

Yiantsios and Higgins (1989) showed that Eq. (10.25a) with  $G < 0$  admits several steady solutions. These consist of various numbers of sinusoidal drops separated by “dry” spots of zero film thickness, as shown in Figure 8 in Yiantsios and Higgins (1989). The examination of an appropriate free energy functional suggests that multidrop states are energetically less preferred than a one-drop state. These analytical results were partially confirmed by numerical simulations. As found in the long time limit, the solutions can asymptotically approach multihumped states with different amplitudes and spacings, as well. This suggests that terminal states depend upon the choice of initial data [Yiantsios and Higgins, 1989]. It was also found that if the overlying semi-infinite fluid phase is more viscous than the thin liquid film, the process of the film rupture slows down in comparison with the single-fluid case.

It is interesting to note that Eq. (10.25a) with  $G < 0$  was also derived and studied by Hammond (1983) in the context of capillary instability of a thin liquid film on the inner side of a cylindrical surface, when gravity was neglected. The gravitational term there was due to the destabilizing effect of the capillary forces arising from longitudinal (along the axis of the cylinder) disturbances. Hammond (1983) also showed that the film ruptures but the process of rupture is infinitely long.

The three-dimensional version of the problem of the Rayleigh–Taylor instability was considered by Fermigier et al. (1992) using the weakly nonlinear analysis. Formation of patterns of different symmetries and transition between these patterns were experimentally studied. Axially symmetric cells and hexagons were found to be preferred. Droplet detachment was observed at the final stage of the experiment as a manifestation of a film rupture. The growth of an axisymmetric drop was shown in Figure 5 in Fermigier et al. (1992). A theoretical study of the Rayleigh–Taylor instability in an extended geometry [Fermigier et al., 1992] on the basis of the long-wave equation showed the tendency of the hexagonal structures to emerge as a preferred pattern in agreement with their own experimental observations.

Saturation of the Rayleigh–Taylor instability of a thin liquid film and therefore prevention of its rupture by an imposed advection in the longitudinal (parallel to the interface) direction was discussed by Babchin et al. (1983). Similarly, capillary instability of an annular film saturates due to a through flow [Frenkel et al., 1987].

Stillwagon and Larson (1988) considered the problem of a film leveling under the action of capillary force on a substrate with topography given by  $z = \ell(x)$ . Using the approach described above, they derived the evolution equation that for the case of zero gravity reads:

$$\mu h_t + \frac{1}{3} \sigma [h^3 (h + \ell)_{xxx}]_x = 0 \quad (10.28)$$

Numerical solutions of Eq. (10.28) showed a good agreement with their own experimental data. At short times there is film deplanarization due to the emergence of capillary humps, but these relax at longer times.

### 10.3.2 van der Waals Forces and Constant Surface Tension

Because of very small typical length scales of MEMS applications in general and of liquid film thickness in particular, which go down into the range of fractions of a micrometer, a new physics related mainly to intermolecular forces has to be brought into consideration. These fundamental types of forces acting on interatomic or intermolecular distances can affect the dynamics of macroscopic thin liquid films. Although some of them, such as weak and strong interactions, are short-range (i.e., much beyond the validity limits of continuum theory considered here), others, such as electromagnetic and gravitational forces, are of a long range and will be thus of a great importance for the subject of the current review.

Israelachvili (1992) presents a classification of electromagnetic forces into three categories. The first category includes purely electrostatic forces that stem from the Coulomb interaction. These forces include interactions between charges, dipoles etc. The second category includes polarization forces that stem from the dipole moments induced in totally neutral particles by the electric fields associated with other neighboring particles and permanent dipoles. These forces include interactions in a solvent medium. The third category includes forces of quantum mechanics origin. Such forces lead to chemical bonding and to repulsive steric interactions. Among these forces one can also find the force that acts, similar to the gravitational force, between all kinds of particles whether charged or neutral. It is called *dispersion force* or *London force*. The origin of the dispersion force is explained by the following consideration: In an electrically neutral particle whose time-averaged dipole moment vanishes, an instantaneous dipole moment does not vanish according to a time-varying relative distribution of negative and positive charges. Such an instantaneous dipole moment gives rise to a dipole moment in the neighboring neutral particles, and the interaction between these dipoles induces the force with a nonvanishing time-averaged value. These dispersion forces are long-range forces acting at distances of several Angstroms to several hundreds of Angstroms. They play, as we shall see later, a very important role in the dynamics of ultrathin liquid films whose average thickness is in the above range and in various phenomena such as wetting and adhesion. The dispersion forces can be either attractive or repulsive affecting by this the properties of good or poor wetting of solids by liquids. The presence of other bodies alters the dispersion interaction between the molecules, thus the latter is nonadditive. As shown in Table 6.3 in Israelachvili (1992), the dispersion force constitutes in many cases, except for highly polar water molecules, the main contribution to the total intermolecular force called *van der Waals force*. Various types of potentials describing the forces acting between molecules were reviewed by Israelachvili (1992), and the reader is referred to pages 112 to 114 therein.

Dzyaloshinskii et al. (1959) developed a theory for van der Waals interactions in which an integral representation is given for the excess Helmholtz free energy of the layer as functions of the frequency-dependent dielectric properties of the materials in the layered system.

The potential  $\phi$  of the van der Waals forces is frequently specified in terms of the excess intermolecular free energy  $\Delta G$ . These two values are related each to other via:

$$\phi = \frac{\partial \Delta G}{\partial h} \quad (10.29)$$

It follows in this case from Eq. (10.22) in the three-dimensional case and Eq. (10.23) in the two-dimensional case that the film is unstable to infinitesimal disturbances only if:

$$\frac{\partial\phi}{\partial h} < 0 \quad \text{or} \quad \text{equivalently} \quad \frac{\partial^2\Delta G}{\partial h^2} < 0 \quad (10.30)$$

It follows from Eq. (10.30) that the film is unstable only if the potential  $\phi$  has a decreasing branch or  $\Delta G$  displays a negative curvature, both as functions of the film thickness  $h$ .

In the special case of an apolar film with parallel boundaries and nonretarded forces,

$$\phi = \phi_r + A'h^{-3}/6\pi \quad (10.31a)$$

where  $\phi_r$  is an additive reference value for the body-force potential omitted hereafter and  $A'$  is the dimensional Hamaker constant [Dzyaloshinskii et al., 1959]. When  $A' > 0$ , there is negative disjoining pressure (referred to sometimes as conjoining pressure), and a corresponding attraction of the two interfaces (solid–liquid and liquid–gas) toward each other causes the instability of the flat state of the film surface and eventually its breakup. When the disjoining pressure is positive,  $A' < 0$ , the interfaces repel each other, and the flat state of the film surface is energetically preferred.

Various forms for the potential  $\phi$  accounting for more complex physical situations are encountered in the literature. Mitlin (1993), Mitlin and Petviashvili (1994), Khanna and Sharma (1998) and others used the Lennard–Jones 6–12 potential for van der Waals interactions between the solid and the apolar liquid:

$$\phi = A'_3 h^{-3} - A'_9 h^{-9} \quad (10.31b)$$

with positive dimensional Hamaker coefficients  $A'_j$ . In this case, the two interfaces of the film are mutually attracting when the separation distance is relatively large, which drives the instability of the flat state of the film surface, and mutually repelling when the separation distance is relatively short, which finally saturates the amplitude of the interfacial undulation.

If the solid substrate is coated with a layer of thickness  $\delta$ , the potential of the intermolecular pairwise interactions among the solid, coating, passive air and apolar liquid phases is given by [Bankoff, 1990; Hirasaki, 1991; Sharma and Reiter, 1996; Khanna et al., 1996; Oron and Bankoff, 1999]:

$$\phi = A'_3 h^{-3} + \hat{A}'_3 (h + \delta)^{-3} \quad (10.31c)$$

where  $A'_3 = (A'_{\ell\ell} - A'_{c\ell})/6\pi$ ,  $\hat{A}'_3 = (A'_{s\ell} - A'_{c\ell})/6\pi$  with  $A'_{ij}$  being the Hamaker constant related to the interaction between the phases  $i$  and  $j$ ,  $A'_{ij} = A'_{ii}{}^{1/2} A'_{jj}{}^{1/2}$  [Israelachvili, 1992], and subscripts  $s$ ,  $c$  and  $\ell$  correspond, respectively, to solid, coating and liquid phases.

Oron and Bankoff (1999) derived the potential topologically similar to the Lennard–Jones potential (10.31a) but with different exponents:

$$\phi = A'_3 h^{-3} - A'_4 h^{-4} \quad (10.31d)$$

to model the simultaneous action of the attractive ( $A'_3 > 0$ ) long-range and repulsive ( $A'_4 > 0$ ) (relatively) short-range van der Waals interactions and their influence on the dynamics of the film. To obtain the potential of Eq. (10.31d), Eq. (10.31a) was expanded into the Taylor series in  $h$  under the assumption of  $\delta \ll d$  with  $\hat{A}'_3 > 0$ ,  $A'_3 + \hat{A}'_3 > 0$ , and only two leading terms of this expansion being kept. Thus, the coefficients  $A'_3$ ,  $A'_4$  are specified by the properties of the three phases. The potential of the form of Eq. (10.31d) is also appropriate for liquid films on a rough solid substrate [Teletzke et al., 1987; Mitlin, 2000].

A combination of long-range apolar (van der Waals) and shorter range polar intermolecular interactions gives rise to the generalized disjoining pressure expressed by the potential:

$$\phi = A'_3 h^{-3} - S^p \exp(-h/\ell)/\ell \quad (10.31e)$$

where  $S^p$  and  $\ell$  are dimensional constants [Williams, 1981; Sharma and Jameel, 1993; Jameel and Sharma, 1994; Paulsen et al., 1996; Sharma and Khanna, 1998; and others], being, respectively, the strength of the polar interaction and its decay length  $\ell$ , called the *correlation length* for polar interaction. The polar component of the potential is repulsive, if  $S^p > 0$ , and attractive, if  $S^p < 0$ . Sharma and Jameel (1993) classified films with polar and apolar components into four groups: type I systems, with both polar and apolar attractive forces ( $A'_3 > 0$ ,  $S^p < 0$ ); type II systems, with apolar attractions and polar repulsions ( $A'_3 > 0$ ,  $S^p > 0$ ); type III systems, with both polar and apolar repulsions ( $A'_3 < 0$ ,  $S^p > 0$ ); and type IV systems, with apolar repulsions and polar attractions ( $A'_3 < 0$ ,  $S^p < 0$ ). Type I films are always unstable and their dynamics in many ways are similar to those of apolar films described by the potential, Eq. (10.31a), while those of type III are always stable. Type II and IV films display ranges of stability and instability according to the sign of the derivative  $\partial\phi/\partial h$ ; see the instability criterion Eq. (10.30c).

### 10.3.3 Homogeneous Substrates

Scheludko (1967) observed experimentally the spontaneous breakup of ultrathin static films and proposed that negative disjoining pressure is responsible. He also used linear stability analysis in order to calculate a critical thickness of the film below which breakup occurs, while neglecting the presence of electric double layers. Since then a great deal of scientific activity has been focused around the phenomenon.

The dynamics of ultrathin liquid films and the process of dewetting of solid surfaces have attracted special interest during the last decade. Progress and development of experimental techniques such as ellipsometry, X-ray reflectometry, atomic force microscopy (AFM) and others, on the one hand, and computational techniques along with the availability and affordability of fast computers, on the other hand, have helped to advance the study of the pertinent phenomena. The main interest was and still is centered around pattern formation and the dominant mechanisms driving film evolution. In the context of the latter issue, the polemics is ongoing between the two candidates, namely, thin-film instability arising from the interaction between the intermolecular and capillary forces (called sometimes in the literature *spinodal dewetting* or *spinodal mode*) and nucleation of holes from impurities or defects. It should be noted that most if not all of the experiments with dewetting recorded in the literature were carried out on liquid polymer films, while the theory is currently available for simple Newtonian liquids. The reasons for using polymer films in terms of controllability of the experiments were discussed by Sharma and Reiter (1996) and Reiter et al. (1999b).

Bischof et al. (1996) performed experiments on ultrathin ( $\approx 40$ -nm-thick) metal (gold, copper and nickel) films on a fused silica substrate irradiated by a laser and turned into the liquid phase. Both isolated and coalesced holes along with typical rims surrounding them were observed. Little humps were found in the center of many holes, and the mechanism of heterogeneous hole nucleation was suggested to be responsible for formation of these. However, along with this mechanism, growing film surface deformations were detected, thus the mechanism of spinodal dewetting is also in effect. The characteristic size of film surface deformations was found to be well correlated with the wavelength of the most amplified linear mode proportional to  $d^2$ . Similar conclusions about the dominance of the nucleation mechanism were drawn later by Jacobs et al. (1998). Experimental evidences of spinodal dewetting were given by Brochard-Wyart and Daillant (1990), Reiter (1992), Sharma and Reiter (1996), Xie et al. (1998), Reiter et al. (1999b; 2000) and others. Reiter et al. (2000) showed for the first time that the spinodal length and time scales are consistent with the results of their experiments. Independent molecular dynamics simulations [Koplik and Banavar, 2000] support the spinodal character of dewetting.

Khanna et al. (2000) presented the first real-time experimental observation of the pattern formation in thin unstable polydimethylsiloxane (PDMS) films placed on coated silicon wafers and bounded by

aqueous surfactant solutions. The process of film disintegration (“self-destruction”) was described as the sequence of the stages of self-organization of the pattern and selective amplification of the interfacial disturbance, breakup of the film and formation of isolated circular holes, lateral expansion of the holes and emergence of long liquid ridges and, finally, breakup of the ridges into droplets standing on an equilibrium film plateau and ripening of the droplet structure.

Muller-Buschbaum et al. (1997) studied the process of dewetting of thin polystyrene films on silicon wafers covered with an oxide layer of different thicknesses and observed the emergence of “nano-dewetting structures” inside the dewetted areas. These structures in the form of troughs about 70 nm in diameter indicated that the dewetted areas were neither completely dry nor covered with a flat ultrathin layer of the liquid. Such patterns were detected along with micrometer-size drops usually observed in similar situations on top of oxide layers 24 Å thick but were not present on thinner oxide layers where only drops emerged. The dependence of the mean drop size as well as the trough diameter on the initial thickness of the film was in agreement with theoretical predictions based on the assumption of spinodal dewetting [Muller-Buschbaum et al., 1997].

Consider now a film under the influence of van der Waals forces and constant surface tension only, so that  $\Pi_1 = \Pi_2 = \Pi_3 = \sigma_x = \sigma_y = 0$ . As we shall see shortly, the planar film is unstable when  $A' > 0$  and stable when  $A' < 0$ . In two dimensions, Eq. (10.23) in the case at hand becomes [Williams and Davis, 1982]:

$$\mu h_t + \frac{1}{6\pi} A' (h^{-1} h_x)_x + \frac{1}{3} \sigma (h^3 h_{xxx})_x = 0 \quad (10.32a)$$

Its dimensionless version reads:

$$H_\tau + A (H^{-1} H_\xi)_\xi + \frac{1}{3} S (H^3 H_{\xi\xi\xi})_\xi = 0 \quad (10.32b)$$

where

$$A = \frac{\epsilon A'}{6\pi\rho\nu^2 d}$$

is the scaled dimensionless Hamaker constant and  $\nu = \mu/\rho$  is the kinematic viscosity of the liquid. Here, the characteristic velocity was chosen as  $U_0 = \nu/d$ .

If Eq. (10.32a) is linearized around  $h = d$ , the following characteristic equation for  $\omega$ ,

$$\mu\omega = \left(\frac{a}{d}\right)^2 \left(\frac{A'}{6\pi d} - \frac{1}{3}\sigma da^2\right) \quad (10.33a)$$

is obtained. It follows from Eq. (10.33a) that there is instability for  $A' > 0$ , driven by the long-range molecular forces, and stabilization is due to surface tension. The cutoff wave number  $a_c$  is given then by:

$$a_c = \frac{1}{d} \left(\frac{A'}{2\pi\sigma}\right)^{1/2} \quad (10.33b)$$

which reflects the fact that an initially corrugated interface has its thin regions thinned further by van der Waals forces while surface tension cuts off the small scales. Instability is possible only if  $0 < a < a_c$ , as seen by combining Eqs. (10.33a) and (10.33b):

$$\mu\omega = \frac{\sigma a^2}{3d} (a_c^2 - a^2) \quad (10.34)$$

Similar results were obtained in the linear stability analysis presented by Jain and Ruckenstein (1974). On the periodic infinite domain of wavelength  $\lambda = 2\pi/k$ , the linearized theory predicts that the film is always unstable as all wave numbers are available to the system. In an experimental situation, the film resides in a container of finite width, say,  $L$ . The solution obtained from the linear stability theory for  $0 \leq \xi \leq L$  would show that only perturbations of the nondimensional wave number lower than  $a_c$  (see Eq. (10.34)) and those of small enough wavelength that “fit” in the box (i.e.,  $\lambda < L$ ) are unstable. Hence, no instability would occur by this estimate if  $2\pi d/L > a_c$ . One sees from this theory that it is inappropriate to seek a “global” critical thickness from the theory but only a critical thickness for a given experiment, as the condition depends on the system size  $L$ .

The evolution of the film interface as described by Eq. (10.32) with periodic boundary conditions and an initial linearly unstable perturbation of the uniform state leads to the rupture of the film in a finite (nondimensional) time  $\tau_R$  [Williams and Davis, 1982]. This rupture manifests itself by the fact that at a certain time the local thickness of the film becomes zero. The time of rupture of the film of an infinite lateral extent can be estimated from the linear stability theory by:

$$t_R = \frac{48\pi^2 d^5 \sigma}{A'} \ln \left( \frac{d}{h'_0} \right)$$

However, the rate of film thinning, measured as the rate of decrease of the minimal thickness of the film, explosively increases with time and becomes much larger than the disturbance growth rate given by Eq. (10.33a) according to the linear theory. This fact could be foreseen by observation of Eq. (10.32b), noticing that the “effective” diffusion coefficient, proportional to  $H^{-1}$ , in the backward diffusion  $A$  term increases indefinitely as the film becomes thinner,  $H \rightarrow 0$ , while the local stabilization effect provided by surface tension weakens proportionally to  $H^3$ . This observation was confirmed numerically from the solution of Eq. (10.32b) [Williams and Davis, 1982] and analytically by weakly nonlinear theory [Sharma and Ruckenstein, 1986; Hwang et al., 1993]. Hwang et al. (1997) studied the three-dimensional version of this problem using the natural extension of Eq. (10.32b). They confirmed the fact of film rupture and found that it occurs pointwise and not along a line. Moreover, the rupture time in the three-dimensional case is shorter than in the two-dimensional one.

Burelbach et al. (1988) used numerical analysis to show that in a certain time range near the rupture point surface tension has a minor effect and therefore the local behavior of the interface there is governed by the backward diffusion equation,

$$H_\tau + A(H^{-1}H_\xi)_\xi = 0 \quad (10.35)$$

Looking for separable solutions for Eq. (10.35) in the form  $H(\xi, \tau) = T(\tau)X(\xi)$ , Oron et al. (1997) used the known temporal asymptotics [Burelbach et al., 1988] and found that [see also Rosenau, 1995]:

$$H(\xi, \tau) = A \frac{b^2}{2} (\tau_R - \tau) \sec^2 \left( \frac{b\xi}{2} \right) \quad (10.36)$$

where  $\tau_R$  is the time of rupture and  $b$  is the constant which should be determined from the matching with the far-from-rupture solution. The minimal thickness of the film close to the rupture point is therefore expected to decrease linearly with time. This allows the long-wave analysis to be extrapolated closer to the point where adsorbed layers and/or moving contact lines appear. However, the solution to Eq. (10.35) is not expected to be valid very close to the rupture point, as the film progresses toward rupture and the fluid velocities diverge. Recently, the existence of infinite sets of similarity solutions in which both van der Waals and surface tension forces are equally important near rupture was shown [Zhang and Lister, 1999; Witelski and Bernoff, 1999; 2000]. These solutions have the same form in both

two-dimensional and axisymmetric cases

$$H(\xi, \tau) = (\tau_R - \tau)^{1/5} g[\xi(\tau_R - \tau)^{-2/5}] \quad (10.37)$$

where  $g$  is a function to be further determined. Among this infinite set of self-similar solutions the fundamental solution stable to linear perturbations was identified as the only asymptotic behavior observed in the direct numerical solution of Eq. (10.32b) [Zhang and Lister, 1999; Witelski and Bernoff, 1999]. It is described by the function  $g$  being the least oscillatory one among the possible solutions of the corresponding ordinary differential equation. The point rupture was found to be the preferred mode of film rupture in three dimensions [Witelski and Bernoff, 2000].

Several authors [Khesghi and Scriven, 1991; Mitlin, 1993; Sharma and Jameel, 1993; Jameel and Sharma, 1994; Mitlin and Petviashvili, 1994; Oron and Bankoff, 1999] have considered the dynamics of thin liquid films in the process of dewetting of a solid surface. The effects important for a meaningful description of the process are gravity, capillarity and, if necessary, the use of a generalized disjoining pressure, which contains a sum of intermolecular attractive and repulsive potentials. The generalized disjoining pressure of the Mie type is destabilizing (attractive) or stabilizing (repulsive) for the film of a larger (smaller) thickness, still within the range of several hundreds of Angstroms [Israelachvili, 1992] where van der Waals interactions are effective. Equations (10.21) and (10.23) can be rewritten in the situation considered, respectively, in the form:

$$H_\tau - \frac{1}{3}[H^3(GH - SH_{\xi\xi} + \Phi)_\xi]_\xi = 0 \quad (10.38a)$$

$$\mu h_t - \frac{1}{3}[h^3(\rho gh - \sigma h_{xx} + \phi)_x]_x = 0 \quad (10.38b)$$

Linearizing Eq. (10.38b) around  $h = d$ , one obtains:

$$\mu \omega = -\frac{1}{3}a^2 d \left( \rho g + \frac{\partial \phi}{\partial h} d + \frac{\sigma a^2}{d^2} \right) \quad (10.39)$$

It follows from Eq. (39) that the necessary condition for linear instability is

$$\frac{\partial \phi}{\partial h} d < -\rho g \quad (10.40)$$

i.e., the destabilizing effect of the van der Waals force has to be stronger than the leveling effect of gravity.

Khesghi and Scriven (1991) studied the evolution of the film using Eq. (10.38a) with the potential (10.31a) and found that smaller disturbances decay due to the presence of gravity leveling, while larger ones grow and lead to film rupture propelled by van der Waals force. Mitlin (1993) and Mitlin and Petviashvili (1994) discussed possible stationary states for the late stage of solid-surface dewetting with the potential (10.31b) and drew the formal analogy between the latter and the Cahn theory of spinodal decomposition [Cahn, 1961]. Sharma and Jameel (1993; 1994) followed the film evolution as described by Eqs. (10.38) and (10.31e) with no gravity ( $G = 0$ ) and concluded that thicker films break up, while thinner ones undergo “morphological phase separation” that manifests itself in creation of steady structures of drops separated by ultrathin, practically flat liquid films (holes). Similar patterns of morphological phase separation were also observed by Oron and Bankoff (1999) in their study of the dynamics of thin spots near film breakup. Figure 2 in Oron and Bankoff (1999) shows typical steady-state solutions for Eq. (10.38a) with the potential (10.31d) and  $G = 0$  for different sets of parameters.

Khanna and Sharma (1998) used the Lennard–Jones potential, Eq. (10.31b), to study the three-dimensional dynamics of an apolar liquid film on a solid substrate. Their investigation based on the

dimensionless evolution equation,

$$H_\tau - \frac{1}{3} \nabla \cdot (H^3 \nabla \Phi) + \frac{1}{3} S \nabla \cdot (H^3 \nabla \nabla^2 H) = 0 \quad (10.41)$$

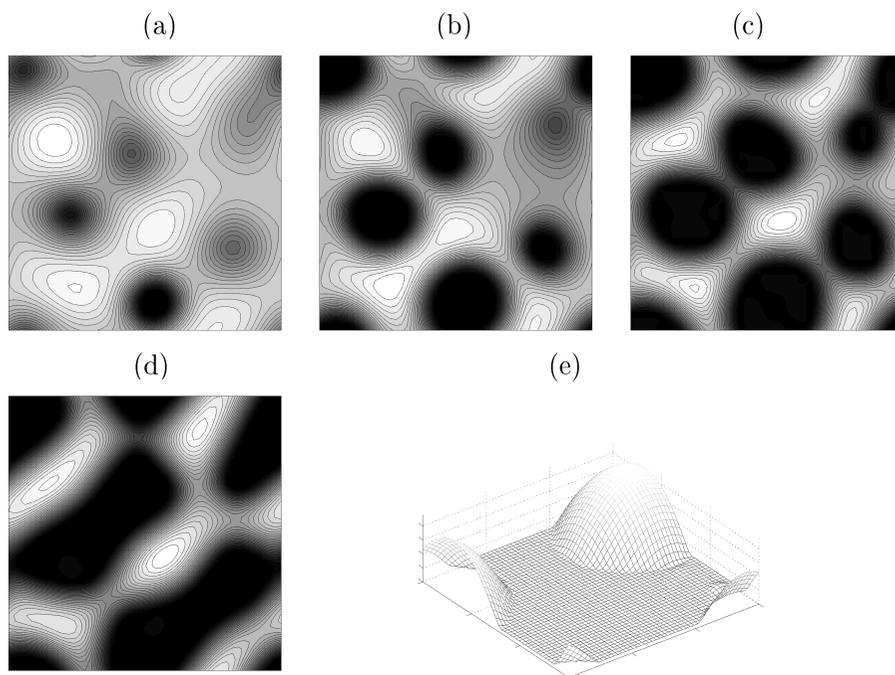

showed that in the case of  $A_9 d^6 \ll A_3'$  the corresponding film evolution displays the formation of steep holes. These holes are axisymmetric when the size of the periodic domain slightly exceeds the critical wavelength. However, they are nonaxisymmetric with uneven rims surrounding the holes for larger domains.

Sharma and Khanna (1998) studied the film dynamics governed by Eq. (10.41) with the potential (10.31e) that engenders short-range polar repulsion, intermediate-range van der Waals attraction and long-range polar repulsion. The linear and weakly nonlinear analyses fail to predict the structure of the emerging patterns. The former, however, can successfully predict the length scale of the resulting pattern. Two characteristic, morphologically different patterns were found and in both of them true dewetting does not occur. A microfilm covering the solid surface emerges and persists instead. The first pattern is typical for films with a thickness closer to the upper critical thickness. In this case, the film undergoes the stages of reorganization into a pattern of a length scale corresponding to the fastest growing linear mode, emergence of circular holes with rims uneven in height, coalescence of the holes and slow evolution into circular drops standing on top of a flat microfilm. The second one typical for relatively thin films of initial thickness near the lower critical thickness does not exhibit formation of circular holes and produces droplets that tend to be circular subject to the capillary forces. This type of a film evolution seems to be less frequent but has also been observed in experiments [Xie et al., 1998]. The flat microfilm covering the substrate emerges after the formation of isolated drops. Finally, a stable state that consists of a single circular drop standing on a flat equilibrium film is reached. In the intermediate range of the initial film thickness, the patterns consisting of holes, ridges and drops coexist when the number of each of these depends on the initial film thickness. As will be discussed below, all kinds of structures that contain holes, drops and ridges may coexist on heterogeneous substrates [Konnur et al., 2000].

Sharma et al. (2000) attributed the type of film dewetting to the relative position of the average thickness of the film  $d$  and the location of the minimum of the function  $\partial\phi/\partial h$ : When the film is thicker than the thickness corresponding to the minimum of  $\partial\phi/\partial h$ , the film dewets by formation of holes, while in the opposite case dewetting sets in by formation of liquid ridges which further break up into droplets. In either case, ripening of the droplet structure takes place and larger droplets grow at the expense of smaller ones.

Oron (2000c) studied the evolution of a film on a coated solid substrate as described by Eq. (10.41) with the potential Eq. (10.31d) given in dimensionless form as  $\Phi = A_3 H^{-3} - A_4 H^{-4}$ , where  $A_3$  and  $A_4$  are positive nondimensional Hamaker constants. As noted above, this potential acts as long-range van der Waals attraction and short-range repulsion, both apolar. The evolution of a small-amplitude disturbance of a flat initial state  $H = 1$  leads to self-organization of the surface, emergence of holes, their expansion, coalescence and formation of polygonal network of liquid ridges on top of the essentially flat microlayer. Later on the liquid ridges break up into isolated drops and ridges that pump their liquid by means of the capillary forces into the largest drop, making the latter bigger and more circular. The existence of a “thick” microlayer facilitates a relatively free liquid flow along the coated substrate and the accumulation of the liquid in an isolated drop standing on a plateau, minimizing by that the free energy of the system. Finally, a steady state is reached, where a circular drop persists standing on a flat equilibrium film (Figure 10.7). The film evolution described was found to follow the typical sequence of events as described in the experiments [Khanna et al., 2000].

Reiter et al. (1999a) carried out theoretical and experimental studies of the dynamics of films on wettable solid surfaces and being in contact with the ambient phase of various physicochemical identity. By exchanging the ambient phase it is possible to vary the total Hamaker constant of the system and even to change its sign, thus turning the initially stable configuration into the unstable one. Experiments with PDMS films on a silicon wafer with alternating air and water ambient phases provided an example

**FIGURE 10.7** Stages of evolution of a nonevaporating film as described by Eq. (10.41) with the potential (10.31d). The first four images are given in the form of a contour plot, while the last one is in the form of a surface plot. Each image has its own brightness, so the film thickness in different images cannot be compared. A polygonal network of liquid ridges qualitatively similar to the experimental observations made by Sharma and Reiter (1996) is seen in parts (b) to (d). Bright and dark shades correspond to elevations and depressions, respectively. (From Oron, A. (2000) *Phys. Rev. Lett.* **85**, pp. 2108–2111. Copyright 2000 by the American Physical Society. With permission.)

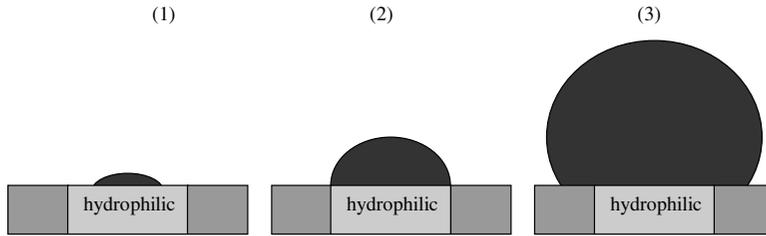

of such a system [Reiter et al., 1999a; 1999b]. When in contact with air, the film remained flat and did not exhibit any evidence of instability; however, while in contact with water, instability set in and the film, whose initial thickness ranged between 30 and 110 nm, finally reached the state in which small droplets stood on top of a thin wetting layer. This phenomenon was studied theoretically [Reiter et al., 1999a] using a three-dimensional evolution equation (10.41) with potential topologically similar to that of Eq. (10.31b). Qualitative agreement between theory and experiments was found to be quite good. However, as noted by Reiter et al. (1999), even quantitative agreement between the two could be achieved but for an “unexpectedly high effective Hamaker constant.” The reason for this is still unclear.

### 10.3.4 Heterogeneous Substrates

A study of the dynamics of thin liquid films on a heterogeneous substrate can be motivated by the presence of dust particles or other types of impurities, oxidized or rough patches, or varying chemical composition leading to nonuniform wettability properties of the solid surface underlying the film. These and other types of heterogeneity of the substrate may be present unintentionally or may be created deliberately to achieve a certain goal.

The governing equation to be studied in this context is again Eq. (10.41) but, in contrast to the case of the homogeneous substrate where the potential of the intermolecular forces depends solely on the film thickness,  $\Phi = \Phi(H)$ , in the current case the potential explicitly depends on the lateral spatial coordinates as well. This dependence enters the equations via spatial variation of the Hamaker coefficients.

A series of papers [Lenz and Lipowsky, 1998; Herminghaus et al., 1999; 2000; Gau et al, 1999; Lenz, 1999; Lipowsky et al., 2000] examined the morphological transitions of liquid layers on heterogeneous

**FIGURE 10.8** Equilibrium states of the droplets on a heterogeneous substrate that consists of alternating hydrophilic and hydrophobic patches. These equilibria depend on the droplet volume.

structured substrates. Lenz and Lipowsky (1998) showed by minimization of the total interfacial free energy that for a domain containing a hydrophilic patch confined between the hydrophobic ones three different regimes, depending on the volume of the droplet, are possible, as shown in Figure 10.8. In regimes 1 and 3, the respective contact angles are prescribed *a priori* by the phases chosen and satisfy the Young equation. Regime 2 is characterized by the droplet volume and the contact angle spanning the range between the respective values of regimes 1 and 3. In the limiting case of perfectly wettable hydrophilic and nonwettable hydrophobic patches, only regime 2 is possible. In the case of a two-dimensional, square, periodic lattice of  $N$  circular hydrophilic patches surrounded by hydrophobic domains, the equilibrium state for a low total liquid volume consists of  $N$  identical droplets, each of them covering its own hydrophilic patch similar to regime 1 for the case of an isolated patch. As the total volume of the liquid increases, the droplets grow and the system undergoes transition to a heterogeneous equilibrium state that consists of one large drop and  $N - 1$  small identical drops. More complex heterogeneous states were found to be unstable [Gau et al., 1999]. When the total volume of the liquid increases further beyond a certain value, a third equilibrium state that represents a single completely wetting layer covering the entire system becomes possible. The transition to this equilibrium state is possible from either of the aforementioned states. For striped periodic domains, all of the three equilibrium states found in the previous case persist. However, a new kind of transition from the homogeneous state to the film state exists here. This transition consists of the stages where identical droplets span over several hydrophilic patches and the hydrophobic ones in between.

Gau et al. (1999) performed a series of experiments with liquid microchannels created by hydrophilic stripes about 40  $\mu\text{m}$  wide and further condensation of water onto the substrate. When the total amount of condensed water was low, the microchannels had a shape of cylindrical caps of a constant cross section with a small contact angle  $\theta$  between the liquid and the solid. However, when the total volume of water exceeded a certain value, the straight channels underwent instability, which led to formation of a single bulge on each of the stripes. Moreover, when the bulges on two neighboring channels were in close proximity, they merged to form a big drop or microbridge between the channels. Gau et al. (1999) found theoretically that the cylindrical cap configuration with contact angle  $\theta$  is linearly stable for  $\theta < 90^\circ$  and unstable to long-wave disturbances for  $\theta > 90^\circ$ , provided that the wavelength of the disturbance is sufficiently large:

$$\lambda > \lambda_c = \left[ \frac{\pi/2}{\theta^2 - (\pi/2)^2} \right]^{1/2} \frac{\theta}{\sin \theta} a_\gamma$$

where  $a_\gamma$  is the width of the hydrophilic stripe. The presence of this instability disallows the emergence of long homogeneous liquid channels with a contact angle larger than  $90^\circ$ . The onset of the instability occurs at  $\theta = 90^\circ$ , and the wavelength of the critical disturbance is infinite. This explains the formation of a single bulge on the microchannel [Herminghaus et al., 2000]. The precise shape of the configuration of liquid microchannels with bulges was numerically calculated by Gau et al. (1999) using minimization of the total free energy. A very good agreement was found between the experimental and theoretical results.

Konnur et al. (2000) and Kargupta et al. (2000) studied the three-dimensional dynamics of liquid crystal films using Eq. (10.41) with the potential (10.31e) with different sets of fixed positive values— $a_3$ ,  $S^p$ ,  $\ell$ —on the patches of the substrate. They reported a new mechanism of film instability associated with the substrate heterogeneity which is driven by the pressure gradient generated by the spatial variation of  $\phi$  and directed from the less to the more wettable domains on the solid. The potential (10.31e) employed by Konnur et al. (2000) prescribes instability for both relatively thin and thick films, while films in the intermediate range are stable. They found that the presence of heterogeneity is able to destabilize even spinodally stable films, speed up the rupture process of the film and produce spatially complex and locally ordered patterns. Destabilization of spinodally stable films arises even when the heterogeneous patch is much smaller than the spinodal length scale determined as the wavelength of the fastest growing linearly unstable disturbance. It was found that true rupture can occur for spinodally stable films if the local thickness of the film is reduced by the heterogeneous mechanism to the value where the spinodal instability condition is met and both of the mechanisms propel the film to rupture. The evolution of an initially flat film typically exhibits such morphological patterns as a lack of surface deformations prior to the formation of a hole, emergence of a non-growing hole on a perfectly wetted substrate or in a spinodally stable film, formation of a “castle-moat” pattern with a central drop surrounded by a ring-like depression or hole and formation of locally ordered structures with alternating depressions and rims [Konnur et al. 2000; Kargupta et al. 2000]. The heterogeneous mechanism was found to be strong for relatively thick films and its time scale several orders of magnitude lower than that of the spinodal mechanism. Kargupta et al. (2000) also considered the two-dimensional dynamics of film on a substrate with a heterogeneous patch of varying size. They found that the presence of heterogeneity always causes the emergence of local interfacial depression, which can evolve into film rupture when the length of the patch becomes sufficiently large. The rupture time was found to rapidly decrease when the patch length increases beyond the critical length and to become independent of the patch length when the latter is large.

Studies of the two- and three-dimensional film dynamics on heterogeneous substrates with alternating parallel stripes of hydrophilic and hydrophobic patterns are now underway [Oron, 2000d; Sharma, 2000] and will be shortly reported elsewhere in the literature.

### 10.3.5 Flow on a Rotating Disc

The isothermal, axisymmetric flow of an incompressible viscous liquid was considered on a horizontal rotating disk by Reisfeld et al. (1991). Cylindrical polar coordinates  $r$ ,  $\theta$ ,  $z$  are used in the frame of reference rotating with the disk. The film interface is located at  $z = h(r, t)$ . In the coordinate system chosen, the outward unit normal vector  $\mathbf{n}$  and unit tangent vector  $\mathbf{t}$  are

$$\mathbf{n} = \frac{(-h_r, 0, 1)}{(1 + h_r^2)^{1/2}}, \quad \mathbf{t} = \frac{(1, 0, h_r)}{(1 + h_r^2)^{1/2}}$$

The hydrodynamic equations analogous to Eq. (10.2) taking into account both the centrifugal forces and Coriolis acceleration are written in the vector form as:

$$\nabla \cdot \mathbf{v} = 0, \quad \rho[\mathbf{v}_t + (\mathbf{v} \cdot \nabla)\mathbf{v}] = -\nabla p + \mu \nabla^2 \mathbf{v} - \rho[\mathbf{g} + 2\boldsymbol{\omega} \times \mathbf{v} + \boldsymbol{\omega} \times \boldsymbol{\omega} \times \mathbf{v}]$$

where  $\boldsymbol{\omega}$  is the angular-velocity vector with the components  $(0, 0, \bar{\omega})$ . The boundary conditions are given by Eq. (10.4) formulated in cylindrical polar coordinates with  $\nabla_s \sigma = 0$  and  $\Pi = 0$ .

The characteristic length scale in the horizontal direction is chosen as the radius of the rotating disk  $\bar{R}$ , and the velocity scale is taken as  $U_0 = \rho \bar{\omega}^2 \bar{R} d^2 / \mu$ . A small parameter  $\varepsilon$  is defined in accordance with Eq. (10.7) as  $\varepsilon = d / \bar{R}$ . The dimensionless parameters of the problem are the Reynolds number  $R$  as given in Eq. (10.12), the scaled inverse capillary number  $S$  given by Eqs. (10.12) and (10.15) and the

Froude number  $F$ ,

$$F = \frac{U_0}{(gd)^{1/2}}$$

Using the procedures outlined above, one obtains at the leading order the following evolution equation:

$$H_\tau + \frac{1}{3r} \left\{ r^2 H^3 + SrH^3 \left[ \frac{1}{r} (rH_r)_r \right] \right\} = 0 \quad (10.42)$$

Here, the terms describing the effect of inertia and gravity appeared in the terms of first order in  $\varepsilon$  and thus were omitted. However, they may be retained to investigate the dynamics of the rotating film in the first phase of the process including inertia and amplification of kinematic waves [Reisfeld et al., 1991]. Equation (10.42) models the combined effect of capillary forces and centrifugal drainage, none of which describes any kind of instability.

For most spin-coating applications,  $S$  is very small and the corresponding term may be neglected, although it may be very important in planarization studies, where the leveling of liquid films on rough surfaces is investigated. Equation (10.42) can be thus simplified as:

$$H_\tau + \frac{1}{3r} (r^2 H^3)_r = 0 \quad (10.43)$$

This simplified equation can then be used for further analysis. Looking for flat basic states  $H = H(\tau)$ , Eq. (10.43) is reduced to the ordinary differential equation which is to be solved with the initial condition  $H(0) = 1$ . The film thins due to centrifugal drainage according to the solution

$$H(\tau) = \left( 1 + \frac{4}{3}\tau \right)^{-1/2}$$

which predicts a decrease of the thickness to zero at the infinite time. The cases where inertia was taken into account were considered by Reisfeld et al. (1991), who also provided linear stability analysis of flat base states.

Stillwagon and Larson (1990) considered the spin-coating process and leveling of a nonvolatile liquid film over an axisymmetric, uneven solid substrate. For a given local dimensionless height of the substrate  $\ell(r)$ , their equation derived from the Cartesian version valid for capillary leveling of a film in a trench resembles Eq. (10.42) and reads:

$$H_\tau + \frac{1}{3\hat{r}} [\alpha \hat{r}^2 H^3 + \hat{S} \hat{r} H^3 (H_{\xi\xi\xi\xi} + \ell_{\xi\xi\xi\xi})]_\xi = 0 \quad (10.44)$$

where  $\hat{r}$  and  $\xi$  are, respectively, the radial coordinate and the radial distance from the trench, both scaled with the trench width, and  $\alpha$  is the ratio of the width and the location of the trench. Equation (10.44) can be further simplified under the assumption that the width of the trench is small compared to its radial position and can be brought to the form:

$$H_\tau + \frac{1}{3} [H^3 + \Omega^2 H^3 (H_{\xi\xi\xi\xi} + \ell_{\xi\xi\xi\xi})]_\xi = 0, \quad (10.45)$$

where  $\Omega^2$  is the ratio between the centrifugal and capillary forces. Stillwagon and Larson (1990) calculated quasi-steady-state solutions close to the trench by solving the time-independent version of Eq. (10.44)

$$H^3 (H_{\xi\xi\xi\xi} + \ell_{\xi\xi\xi\xi}) + \Omega^2 H^3 = \Omega^2 \quad (10.46)$$

where the term on the right arises from the condition of uniformity of the film far from the trench. Experiments with liquid films reported by Stillwagon and Larson (1990) demonstrated quantitative agreement between measured film profiles and those obtained from Eq. (10.46).

Wu et al. [Wu and Chou, 1999; Wu et al., 1999] used Eq. (10.46) to study the degree of planarization for periodic uneven substrates expressed as the ratio between the amplitude of the deformed film interface and the average thickness of the film. They showed that this value is independent of  $\Omega$  and varies slightly with the trench spacing for large  $\Omega$ , while it decreases with the increase of spacing for small fixed values of  $\Omega$ .

Chou and Wu (2000) studied the effect of air shear on the process of film planarization. Similar to the case considered in Section IIC of Oron et al. (1997; see Eq. (2.31)), where the term proportional to the imposed shear stress multiplied by  $hh_x$  arises in the evolution equation, air shear produces the advective term proportional to  $H^2$ , which has to be added to the expressions in the square brackets of the left-hand side of Eqs. (10.44) and (10.45). Corresponding additional terms will appear in Eq. (10.46) as well. Chou and Wu (2000) studied such an extended Eq. (10.46) and found that the shear stress enhances the amplitude of the film interface and thus opposes film planarization during spin coating for both isolated and periodic features of the substrate.

Puerrung and Graves (1993) considered three-dimensional quasi-steady states for spin coating over topography using the natural extension of Eq. (10.45) into three dimensions. Their theoretical and experimental results agree qualitatively, both showing the emergence of wake-like structures at the downstream side of the protrusion with crests extending along each of the corners and the depression near the center.

## 10.4 Thermal Effects

One of the best known fluid flows under the influence of heat transfer is the buoyancy or Rayleigh convection [Chandrasekhar, 1961] of a stagnant liquid layer lying on a horizontal solid surface triggered by heating from below and subsequent establishment of unstable density stratification. This convection sets in when the temperature difference across the layer exceeds a certain critical value, which is proportional among other physical parameters of the system to the third power of the layer thickness  $d$ . Due to the fact that the range of very small values of the film thickness is of a major interest in the context of MEMS, the Rayleigh effect is much weaker than the thermocapillary or Marangoni effect addressed next. The latter scales with the first power of  $d$  in contrast with  $d^3$  in the case of the Rayleigh effect.

### 10.4.1 Thermocapillarity, Surface Tension and Gravity

The thermocapillary or Marangoni effect (e.g., see Davis [1987]) accounts for the emergence of interfacial shear stresses, due to the variation of surface tension with temperature  $\vartheta$ ,  $\sigma = \sigma(\vartheta)$ , which is in most cases monotonically decreasing. Such a shear stress is mathematically expressed by  $\nabla_s \sigma$  [Edwards et al., 1991]. In order to incorporate the thermocapillary effect into the equations, one needs to add an energy equation and the appropriate boundary conditions related to heat transfer to the governing system Eqs. (10.2) to (10.4).

The energy equation in three dimensions and the boundary conditions have the form:

$$\rho c (\vartheta_t + u\vartheta_x + v\vartheta_y + w\vartheta_z) = k_{th} (\vartheta_{xx} + \vartheta_{yy} + \vartheta_{zz}) + \dot{q} \quad (10.47)$$

$$\vartheta = \vartheta_0 \quad \text{at} \quad z = 0 \quad (10.48a)$$

$$k_{th} \mathbf{n} \cdot \nabla \vartheta + \alpha_{th} (\vartheta - \vartheta_\infty) = 0 \quad \text{at} \quad z = h(x, y, t) \quad (10.48b)$$

Here,  $c$  is the specific heat of the fluid;  $k_{th}$  is its thermal conductivity;  $\vartheta_0$  is the temperature of the rigid substrate, assumed to be uniform; and  $\dot{q}$  is the rate of internal heat generation. The boundary condition

(Eq. 10.48b) is Newton's cooling law, and  $\alpha_{th}$  is the heat-transfer coefficient describing the rate of heat transfer from the liquid to the ambient gas phase held at the constant temperature  $\vartheta_\infty$ .

Turning to the two-dimensional case, scaling the temperature by:

$$\Theta = \frac{\vartheta - \vartheta_\infty}{\vartheta_0 - \vartheta_\infty} \quad (10.49)$$

and substituting scales (10.8) into Eqs. (10.47) and (10.48) yield:

$$\varepsilon RP(\Theta_\tau + U\Theta_\xi + W\Theta_\zeta) = \varepsilon^2 \Theta_{\xi\xi} + \Theta_{\zeta\zeta} + 2Qf(\zeta) \quad (10.50)$$

$$\Theta = 1 \quad \text{at } \zeta = 0 \quad (10.51a)$$

$$\Theta_\zeta - \varepsilon^2 \Theta_\xi H_\xi + B\Theta(1 + \varepsilon^2 H_\xi^2)^{1/2} = 0 \quad \text{at } \zeta = H \quad (10.51b)$$

where  $P$  and  $B$  are, respectively, the Prandtl and Biot numbers;  $Q$  is the dimensionless measure of the rate of internal energy generation defined by:

$$P = \frac{\rho c \nu}{k_{th}}, \quad B = \frac{\alpha_{th} d}{k_{th}}, \quad Q = \frac{\dot{q} d^2}{2k_{th} \vartheta_r}, \quad (10.52)$$

where  $\vartheta_r$  is the reference temperature chosen as  $\vartheta_r = \vartheta_0 - \vartheta_\infty$  if  $\vartheta_0 > \vartheta_\infty$ , and as  $\vartheta_r = \vartheta_0$  if  $\vartheta_0 = \vartheta_\infty$ . Furthermore,  $f(\zeta)$  expresses the dependence of the rate of internal energy generation on the vertical coordinate  $\zeta$ .

Begin first with the case of no internal heat generation,  $\dot{q} = 0$ , leading to  $Q = 0$ . Expand the temperature  $\Theta$  in a perturbation series in  $\varepsilon$ , along with the expansions, Eq. (10.14), and substitute these into the system given by Eqs. (10.50) and (10.51). Assume again that  $R = O(1)$  and further let  $P, B = O(1)$  so that the convective terms in Eq. (10.50) are delayed to the next order; that is, declare that conduction in the liquid is dominant, and the conductive heat flux at the interface balances the heat lost to the environment.

At the leading order in  $\varepsilon$  the governing system for  $\Theta^{(0)}$  consists of condition (10.51a):

$$\Theta_{\zeta\zeta} = 0 \quad (10.53)$$

and

$$\Theta_\zeta + B\Theta = 0 \quad \text{at } \zeta = H \quad (10.54)$$

where the superscript zero has been dropped. The solution to this system is

$$\Theta = 1 - \frac{B\zeta}{1 + BH} \quad \text{and} \quad \Theta_i = \frac{1}{1 + BH} \quad (10.55)$$

where  $\Theta_i = \Theta(\tau, \xi)$  is the surface temperature.

According to Eq. (10.21) we are now required to determine the thermocapillary stress  $\Sigma_\xi$ . By the chain rule,

$$\Sigma_\xi = M(d\Sigma/d\Theta)(\Theta_\xi + H_\xi \Theta_\zeta) \equiv -M \frac{\gamma(H) H_\xi}{(1 + BH)^2} \quad (10.56a)$$

where

$$\begin{aligned}\gamma(H) &= -(d\Sigma/d\Theta)_{\Theta=\Theta_i} \\ M &= \frac{\Delta\sigma}{\mu U_0}\end{aligned}\quad (10.56b)$$

is the Marangoni number, and the sign change is inserted because  $d\Sigma/d\Theta$  is negative for most common materials. Here,  $\Delta\sigma$  is the change of surface tension over the temperature domain between the characteristic temperatures, usually  $\vartheta_\infty$  and  $\vartheta_0$ . To be more precise, if  $\vartheta_\infty < \vartheta_0$  (heating at the bottom of the layer), then  $\Delta\sigma > 0$  for standard fluid pairs with surface tension decreasing with temperature. For heating at the interface side,  $\vartheta_\infty > \vartheta_0$  and  $\Delta\sigma < 0$ . The shear stress condition, Eq. (10.18b), has at the leading order in  $\varepsilon$  the form:

$$U_\zeta + M \frac{\gamma(H)H_\xi}{(1+BH)^2} = 0 \quad \text{at } \zeta = H \quad (10.57)$$

Thus, in this case,  $\hat{\Pi}_1 = \hat{\Pi}_3 = \Phi = 0$ , and Eq. (10.21) becomes:

$$H_\tau + \frac{1}{2}MB \left[ \frac{H^2\gamma(H)H_\xi}{(1+BH)^2} \right]_\xi + \frac{1}{3}S(H^3H_{\xi\xi\xi})_\xi = 0 \quad (10.58)$$

If gravity forces are to be included,  $\Phi = g\zeta$  and Eq. (10.58) becomes:

$$H_\tau + \left\{ \left[ \frac{1}{2}MB \frac{H^2\gamma(H)}{(1+BH)^2} - \frac{1}{3}GH^3 \right] H_\xi \right\}_\xi + \frac{1}{3}S(H^3H_{\xi\xi\xi})_\xi = 0. \quad (10.59)$$

For the most ubiquitous case in which surface tension is a linearly decreasing function of temperature  $\sigma = \sigma(\vartheta)$ , the value  $(d\Sigma/d\Theta) = \text{const}$  and  $\gamma(H) = 1$ . Equations (10.58) and (10.59), with  $\gamma(H) = 1$ , appeared in Davis (1983) for  $B \ll 1$ , Kopbosynov and Pukhnachev (1986), Bankoff and Davis (1987), Burelbach et al. (1988), Oron and Rosenau (1992), Deissler and Oron (1992), Van Hook et al. (1995) and Oron (2000b).

For  $B \ll 1$ , Eq. (10.59) in dimensional form becomes:

$$\mu h_t + \frac{\alpha_{th}\Delta\sigma}{2k_{th}}(h^2h_x)_x - \frac{1}{3}\rho g(h^3h_x)_x + \frac{1}{3}\sigma(h^3h_{xxx})_x = 0 \quad (10.60)$$

Linearization of Eq. (10.60) around the state  $h = d$  yields the characteristic equation:

$$\mu\omega = \left( \frac{\alpha_{th}\Delta\sigma}{2k_{th}} - \frac{1}{3}\rho g d - \frac{\sigma}{3d}a^2 \right) a^2 \quad (10.61)$$

Equation (10.61) shows that if  $g > 0$  (gravity acting toward the base of the film), gravity has a stabilizing effect (similar to that described in Section 10.3), while thermocapillarity has a destabilizing effect on the interface. It is clear from Eq. (10.61) that the gravitational stabilization is enhanced with the thickness

of the film. The dimensionless cutoff wave number  $a_c$  is given in this case by:

$$a_c = \left( \frac{3}{2} B \frac{\Delta\sigma}{\sigma} - Bo \right)^{1/2} \quad (10.62a)$$

Thermocapillary destabilization of a film can be explained by examining the behavior of an initially deformed interface in the linear temperature field produced by the heat transfer at the interface. The depression lies in the region of higher temperature than its neighbors; hence, if surface tension is a decreasing function of temperature, interfacial stresses proportional to the surface gradient of the surface tension [e.g., Levich, 1962; Landau and Lifshitz, 1987] drive the interfacial liquid away from it. Because the liquid is viscous, it is dragged away from the depression, causing it to deepen further. Hydrostatic and capillary forces cannot prevent this deepening, and as shall be seen further the film proceeds to zero thickness at some location (i.e., ruptures).

Studies of Eq. (10.58) with  $\gamma(H) = 1$  [Oron and Rosenau, 1992] reveal that evolution of small-amplitude initial data usually results in rupture of the film qualitatively similar to that displayed in Figure 2 in Oron and Rosenau (1992). The three-dimensional version of Eq. (10.58) was studied by Van Hook et al. (1995) and the results were tested against their experiments. The existence of a ruptured region predicted by Eq. (10.58) was qualitatively confirmed by the experiment. However, the theoretical predictions of the instability threshold were about 50% higher than the experimental data. Becerril et al. (1998) recently addressed this discrepancy in terms of side-wall effects and deflected initial interface shapes.

Van Hook et al. (1997) developed a “two-layer” theory modeling the dynamics of systems containing superposed layers of a liquid and a passive gas confined between two horizontal, rigid, differentially heated surfaces. This approach takes into consideration the change in the temperature profile in the air due to deformation of the interface. The two-layer setting leads to the thermal problem containing Eq. (10.53) formulated in each layer with the boundary conditions of temperature and heat flux continuity at the liquid–gas interface. Two new parameters arise from the solution of this thermal problem:

$$\eta = \frac{k_{th,g} d}{k_{th} d_g}, \quad F = \frac{(d/d_g) - \eta}{1 + \eta} \quad (10.63)$$

where  $d_g$  is the thickness of the gas layer and  $k_{th,g}$  is its thermal conductivity. The parameter  $\eta$  replaces the Biot number in the “one-layer” model described above.

In the case at hand, the dimensionless interfacial temperature is found to be

$$\Theta_i = 1 - \frac{H}{1 + F - FH} \quad (10.64)$$

and the corresponding dimensionless evolution equation in the standard case of  $\gamma(H) = 1$  in two dimensions is obtained in the form [Van Hook et al., 1997]:

$$H_\tau + \left\{ \left[ \frac{1}{2} M(1 + F) \frac{H^2}{(1 + F - FH)^2} - \frac{1}{3} GH^3 \right] H_\xi \right\}_\xi + \frac{1}{3} S(H^3 H_{\xi\xi\xi})_\xi = 0 \quad (10.65)$$

Equation (10.65) reduces to the “one-layer” model, Eq. (10.59) when  $F = -\eta/(1 + \eta)$  which corresponds to  $d/d_g \rightarrow 0$ . For one-layer systems, the parameter  $F$  is always non-positive, while for two-layer systems  $F$  is usually positive. For both of these cases,  $F > -1$ . The solutions of Eq. (10.65) were found to be of two distinct types, namely, “dry spots” that represent rupture at the bottom solid surface (see Figure 10.4a),

and “high spots” that represent rupture at the top solid surface by the elevated film interface (see Figure 10.4b). Dry spots emerge for  $F < 1/2$ , while high spots form when  $F > 1/2$ . The transition between these two different kinds of solutions, which was found to depend on the value of the Bond number  $Bo$  and the initial condition, occurs in the vicinity of  $F = 1/2$  [Van Hook et al., 1997]. As in the “one-layer” theory reviewed above, steady nonruptured states of the system were not found. The experimental results of Van Hook et al. (1997) are found to qualitatively agree for certain liquid depths with a “two-layer” model.

In the case of “negative gravity,”  $g < 0$ ; that is, when the film is on the underside of the solid plane, the Rayleigh–Taylor instability (heavy fluid overlying light fluid) enhances the thermocapillary instability and broadens the band of linearly unstable modes:

$$a_c = \left( \frac{3}{2} B \frac{\Delta\sigma}{\sigma} + Bo \right)^{1/2} \quad (10.66)$$

Stabilization of the Rayleigh–Taylor instability by thermocapillarity was investigated by Oron and Rosenau (1992) and Deissler and Oron (1992) for two- and three-dimensional cases, respectively. They found that negative thermocapillarity (i.e., with  $\Delta\sigma < 0$ ), corresponding to heating at the interface side or cooling at the rigid bottom, in conjunction with surface tension can lead to saturation of the Rayleigh–Taylor instability and formation of steady drops. The experimental confirmation of such a saturation was recently obtained by Burgess et al. (2001).

We now turn to the case where the  $\dot{q}$  term is present in Eq. (10.47). Its presence stands for the effect of internal energy generation, which might be induced by irradiation of the film and further absorption of the radiation energy within the nonscattering liquid phase. In this context, the solid substrate is assumed to be black (i.e., absorbing all radiation penetrating through the liquid film). Oron and Peles (1998) considered the simplified case of spatially uniform energy absorption,  $f(\zeta) \equiv 1$ . In this situation, the solution of the thermal problem of Eqs. (10.50) and (10.51) is given at the leading order by:

$$\Theta = \Theta_0 \left( 1 - \frac{B\zeta}{1+BH} \right) + Q \left( -\zeta^2 + \frac{BH^2 + 2H}{1+BH} \zeta \right) \quad \text{and} \quad \Theta_i = \frac{1}{1+BH} (\Theta_0 + QH^2) \quad (10.67)$$

where  $\Theta_0 = 1$  if  $\vartheta_0 > \vartheta_\infty$  and  $\Theta_0 = 0$  if  $\vartheta_0 = \vartheta_\infty$ . The corresponding evolution equation of the film obtained upon calculation of the corresponding value of  $\Sigma_\xi$  using Eq. (10.67) and its substitution into Eq. (10.21) with gravity neglected and  $\gamma(H) = 1$  is

$$H_\tau + \frac{1}{2} M \left[ H^2 \frac{B\Theta_0 - Q(BH^2 + 2H)}{(1+BH)^2} H_\xi \right]_\xi + \frac{1}{3} S (H^3 H_{\xi\xi\xi})_\xi = 0 \quad (10.68)$$

The main result found by Oron and Peles (1998) was that internal heat generation stabilizes the interface via the thermocapillary effect associated with it. In the simplest case, where the temperature of the solid is equal to the saturation temperature,  $\vartheta_0 = \vartheta_\infty$  (i.e.,  $\Theta_0 = 0$ ), which follows directly from the fact that the interfacial temperature  $\Theta_i$  is an increasing function of the film thickness  $H$ . The effect of stabilization becomes apparent, as at the leading order the heat transfer in a thin liquid film is one dimensional across it, and the energy input from absorption of radiation energy in the thicker part of the film is greater than in its thinner part. Thus, the interfacial temperature at the depression is lower than at the crest of the interface, and the thermocapillary stress drives the liquid into the depression, promoting stabilization of the interface. All this is different from the standard case discussed in the literature, when internal energy generation is absent. In the latter case of  $Q = 0$  and  $\Theta_w = 1$ , the interfacial temperature decreases with  $H$ , and instability of the spatially uniform state of the interface is thus triggered. Also, when the internal heat generation is sufficiently large ( $Q \geq 1$ ), the film becomes unconditionally stable. When the film is linearly unstable, the range of unstable modes narrows with the increase of  $Q$  for a fixed value of  $B$  [Oron and Peles, 1998].

Oron (2000a) considered thin liquid films with an optically smooth, nonreflective, deformed interface irradiated with a monochromatic beam of specified wavelength  $\lambda$ . The intensity of radiation  $i_\lambda$  of such a beam normally impinging on the optically smooth, nonreflective interface was shown in the absence of emission by the irradiated liquid phase to decay exponentially with distance from the flat liquid surface [Siegel and Howell, 1992]:

$$i_\lambda(z) = i_\lambda(z_0)e^{-K_\lambda(z_0-z)} \quad (10.69)$$

where  $z_0$  is the location of the film surface, and  $K_\lambda$  is the extinction coefficient of the given liquid assumed to be constant. The extinction coefficient is a property of the medium and in general varies with its temperature, pressure and the wavelength of the incident radiation.

Equation (10.69) is often referred as to Bouguer's [Siegel and Howell, 1992] or Beer's law. The attenuation of the radiation intensity is associated with the absorption and scattering of energy. The extinction coefficient is, in general, represented as a sum of the absorption and scattering components  $K_\lambda = a_\lambda + a_{s,\lambda}$ . In the case of a vanishing scattering  $a_{s,\lambda} = 0$ ,  $K_\lambda = a_\lambda$ , and the optical thickness  $\kappa_\lambda$  of a liquid film of a uniform thickness  $d$  can be defined as:

$$\kappa_\lambda \equiv a_\lambda d = d/\ell_m$$

where  $\ell_m$  is the mean penetration length of the incident radiation by the wave  $\lambda$ . Assuming that the film is nonscattering with a nonreflecting surface, Oron (2000a) used an expression compatible with Eq. (10.69) for the intensity of absorbed radiation and therefore for the intensity of the induced internal heat sources:

$$\dot{q}(z) = \dot{q}\exp[-a_\lambda(h-z)]$$

where  $h$  represents the location of the interface and  $\dot{q} = i_\lambda(z_0)a_\lambda$  is the *constant* representing the rate of energy absorption at the film interface. Note that the intensity of the heat sources  $\dot{q}(z)$  varies with  $x, y, z, t$  when  $a_\lambda \neq 0$ . By comparing the value of the optical thickness of the film with unity, one can examine the following limiting cases: (1) if  $\kappa_\lambda \ll 1$ , the radiation passes through the film, and such a film is called *optically thin* or *transparent*; or (2) if  $\kappa_\lambda \gg 1$ , the radiation penetrates only into a very thin boundary layer adjacent to the film interface, and in this case the film is called *optically thick* or *opaque*.

Solving the thermal problem given by Eqs. (10.50) and (10.51) with  $f(\zeta) = \exp[-\beta(H-\zeta)]$ , constant  $a_\lambda$ , and  $\beta = a_\lambda d$  being a nondimensional attenuation coefficient yields the interfacial temperature in the form:

$$\Theta_i = \frac{B}{1+BH} \left[ \Theta_0 + \frac{2Q}{\beta^2} (e^{-\beta H} + \beta H - 1) \right] \quad (10.70)$$

The corresponding evolution equation of the film obtained upon calculation of the term  $\Sigma_\xi$  based on Eq. (10.70) and its substitution into Eq. (10.21) with gravity neglected and  $\gamma(H) = 1$  is

$$H_\tau + \frac{M}{2} \left\{ \frac{H^2}{(1+BH)^2} \left[ B\Theta_0 - \frac{2Q}{\beta^2} ((\beta+BH)(1-e^{-\beta H}) - \beta BH e^{-\beta H}) \right] H_\xi \right\}_\xi + \frac{S}{3} (H^3 H_{\xi\xi\xi})_\xi = 0 \quad (10.71)$$

As in the case of uniform heat generation, Oron (2000a) found for irradiated films following the Bouguer's law that an increase of the radiation intensity leads to stabilization of the interface due to the appropriate change in the profile of the interfacial temperature. In the presence of heating across the film,  $\Theta_0 = 1$ , there exists a critical value of  $Q = Q_c$  depending on the Biot number  $B$  such that the film becomes

linearly stable when  $Q > Q_c$  and remains linearly unstable when  $Q < Q_c$ , although the rate of disturbance growth slows down in comparison to the case of  $Q = 0$ . This critical value  $Q_c$  is obtained from the linear stability analysis as:

$$Q_c = \frac{\beta^2}{2} [(1 + \beta B^{-1})(1 - e^{-\beta}) - \beta e^{-\beta}]^{-1} \quad (10.72)$$

This critical value tends to its limiting value of  $Q_c = B/(2 + B)$  for optically thin films  $\beta \ll 1$ , which is the limit of the spatially uniform absorption, and to  $Q_c = \beta B/2$  for optically thick films,  $\beta \gg 1$ .

It was experimentally discovered that dilute aqueous solutions of long-chain alcohols exhibit non-monotonic dependence of surface tension on temperature [Legros et al., 1984; Legros, 1986]. This dependence can be approximated quite well by the quadratic polynomial,

$$\sigma(\vartheta) = \delta(\vartheta - \vartheta_m)^2 \quad (10.73a)$$

where  $\delta$  is constant and  $\vartheta_m$  is the temperature corresponding to the minimal surface tension. In this case,

$$\gamma(H) \propto \left( \frac{\vartheta_m - \vartheta_\infty}{\vartheta_0 - \vartheta_\infty} - \frac{1}{1 + BH} \right) \quad (10.73b)$$

The instability arising from the variation of surface tension given by Eq. (10.73a) was called “quadratic Marangoni (QM)” instability and studied by Oron and Rosenau (1994). In contrast with the case of the standard thermocapillary instability described by Eq. (10.58) with  $\gamma(H) = 1$ , evolution of QM instability may result in a nonruptured steady state. Figure 4 in Oron and Rosenau (1994) displays such a state along with the streamlines of the flow field. It results from solving Eq. (10.58) with  $\gamma(H)$  given by Eq. (10.73b). The intersections of the  $\Theta_0$  line with the film interface in Figure 4 in Oron and Rosenau (1994) correspond to the locations of the minimal surface tension. The existence of these creates surface shear stresses acting in opposite directions and leads to film stabilization.

## 10.4.2 Liquid Film on a Thick Substrate

The methods described in the previous sections can be easily implemented in the case of a liquid film lying on top of a solid slab of thickness small compared to the characteristic wavelength of the interfacial disturbance [Oron et al., 1996]. In this case, the thermal conduction equation in the solid has to be solved simultaneously with the energy equation in the liquid. This coupled thermal problem is written at the leading order in  $\epsilon$  as:

$$\begin{aligned} \Theta_{w,\zeta\zeta} &= 0, & -\frac{d_w}{d} \leq \zeta \leq 0 \\ \Theta_{\zeta\zeta} &= 0, & 0 \leq \zeta \leq H \end{aligned} \quad (10.74)$$

with the boundary conditions:

$$\begin{aligned} \Theta_w &= \Theta, & -k_{th,w}\Theta_{w,\zeta} &= -k_{th}\Theta_\zeta & \text{at } \zeta = 0 \\ \Theta_w &= 1 & \text{at } \zeta &= -\frac{d_w}{d} \end{aligned} \quad (10.75)$$

where  $\Theta_w$  and  $d_w/d$  are the dimensionless temperature and scaled with  $d$  thickness of the solid slab;  $k_{th,w}$  is its thermal conductivity. The upper equations in Eq. (10.75) express the conditions of continuity of both the temperature and heat flux at the solid–liquid boundary, while the lower one defines a uniform

temperature at the bottom of the solid substrate. The last boundary condition is taken at the film interface, and at the leading order in  $\epsilon$  it is given by Eq. (10.54). Appropriate extension has to be made in the case of a volatile liquid (see Section 10.5).

Solution of Eqs. (10.74) and (10.75) results in:

$$\Theta = 1 - \frac{B(\bar{\kappa}\zeta + d_w/d)}{\bar{\kappa}(1 + BH) + Bd_w/d}, \quad \Theta_w = 1 - \frac{B(\zeta + d_w/d)}{\bar{\kappa}(1 + BH) + Bd_w/d} \quad (10.76a)$$

with  $\bar{\kappa} = k_{th,w}/k_{th}$ , which implies the interfacial temperature in the form:

$$\Theta_i = \left[ 1 + B \left( H + \frac{d_w/k_{th,w}}{d/k_{th}} \right) \right]^{-1} \quad (10.76b)$$

Comparing the expressions for the interfacial temperatures  $\Theta_p$  as given by Eqs. (10.55) and (10.76b), one notices that, in addition to the thermal resistance due to each conduction and convection at the interface in the former case, the latter contains a thermal resistance owing to conduction in the solid. The evolution equation, analogous to Eq. (10.58), will have the same form, except for the obvious change in the denominator of the second term containing an additional additive term:

$$a \equiv \frac{d_w/k_{th,w}}{d/k_{th}} \quad (10.77)$$

This additional term represents the ratio between the values of the thermal conductive resistance of the solid and the liquid.

Using Eq. (10.76) one can derive the expressions for the temperatures along the gas–liquid (GL) and solid–liquid (SL) interfaces:  $\Theta_{GL} \equiv \Theta(\zeta = H)$  and  $\Theta_{SL} \equiv \Theta_w(\zeta = 0)$ . When the film ruptures (i.e.,  $H = 0$ ), the values for  $\Theta_{GL}$  and  $\Theta_{SL}$  are equal if:

$$a = \frac{d_w}{\bar{\kappa}d} \neq 0 \quad (10.78)$$

However, the temperature singularity,  $\Theta_{GL} \neq \Theta_{SL}$ , emerges at the rupture point when  $a = 0$ . Equation (10.78) is the sufficient condition to be satisfied in order to relieve this singularity [Oron et al., 1996a]. Indeed, if it is satisfied,

$$\lim_{H \rightarrow 0} \lim_{a \rightarrow 0} \Theta_{GL} = \lim_{H \rightarrow 0} \lim_{a \rightarrow 0} \Theta_{SL} = 0$$

and the singularity is removed. The problematic case of  $a \rightarrow 0$  materializes if the substrate is of a negligible thickness.

## 10.5 Change of Phase: Evaporation and Condensation

### 10.5.1 Interfacial Conditions

We now consider the case of an evaporating (condensing) thin film of a simple liquid lying on a heated (cooled) plane surface held at constant temperature  $\vartheta_0$  which is higher (lower) than the saturation temperature at the given vapor pressure. It is assumed that the speed of vapor particles is sufficiently low so that the vapor can be considered an incompressible fluid.

The boundary conditions appropriate for phase transformation at the film interface  $z = h$  are now formulated. The mass conservation equation at the interface is given by the balance between the liquid

and vapor fluxes through the interface:

$$j = \rho_v(\mathbf{v}_v - \mathbf{v}_i) \cdot \mathbf{n} = \rho_f(\mathbf{v}_f - \mathbf{v}_i) \cdot \mathbf{n} \quad (10.79a)$$

where  $j$  is the mass flux due to evaporation;  $\rho_v$  and  $\rho_f$  are, respectively, the densities of the vapor and the liquid;  $\mathbf{v}_v$  and  $\mathbf{v}_f$  are the vapor and liquid velocities at  $z = h$ ; and  $\mathbf{v}_i$  is the velocity of the interface. Equation (10.79a) provides the relationship between the normal components of the vapor and liquid velocities at the interface. The tangential components of both of the velocity fields are equal at the interface:

$$(\mathbf{v}_f - \mathbf{v}_v) \cdot \mathbf{t}_m = 0, \quad m = 1, 2 \quad (10.79b)$$

The boundary condition that expresses the stress balance and extends Eq. (10.4b) to the case of phase transformation reads [Delhaye, 1974; Burelbach et al., 1988]:

$$j(\mathbf{v}_f - \mathbf{v}_v) - (\mathbf{T} - \mathbf{T}_v) \cdot \mathbf{n} = 2\tilde{H}\sigma(\vartheta)\mathbf{n} - \nabla_s\sigma \quad (10.80a)$$

where  $\mathbf{T}_v$  is the stress tensor in the vapor phase and temperature dependence of surface tension is accounted for.

The energy balance at  $z = h$  is given by [Delhaye, 1974; Burelbach et al., 1988]:

$$j\left(L + \frac{1}{2}\mathfrak{v}_{v,n}^2 - \frac{1}{2}\mathfrak{v}_{f,n}^2\right) + (k_{th}\nabla\vartheta - k_{th,v}\nabla\vartheta_v) \cdot \mathbf{n} + 2\mu(\mathbf{e}_f \cdot \mathbf{n}) \cdot \mathbf{v}_{f,r} - 2\mu_v(\mathbf{e}_v \cdot \mathbf{n}) \cdot \mathbf{v}_{v,r} = 0 \quad (10.80b)$$

where  $L$  is the latent heat of vaporization per unit mass;  $k_{th,v}$ ,  $\mu_v$ ,  $\vartheta_v$  are, respectively, the thermal conductivity, viscosity and the temperature of the vapor;  $\mathbf{v}_{v,r} = \mathbf{v}_v - \mathbf{v}_i$  and  $\mathbf{v}_{f,r} = \mathbf{v}_f - \mathbf{v}_i$  are the vapor and liquid velocities relative to the interface, respectively;  $\mathfrak{v}_{v,r} = \mathbf{v}_{v,r} \cdot \mathbf{n}$  and  $\mathfrak{v}_{f,r} = \mathbf{v}_{f,r} \cdot \mathbf{n}$  are the normal components of the latter; and  $\mathbf{e}_f$  and  $\mathbf{e}_v$  are the rate-of-deformation tensors in the liquid and the vapor, respectively. In Eq. (10.80b) the first term represents the contribution of the latent heat, the combination of the second and the third terms represents the interfacial jump in the momentum flux, the combination of the fourth and the fifth terms represents the jump in the conductive heat flux at both sides of the interface, while the combination of the last two terms is associated with the viscous dissipation of energy at both sides of the interface.

Because  $\rho_v/\rho_f \ll 1$ , typically of order  $10^{-3}$ , it follows from Eq. (10.79a) that the magnitude of the normal velocity of the vapor relative to the interface is much greater than that of the liquid. Hence, the phase transformation causes large accelerations of the vapor at the interface, where the back reaction, called the *vapor recoil*, represents a force exerted on the interface. During evaporation (condensation) the troughs of the deformed interface are closer to the hot (cold) plate than the crests, so they have greater evaporation (condensation) rates  $j$ . The dynamic pressure at the vapor side of the interface is much larger than that at the liquid side:

$$\rho_v\mathfrak{v}_{v,n}^2 = \frac{j^2}{\rho_v} \gg \rho_f\mathfrak{v}_{f,n}^2 = \frac{j^2}{\rho_f} \quad (10.81)$$

Momentum fluxes are thus greater in the troughs than at the crests of surface waves. Vapor recoil is found to be a destabilizing factor for the interface dynamics for both evaporation ( $j > 0$ ) and condensation ( $j < 0$ ) [Burelbach et al., 1988]. Being scaled with  $j^2$  (see Eq. (10.84) below), the vapor recoil is only important for applications where very high mass fluxes are involved.

Vapor recoil generally exerts a reactive downward pressure on a horizontal evaporating film. Bankoff (1961) introduced the effect of vapor recoil in the analysis of film boiling, where the liquid overlays the vapor layer generated by boiling, thus leading to the Rayleigh–Taylor instability of an evaporating

liquid–vapor interface above a hot horizontal wall. In this case, the vapor recoil stabilizes the film boiling, as the reactive force is greater for the wave crests approaching the wall than for the troughs.

To obtain closure for the system of governing equations and boundary conditions, an equation relating the dependence of the interfacial temperature  $\vartheta_i$  and the local pressure in the vapor phase is added [Plesset and Prosperetti, 1976; Palmer, 1976; Sadhal and Plesset, 1979]. Its linearized form is

$$\tilde{K}j = \vartheta_i - \vartheta_s \equiv \Delta\vartheta_i, \quad (10.82)$$

where

$$\tilde{K} = \frac{\vartheta_s^{3/2}}{\hat{\alpha}\rho_v L} \left( \frac{2\pi R_v}{M_w} \right)^{1/2}$$

$\vartheta_s$  is the absolute saturation temperature,  $\hat{\alpha}$  is the accommodation coefficient,  $R_v$  is the universal gas constant and  $M_w$  is the molecular weight of the vapor [Palmer, 1976; Plesset and Prosperetti, 1976; Burelbach et al., 1988]. Note that the absolute saturation temperature  $\vartheta_s$  serves now as the reference temperature instead of  $\vartheta_\infty$  in the normalization equation, Eq. (10.49). When  $\Delta\vartheta_i = 0$ , the phases are in thermal equilibrium with each other, and, in order for net mass transport to take place, a vapor pressure driving force must exist and is given for ideal gases by kinetic theory [Schrage, 1953], which is represented in the linear approximation by the parameter  $\tilde{K}$  [Burelbach et al., 1988]. Departure from ideal behavior is addressed in the parameter  $\tilde{K}$  by the presence of an accommodation coefficient  $\hat{\alpha}$ , which depends on interface/molecule orientation and steric effects and represents the probability of a vapor molecule sticking upon hitting the liquid–vapor interface.

The set of the boundary conditions Eq. (10.80) can be simplified to what is known as a “one-sided” model for evaporation or condensation [Burelbach et al., 1988] in which the dynamics of the liquid are decoupled from those of the vapor. This simplification is enabled due to the assumption of smallness of density, viscosity and thermal conductivity of the vapor with respect to the respective properties of the liquid. The vapor dynamics are ignored in the one-sided model and only the mass conservation and the effect of vapor recoil indicate the presence of the vapor phase.

The energy balance (10.80b) becomes:

$$-k_{th}\nabla\vartheta \cdot \mathbf{n} = j \left( L + \frac{1}{2} \frac{j^2}{\rho_v^2} \right) \quad (10.83)$$

suggesting that the heat flux conducted to the interface in the liquid is converted to latent heat of evaporation and the kinetic energy of vapor particles.

The stress balance at the interface equation, Eq. (10.80a), is reduced and now rewritten explicitly for the components of the normal and tangential stresses there as:

$$\begin{aligned} -\frac{j^2}{\rho_v} - \mathbf{T} \cdot \mathbf{n} \cdot \mathbf{n} &= 2\tilde{H}\sigma(\vartheta) \\ \mathbf{T} \cdot \mathbf{n} \cdot \mathbf{t} &= \nabla_s \sigma \cdot \mathbf{t} \end{aligned} \quad (10.84)$$

In Eq. (10.84) the  $j^2$  term stands for the contribution of vapor recoil. Finally, the remaining boundary conditions (10.79) and (10.82) are unchanged.

The procedure of asymptotic expansions outlined in the beginning of the chapter is used again to derive the pertinent evolution equation. The dimensionless mass balance Eq. (10.13) is modified by the presence of the nondimensional evaporative mass flux,  $J = jdL/k_{th}(\vartheta_0 - \vartheta_s)$ .

$$EJ = (-H_\tau - UH_\xi - VH_\eta + W)(1 + H_\xi^2)^{-1/2} \quad (10.85a)$$

or at the leading order of approximation:

$$H_\tau + Q_\xi^{(x)} + Q_\eta^{(y)} + EJ = 0 \quad (10.85b)$$

where  $Q^{(x)}(\xi, \eta, \tau) = \int_0^H U d\zeta$ ,  $Q^{(y)}(\xi, \eta, \tau) = \int_0^H V d\zeta$  are the components of the scaled volumetric flowrate per unit width parallel to the wall. The parameter  $E$  in Eq. (10.85) is an evaporation number:

$$E = \frac{k_{th}(\vartheta_0 - \vartheta_s)}{\rho\nu L}$$

which represents the ratio of the viscous time scale,  $t_v = d^2/\nu$ , to the evaporative time scale,  $t_e = \rho d^2 L/k_{th}(\vartheta_0 - \vartheta_s)$  [Burelbach et al., 1988].

The dimensionless versions of Eqs. (10.82) and (10.83) are

$$\begin{aligned} KJ &= \Theta & \text{at } \zeta = H \\ \Theta_\zeta &= -J & \text{at } \zeta = H \end{aligned} \quad (10.86)$$

where

$$K = \tilde{K} \frac{k_{th}}{dL}$$

In the lower equation in Eq. (10.86) the kinetic energy term is neglected. For details, the reader is referred to Burelbach et al. (1988). Equations (10.18), (10.19), (10.53) and (10.86) pose the problem, whose solution is substituted into Eq. (10.85b) to obtain the sought evolution equation. The general dimensionless evolution equation, Eq. (10.21), will then contain an additional term  $EJ$ , which arises from the mass flux due to evaporation/condensation now being expressed via the local film thickness  $H$ .

A different approach to theoretically describing the rate of evaporative flux  $j$  in the *isothermal* case is known in the literature [Sharma, 1998; Padmakar et al., 1999]. This approach is based on the extended Kelvin equation that accounts for the local interfacial curvature and the disjoining/conjoining pressures, both entering the resulting expression for the evaporative mass flux  $j$ . It was shown by Padmakar et al. (1999) that their evaporation model admits the emergence of a flat adsorbed layer remaining in equilibrium with the ambient vapor phase, and thus in this state the evaporation rate from the film vanishes. This adsorbed layer, however, is usually several molecular spacings thick, which is beyond the resolution of continuum theory.

## 10.5.2 Evaporation/Condensation Only

We first consider the case of an evaporating/condensing thin liquid layer lying on a rigid plane held at constant temperature. Mass loss or gain is retained, while all other effects are neglected.

Solving first Eq. (10.53) along with boundary conditions Eqs. (10.51a) and (10.86) and eliminating the mass flux  $J$  from the latter yield the dimensionless temperature field and evaporative mass flux through the interface,

$$\Theta = 1 - \frac{\zeta}{H+K}, \quad J = \frac{1}{H+K} \quad (10.87)$$

An initially flat interface will remain flat as evaporation or condensation proceeds and if surface tension, thermocapillary and convective thermal effects are negligible; if  $M = S = \varepsilon RP = 0$ , it will give rise to a scaled evolution equation of the form:

$$H_\tau + \frac{\bar{E}}{H+K} = 0 \quad (10.88)$$

where  $\bar{E} = \varepsilon^{-1}E$ , positive in the evaporative case and negative in the condensing one.  $K$ , the scaled interfacial thermal resistance, is equivalent to the inverse Biot number,  $B^{-1}$ . On the physical grounds,  $K \neq 0$  represents a temperature jump from the liquid surface temperature to the uniform temperature of the saturated vapor,  $\vartheta_s$ . This jump drives the mass transfer. The conductive resistance of the liquid film is proportional to  $H$ , and the total thermal resistance, assuming infinite thermal conductivity of the solid, is given by  $(H + K)^{-1}$ . For a specified temperature difference,  $\vartheta_0 - \vartheta_s$ , Eq. (10.88) represents a volumetric balance, whose solution, subject to the initial condition  $H(\tau = 0) = 1$ , is

$$H = -K + [(K + 1)^2 - 2\bar{E}\tau]^{1/2} \quad (10.89)$$

In the case of evaporation  $\bar{E} > 0$ , and when  $K \neq 0$  the film vanishes in a finite time  $\tau_e = (2K + 1)/2\bar{E}$ , and the rate of disappearance of the film at  $\tau = \tau_e$  is finite:

$$\left. \frac{dH}{d\tau} \right|_{\tau=\tau_e} = -\frac{\bar{E}}{K}$$

For  $K \neq 0$ , the value of  $dH/d\tau$  remains finite, because as the film thins the interface temperature  $\vartheta_p$ , nominally at its saturation value  $\vartheta_s$ , increases to the wall temperature. If  $K = 0$ , however, the problem becomes singular. In this case, the thermal resistance vanishes and the mass flux will increase indefinitely if a finite temperature difference  $\vartheta_0 - \vartheta_s$  is sustained. The speed of the interface at rupture becomes infinite as well.

Burelbach et al. (1988) showed that the interfacial thermal resistance  $K = 10$  for a 10-nm-thick water film. Because  $K$  is inversely proportional to the initial film thickness,  $K \approx 1$  for  $d = 100$  nm, so  $H/K \approx 1$  at this point. However,  $H/K \approx 10^{-1}$  at  $d = 30$  nm, so the conduction resistance becomes small compared to the interfacial transport resistance shortly after van der Waals forces become appreciable.

### 10.5.3 Evaporation/Condensation, Vapor Recoil, Capillarity and Thermocapillarity

The dimensionless vapor recoil gives an additional normal stress at the interface determined by the  $j^2$  term in Eq. (10.84),  $\bar{\Pi}_3 = -\frac{3}{2}\bar{E}^2 D^{-1} j^2$ , where  $D$  is a unit-order scaled ratio between the vapor and liquid densities:

$$D = \frac{3}{2} \varepsilon^{-3} \frac{\rho_v}{\rho}$$

This stress can be calculated using Eq. (10.87). The resulting scaled evolution equation for an evaporating film on an isothermal horizontal surface neglecting the thermocapillary effect and body forces is obtained using the combination of Eqs. (10.21) and (10.88) with  $\Pi_1 = 0$ ,  $\Sigma_\xi = 0$  [Burelbach et al., 1988]:

$$H_\tau + \frac{\bar{E}}{H + K} + \left[ \bar{E}^2 D^{-1} \left( \frac{H}{H + K} \right)^3 H_\xi \right]_\xi + \frac{1}{3} S (H^3 H_{\xi\xi\xi})_\xi = 0 \quad (10.90)$$

Because usually  $t_e \gg t_v$ ,  $\bar{E}$ , can itself be a small number and then  $t_e$  can be used as an expansion parameter for slow evaporation compared to the nonevaporating base state [Burelbach et al., 1988] appropriate to very thin evaporating films.

Taking into account van der Waals forces and thermocapillarity, the complete evolution equation for a thin heated or cooled film on a horizontal plane surface was given by Burelbach et al. (1988) in the form:

$$H_\tau + \frac{\bar{E}}{H + K} + \left\{ \left[ AH^{-1} + \bar{E}^2 D^{-1} \left( \frac{H}{H + K} \right)^3 + K\bar{M}P^{-1} \left( \frac{H}{H + K} \right)^2 \right] H_\xi \right\}_\xi + \frac{1}{3} S (H^3 H_{\xi\xi\xi})_\xi = 0 \quad (10.91)$$

with  $\bar{M} = \varepsilon M$ . Here, the first term represents the rate of volumetric change; the second one, the mass loss/gain; the third, fourth and fifth ones, the attractive van der Waals, vapor recoil and thermocapillary

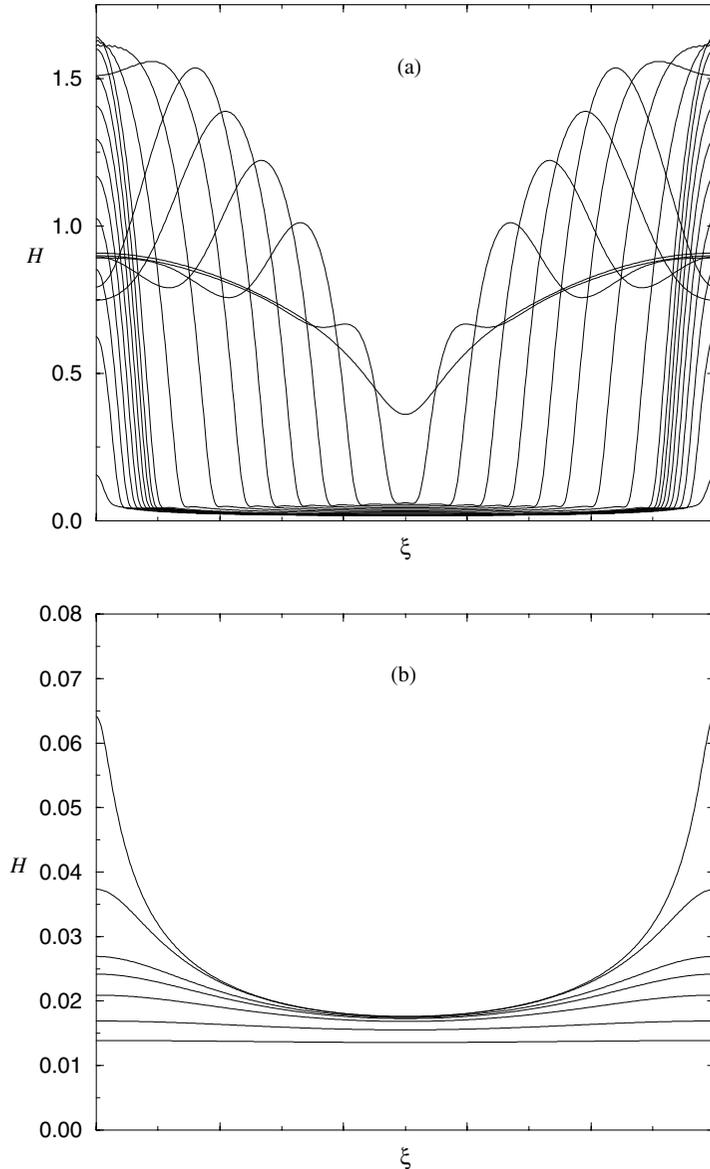

terms, respectively, all destabilizing; while the sixth term describes the stabilizing capillary force. This was the first full statement of the possible competition among various stabilizing and destabilizing effects on a horizontal plate, with scaling taken to make them present at the same order. Other effects such as gravity may be also included in Eq. (10.91). Joo et al. (1991) extended the work to an evaporating (condensing) liquid film draining down a heated (cooled) inclined plate.

Oron and Bankoff (1999) studied the two-dimensional dynamics of an evaporating ultrathin film on a coated solid surface when the potential (Eq. (10.31d)) was used. Three different types of the evolution of a volatile film were identified. One of them is related to low evaporation rates associated with relatively small  $\bar{E} > 0$ , when holes covered by a liquid microlayer emerge and expansion of such holes is governed mainly by the action of the attractive molecular forces. These forces impart the squeeze effect to the film, and, as a result, the liquid flows away from the hole. In this stage the role of evaporation is secondary. Figure 10.9 displays such an evolution of a volatile liquid film. Following the nucleation of the hole and during the process of surface dewetting, one can identify the formation of a large ridge, or drop, on either side of the trough. The former grows during the evolution of the film until the drops at both ends of the periodic domain collide. A further recession of the walls of the dry spot leads to the formation of a single large drop that flattens and ultimately disappears, according to Eq. (10.89). The stages of the film evolution shown in Figure 10.9a are found to be very similar to that sketched in Figure 3 in Elbaum and Lipson (1995). This type of evolution also resembles the results obtained by Padmakar et al. (1998) for the isothermal film subject to hydrophobic interactions and evaporation driven by the difference between the equilibrium vapor pressure and the pressure in the vapor phase. Such films were found to thin uniformly to a critical thickness and then spontaneously to dewet the solid substrate by the formation of growing dry spots, when the solid was partially wetted. In the completely wetted case, thin liquid films evolved to an array of islands that disappeared by evaporation to a thin equilibrium flat film. Two other regimes corresponding to intermediate and high evaporation rates were discussed by Oron and Bankoff (1999).

An important phenomenon was found in the last stage of the evolution of an evaporating film, when the latter finally disappears by evaporation: Prior to that the film equilibrates, so that its disappearance is practically uniform in space. The film equilibration is due to what has been called the *reservoir effect*, which is driven by the difference in disjoining pressures and manifests itself by feeding the liquid from the large drops into the ultrathin film that bridges between them.

Oron and Bankoff (2001) studied the dynamics of condensing thin films on a horizontal coated solid surface. In the case of a relatively fast condensation, where the initial depression of the interface rapidly fills up due to the enhanced mass gain there, the film equilibrates and grows uniformly in space according to Eq. (10.89); note that  $\bar{E} < 0$ . When condensation is relatively slow, the evolution of the film exhibits several distinct stages. The first stage dominated by attractive van der Waals forces leads to opening of a hole covered by a microlayer, as shown in the first three snapshots of Figure 10.10a. This is accompanied by continuous condensation with the highest rate of mass gain attained in the microlayer region corresponding to the smallest thickness  $H$  in Eq. (10.87). However, opposite to the evaporative case [Oron and Bankoff, 1999], where the reservoir effect arising from the difference between the disjoining pressures causes feeding of the liquid from the large drops into the microlayer and film equilibration, in the condensing case the excess liquid is driven from the microlayer into the large drops. This effect has been referred as to the *reversed reservoir effect*. The thickness of the microlayer remains nearly constant due to local mass gain by condensation compensating for the impact of the reverse reservoir effect. The first stage of the film evolution terminates in the situation where the size of the hole is the largest. The receding of the drops stops due to the increase of the drop curvature and buildup of the capillary pressure that comes to balance with the squeeze effect of the attractive van der Waals forces. From this moment on, the hole closes, driven by condensation (as shown in Figures 10.10a, b). Once the hole closes, the depression fills up rapidly, the amplitude of the interfacial disturbance decreases and the film thus tends to flatten out. The film then grows uniformly in space following the solution of Eq. (10.89) with negative  $\bar{E}$ .

Oron (2000c) studied the three-dimensional evolution of an evaporating film on a coated solid surface subject to the potential [Eq. (10.31d)]. The main stages of the evolution repeat those mentioned above

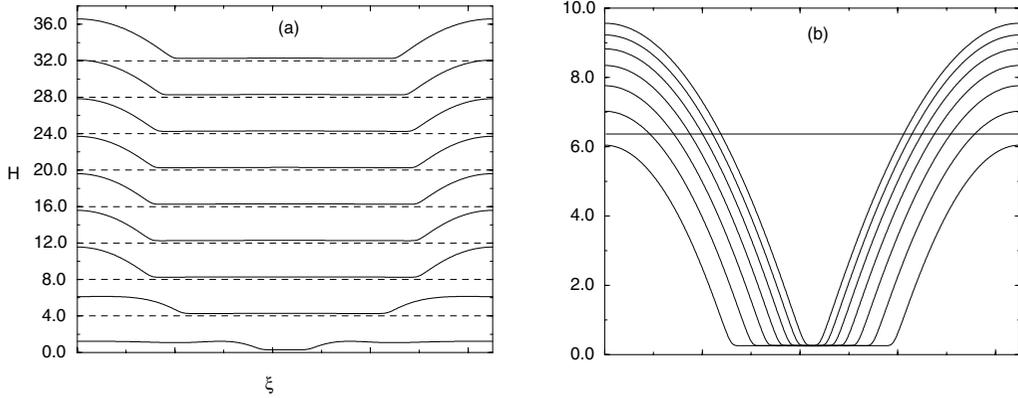

**FIGURE 10.9** Evolution of a slowly evaporating film. (a) Initial and intermediate stages of the film evolution. (b) Final stage of the evolution. The curves in both graphs correspond to the interfacial shapes in consecutive times (not necessarily equidistant). (From Oron, A., and Bankoff, S.G. (1999) *J. Coll. Interface Sci.* **218**, 152–166. With permission.)

in the case of a nonvolatile film (Section 10.3), except for the stage of disappearance accompanied by the reservoir effect. Because of the reservoir effect, the minimal film thickness decreases very slowly during the stage of film equilibration.

### 10.5.4 Flow on a Rotating Disc

Reisfeld et al. (1991) considered the axisymmetric flow of an incompressible viscous volatile liquid on a horizontal, rotating disk. The liquid was assumed to evaporate due to the difference between the vapor pressures of the solvent species at the fluid–vapor interface and in the gas phase. This situation is analogous to phase two of the spin coating process.

**FIGURE 10.10** Evolution of a slowly condensing film on the horizontal plane. (a) Curves from the bottom to the top correspond to consecutive times (not necessarily equidistant). (b) Curves from the left to the right correspond to consecutive times (not necessarily equidistant). The flat curve corresponds to the interface at a certain time after which the film grows uniformly in space according to Eq. (10.89). In part (a), the dashed lines represent the location of the solid substrate  $H = 0$ . (From Oron, A., and Bankoff, S.G. (2001) *Phys. Fluids* **18**, pp. 1107–1117. With permission.)

The analysis is similar to what was done in Section 10.3, but now it includes an additional parameter describing the process of evaporation, which for a prescribed evaporative mass flux  $j$  is defined as:

$$E = \frac{3j}{2\varepsilon\rho U_0}$$

Using the procedures outlined before one obtains at the leading order the following evolution equation:

$$H_\tau + \frac{2}{3}E + \frac{1}{3r} \left\{ r^2 H^3 + SrH^3 \left[ \frac{1}{r} (rH_r)_r \right]_r \right\} = 0 \quad (10.92)$$

Equation (10.92) models the combined effect of local mass loss, capillary forces and centrifugal drainage, none of which describes any kind of instability.

For most spin coating applications,  $S$  is very small and the corresponding term may be neglected, although it may be very important in planarization studies, where the leveling of liquid films on rough surfaces is investigated. Equation (10.92) can be thus simplified:

$$H_\tau + \frac{2}{3}E + \frac{1}{3r} (r^2 H^3)_r = 0 \quad (10.93)$$

This simplified equation can then be used for further analysis. Looking for flat basic states  $H = H(\tau)$ , Eq. (10.93) is reduced to the ordinary differential equation which is to be solved with the initial condition  $H(0) = 1$ . In the case of  $E > 0$ , both evaporation and drainage cause thinning of the layer. Equation (10.93) describes the evolution in which the films thin monotonically to zero thickness in a finite time in contrast with an infinite thinning time by centrifugal drainage only. Explicit expressions for  $H(\tau)$  and for the time of film disappearance are given by Reisfeld et al. (1991). In the condensing case,  $E < 0$ , drainage competes with condensation to thin the film. Initially, the film thins due to drainage, until the rate of mass gain due to condensation balances the rate of mass loss by drainage. At this point, the film interface reaches its steady location  $H = |E|^{1/3}$ . The cases where inertia is taken into account are also considered by Reisfeld et al. (1991), who provide a linear stability analysis of flat base states.

Experiments with volatile rotating liquid films [Stillwagon and Larson, 1990] showed that the final stage of film leveling was affected by an evaporative shrinkage of the films. Therefore, they suggested to separate the analysis of the evolution of evaporating spinning films into two stages with fluid flow dominating the first stage and solvent evaporation dominating the second one [Stillwagon and Larson, 1992].

## 10.6 Closing Remarks

---

In this chapter, the physics of thin liquid films was reviewed and various examples of their dynamics relevant for MEMS were presented, some of them along with reference to the corresponding experimental results. The examples discussed examined isothermal, nonisothermal with no phase changes and evaporating/condensing films under the influence of surface tension, gravity, van der Waals and centrifugal forces. The long-wave theory has been proven to be a powerful tool of research for the dynamics of thin liquid films.

However, several optional approaches are suitable for a study of the dynamics of thin liquid films. Direct numerical simulation of the hydrodynamic equations (Navier–Stokes and continuity) [Scardovelli and Zaleski, 1999] mentioned briefly in the introduction represents one of these options. A variety of methods have been developed to carry out such simulations: techniques based on finite elements method (FEM) [Ho and Patera, 1990; Salamon et al., 1994; Krishnamoorthy et al., 1995; Tsai and Yue, 1996; Ramaswamy et al., 1997], techniques based on the boundary-integral method [Pozrikidis, 1992; 1997; Newhouse and Pozrikidis, 1992; Boos and Thess, 1999], surface tracking technique [Yiantsios and Higgins, 1989] and others. Another optional approach is that of molecular dynamics (MD) simulations [Allen and Tildesley, 1987; Koplik and Banavar, 1995; 2000]. The details of all these are not given here and the reader is referred directly to these works and the references therein.

## Acknowledgments

---

It is a pleasure to express my gratitude to A. Sharma, G. Reiter and U. Thiele for reading the manuscript and sharing their comments and thoughts with me. A. Sharma, S. Herminghaus, M.F. Schatz and E. Zussman are acknowledged for providing me with their experimental results to be used in this chapter.

## 11.1 Introduction

---

Many microdevices involve fluid flows. Microducts, micronozzles, micropumps, microturbines and microvalves are examples of small devices with gas or liquid flow. It would be extremely desirable to design similar devices for two-phase flows, and many attractive applications can be envisioned if microreactors and microlaboratories could include immiscible liquid–liquid and gas–liquid systems. Miniature evaporative and distillation units, bubble generators, multiphase extraction/separation units and many other conventional multiphase chemical processes could then be fabricated at microscales. Efficient multiphase heat exchangers could be designed for MEM devices to minimize Joule or frictional heating effects. Even for the current generation of microlaboratories using electrokinetic flow, multiphase flow has many advantages. Drops of organic samples could be transported by flowing electrolytes, thus extending the electrokinetic concept to a broader class of samples. Gas bubbles could be used as spacers for samples in a channel or to act as a piston to produce pressure-driven flow on top of the electrokinetic flow. Flow valves and pumps that employ air bubbles, like those in the ink reservoirs of ink jet printers, are already being tested for microchannels. Drug-delivery and diagnostic devices involving colloids, molecules and biological cells are also active areas of research.

Before multiphase flow in microchannels becomes a reality, however, several fundamental problems that arise from the small dimension of the channels must be solved. Most of these problems originate from the large curvature of the interface between two phases in these small channels. As a result, capillary effects and other related phenomena dominate in multiphase microfluidics. Contact-line resistance, for example, is often negligible in macroscopic flows. The contact-line region, defined by intermolecular and capillary forces, is small compared to the macroscopic length scales. However, in microchannels, the contact-line region is comparable in dimension to the channel size. As a result, the large stress in that region (the classical contact-line logarithm stress singularity) can dominate the total viscous dissipation [Kalliadasis and Chang, 1994; Veretennikov et al., 1998; Indeikina and Chang, 1999]; hence, it is inadvisable to have contact lines in microchannels unless one is prepared to apply enormous pressure or electric potential driving forces. One fluid should wet the channel or capillary walls while the other is

dispersed in the form of drops or bubbles. Due to the small channel dimension, though, the drops and bubbles usually have a free radius larger than the channel radius—it is typically difficult to generate colloid-size drops or bubbles smaller than the channel. Biological cells and protein molecules are also comparable in dimension to microchannels and represent a unique class of “drops” in such devices. This chapter addresses several fundamental issues in the transport of these “large” bubbles/drops and suggests the most realistic and attainable conditions for such multiphase microfluidic flows.

## 11.2 Fundamentals

Schematics of a bubble immersed in a wetting liquid within a capillary of radius  $R$  are shown in Figure 11.1. The dimensionless coordinate  $r$  is scaled by the capillary radius  $R$ . If the bubble is not translating, the capillary pressure drop across the bubble cap is of order  $\sigma/R$ , where  $\sigma$  is the interfacial tension. In contrast, the pressure drop necessary to drive a liquid slug of length  $l$  at speed  $U$  in the same channel is of order  $Ul\mu/R^2$ . Hence, the slug length  $l$  scales as  $RCa^{-1}$  where  $Ca = \mu U/\sigma$  is the capillary number. In microchannels,  $Ca$  ranges from  $10^{-8}$  to  $10^{-4}$  (for aqueous solutions moving at  $10^{-4}$  to 1 mm/sec), thus the equivalent slug length  $l$  is many orders of magnitude higher than  $R$ . Equivalently, the capillary pressure across the static meniscus can drive a liquid slug of length  $R$  at the astronomically large dimensionless speed of  $Ca = 1$ . For electrokinetic flow, in contrast, such speeds can only be achieved by an electric field of more than  $10^4$  volts/cm! The capillary pressure across a static meniscus in a capillary is sometimes called the *invasion pressure* and it is the required pressure to insert a meniscus in the capillary. Once the bubble is set into motion, the required pressure to sustain its motion is less than  $\sigma/R$  but, as will be shown below, it is still significant.

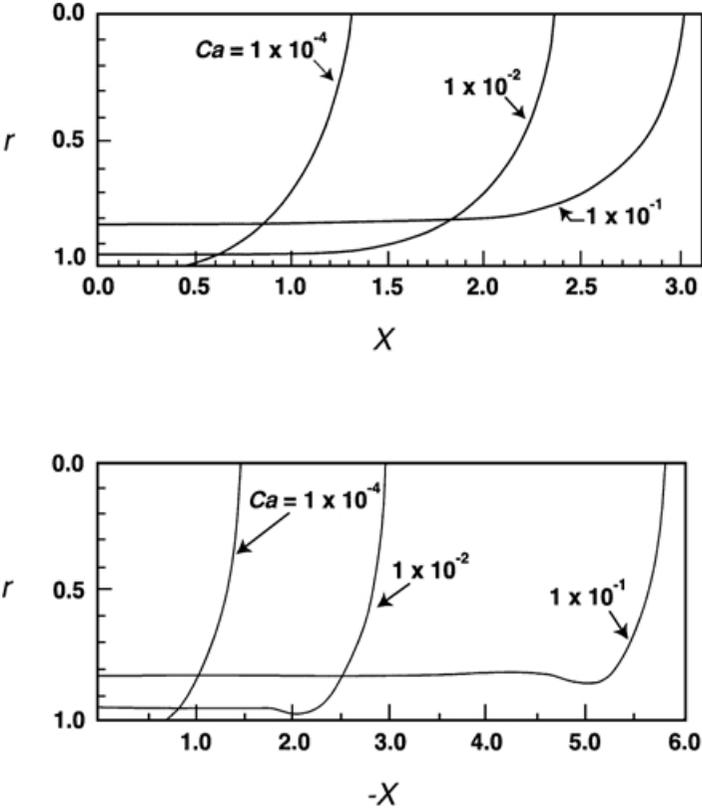

FIGURE 11.1 Front and back profiles for very long bubbles.

The thickness of the wetting film around a moving bubble in a capillary and the pressure drop across it were first studied by Bretherton (1961). For capillary radii  $R$  smaller than the capillary length  $(\sigma/\Delta\rho g)^{1/2}$ , which is about 1 mm for aqueous solutions, buoyancy effects are negligible and the bubble is axisymmetrically placed within the capillary. The flat annular film around the bubble allows only unidirectional longitudinal flow. Moreover, this lubrication limit stipulates that the pressure be constant across the film and determined by the local interfacial curvature, the sum of the axial and azimuthal curvatures of the axisymmetric bubble. Pressure variation is hence only in the longitudinal direction. For pressure-driven mobile bubbles, however, the flat annular film at the middle of the drop indicates that no pressure gradient is present and there is no flow in the film. Liquid flow only occurs at the transition regions near the caps where the film is no longer flat in the longitudinal direction. Near the front cap, the azimuthal curvature decreases behind the tip and the resulting capillary pressure gradient drives fluid into the annular film. The reverse happens near the back cap to pick up the stagnant liquid laid down by the front cap. Unlike the usual symmetric Stokes flow, however, the flow around the two caps are not mirror images of each other in this free-surface problem. If they were reflectively symmetric, the net pressure drop across the bubble would be zero, which is impossible for a translating bubble. In essence, pressure-driven liquid flow before and after the bubble is due to the same negative bulk pressure gradient. However, the capillary pressure gradients at the two caps are in opposite directions relative to this bulk gradient. As such, the two caps are not mirror images of each other and the capillary pressure across the back cap must be smaller than that at the front cap.

Simple scaling arguments can immediately determine the pressure drop across the bubble and the thickness of the surrounding film. The leading order estimate of capillary pressure drops at both caps is indeed identical at  $2\sigma/R$  and the axial curvature at the tips is  $1/R$ . The axial curvature at the surrounding annular film is  $d^2h/dx^2$  where  $h$  is the interfacial thickness measured from the capillary wall and  $x$  is the longitudinal direction. (The azimuthal curvature gradient scales as  $h_x$  and is negligible compared to the axial curvature gradient  $h_{xxx}$  in the short transition region.) Balancing the axial curvature  $d^2h/dx^2$  to  $1/R$  immediately reveals that the ratio of the length of the transition region scales as the square root of the film thickness, with both lengths small compared to the capillary radius  $R$ . However, the pressure gradient in the transition regions provided by the capillary pressure drives a liquid flow at the speed  $U$  of the bubble. Balancing the viscous dissipation estimate  $\mu U/h^2$  with  $dp/dx$  and using the above scalings for each quantity, we immediately conclude that the ratio of  $h^2$  to the transition length  $x$  is of order  $Ca$ . Reconciling this with the relative scalings imposed by curvature matching, we obtain the classical Bretherton scalings—the film thickness scales as  $RCa^{2/3}$  while the transition regions near the cap are of the order of  $RCa^{1/3}$  long, with  $Ca \ll 1$ . The total viscous dissipation due to the flow at the caps is the integral of  $\mu$  times the normal gradient of the flow field at the wall over the transition length. This is just the capillary pressure required to balance the dissipation and, using the above scaling, this capillary pressure is of the order  $(\sigma/R)Ca^{2/3}$ . Due to the asymmetry of the two caps, this capillary pressure is different at the two caps. The difference in the pressure drop across the two caps is then of the order  $(\sigma/R)Ca^{2/3}$ .

Using this new estimate for the pressure drop, we conclude that the equivalent slug length  $l$  scales as  $RCa^{-1/3}$ . Equivalently, in a train of translating bubbles spaced by continuous liquid slugs, the pressure drop across each bubble roughly corresponds to a liquid slug of length  $RCa^{-1/3}$ , or 10 to 1000 times the capillary radius! Hence, the pressure drop required to drive most bubble trains occurs at the bubble caps. Even without contact-line resistance, pressure-driven multiphase transport in microchannels is thus expected to require orders of magnitude higher pressure drops. In the next section, we will estimate this pressure drop with and without Marangoni traction introduced by surfactants and sketch the effects of drop viscosity and noncircular capillaries. It is unlikely, however, that pressure-driven multiphase flow can be achieved under realistic conditions. In the following section, we show that electrokinetically driven multiphase flow is very much achievable and demonstrate that bubble speed can reach as high as the electrokinetic speed of pure liquids. However, such flows occur under very specific conditions, which will be described in some detail. We conclude with some conjectures on other multiphase microfluidics in the final section.

### 11.3 The Bretherton Problem for Pressure-Driven Bubble/Drop Transport

The above scaling arguments can be made more precise with matched asymptotics. Using a local Cartesian coordinate for the thin-film region, the usual lubrication analysis yields the following longitudinal velocity profile:

$$u(y) = \frac{-\sigma}{\mu} \frac{\partial^3 h}{\partial x^3} \left( \frac{y^2}{2} - yh \right) \quad (11.1)$$

The normal coordinate  $y$  is measured from the capillary wall. The pressure  $p$  is independent of  $y$  and is equal to  $-\sigma h_{xx}$ , the axial curvature of the film. Hence, integrating over the film thickness, one obtains the flow rate  $q = \left( \frac{\sigma h^3}{3\mu} \right) \frac{\partial^3 h}{\partial x^3}$ . The cubic power dependence arises from the parabolic profile of  $u(y)$  in Eq. (11.1). Mass balance over the entire film cross section yields:

$$\frac{\partial h}{\partial t} = -\frac{\partial q}{\partial x} \quad (11.2)$$

In a frame moving with the bubble speed  $U$ , the time derivative is converted into  $-Uh_x$  in the moving frame. Integrating from the flat-film region where the third derivative vanishes into the transition region yields:

$$3 \left( \frac{\mu U}{\sigma} \right) (h - h_\infty) = h^3 h_{xx} \quad (11.3)$$

Scaling  $h$  by the unknown flat-film thickness  $h_\infty$  and the  $x$  coordinate by  $h_\infty / (3Ca)^{1/3}$ , respectively, we obtain the Bretherton equation:

$$H_{xxx} = \frac{H-1}{H^3} \quad (11.4)$$

This nonlinear equation for  $H$  describes the transition regions of both caps. However, the front one corresponds to  $X \rightarrow \infty$  while the back one corresponds to  $X \rightarrow -\infty$ . The two asymptotic behaviors are clearly not identical, indicating that the two caps are not mirror images. Nevertheless, as  $H$  blows up in both infinities, its third derivative must vanish according to Eq. (11.4) and one expects quadratic blowup in both directions. These quadratic asymptotes must then be matched to the outer cap solutions. As  $h$  blows up, viscous effects become negligible and the outer caps are, to the leading order, just static solutions of the Laplace–Young equation. Without gravitational effects, these axisymmetric solutions are just spherical caps of radius  $R$  that make quadratic contact with the wall.

Linearizing about  $H = 1$ , the behavior away from the flat film is seen to be governed by three eigenvalues, 1 and  $-\frac{1}{2} \pm \frac{\sqrt{3}}{2} i$ . There is, then, only monotonic blowup in the positive  $X$  direction due to a lone positive real eigenvalue, and a numerical integration of Eq. (11.4) yields the front cap asymptote:

$$H(X \rightarrow \infty) = \alpha^+ X^2 + \gamma^+ X + \beta^+ \quad (11.5)$$

The second coefficient can be changed due to an arbitrary shift of  $X$  but the quadratic coefficient is universal.

We then choose the origin of  $X$  until  $\gamma^+$  vanishes. Equivalently, we can vary  $H - 1$  with  $H_x = H_{xx} = 0$  for the initial condition in our forward integration of Eq. (11.4). This one-parameter iteration yields:

$$\alpha^+ = 0.32171 \quad \beta^+ = 2.898 \quad (11.6)$$

Hence, the asymptotic curvature of the annular film toward the front cap is  $H_{xx} = 2\alpha^+$  or, in the original dimensional coordinate:

$$h_{xx} = \frac{(3Ca)^{2/3}}{h_\infty} H_{xx} = \frac{2\alpha^+(3Ca)^{2/3}}{h_\infty} \quad (11.7)$$

This must match with the front spherical cap of radius  $R$  that makes the quadratic tangent with the capillary. Hence, matching Eq. (11.7) to this quadratic contact, we obtain the leading order estimate of the film thickness:

$$h_\infty/R = 0.6434(3Ca)^{2/3} \quad (11.8)$$

The back matching is more intricate. We note first that the complex eigenvalues suggest that the back film is undulating. A pronounced dimple due to this undulation is evident in the back profiles of [Figure 11.1](#) computed by Lu and Chang (1988). This film oscillation is indeed confirmed by the photographs of Friz (1965). There is an arbitrary phase between these two complex modes that must be specified. This extra degree of freedom is not present for the positive direction with only one real eigenvalue. Due to the quadratic contact of the back cap, we again iterate on the origin of  $X$  to obtain the back asymptote:

$$H(X \rightarrow -\infty) = \alpha^- X^2 + \beta^- \quad (11.9)$$

Because of the extra degree of freedom in the phase of the two complex conjugate modes, both  $\alpha^-$  and  $\beta^-$  are functions of the phase, thus the pair  $(\alpha^-, \beta^-)$  is a one-parameter family. To the leading order, however, this asymptote must also match a sphere of radius  $R$  that makes tangential contact with the capillary. Hence,  $\alpha^- = \alpha^+ = 0.32171$ . For this value of  $\alpha^-$ , the corresponding value of  $\beta^-$  is  $\beta^- = -0.8415$ . (This is the most accurate estimate obtained by Chang and Demekhin [1999]. It is slightly different from many earlier values, including Bretherton's.)

The capillary pressure drops at the two caps arise from the  $\beta^\pm$  terms. Consider the two spherical caps of radius  $R' = R(1 + \epsilon)$  different from the capillary radius  $R$ . Then, the expansion of the cap near the contact point,  $\frac{dh(0)}{dx} = 0$ , is

$$h \sim \frac{x^2}{R} - R\epsilon \quad (11.10)$$

Matching this expansion of the outer cap solution near the capillary to the two asymptotes of the inner film solutions, Eqs. (11.5) and (11.9), one immediately sees that the front cap has a radius smaller than  $R$  and the back has a larger radius. The difference is of order  $Ca^{2/3}$ , the scalings for  $H$  in both equations. Hence, the pressure drop across the entire bubble is then the difference in the two cap capillary pressures  $\sigma/R'$ :

$$\begin{aligned} \Delta p/(\sigma/R) &= \frac{2}{1 + \epsilon^-} - \frac{2}{1 + \epsilon^+} \sim 2(\epsilon^+ - \epsilon^-) \\ &= 2(\beta^+ - \beta^-)(h_\infty/R) = 10.0Ca^{2/3} \end{aligned} \quad (11.11)$$

The scaling of this pressure drop is consistent with the earlier order-of-magnitude arguments of the previous section. The unit-order coefficients are now specified by this classical matched asymptotic analysis. We note in passing that there is also an inner  $X \ln X$  asymptotic behavior that needs to be matched to similar expansions in the outer solution [Kalliadasis and Chang, 1996]. Such high-order matching becomes important only when contact lines appear.

### 11.3.1 Corrections to the Bretherton Results for Pressure-Driven Flow

At higher values of  $Ca$ , between 0.01 and 0.1, the film thickness and pressure drop across the bubble must be solved numerically instead of by matched asymptotics. This effort was carried out by Reinelt and Saffman (1985) and Lu and Chang (1988). The pressure drop can be correlated up to  $Ca = 0.1$  as [Ratulowski and Chang, 1989]:

$$\Delta p/(\sigma/R) = 10.0Ca^{2/3} - 12.6Ca^{0.95} \quad (11.12)$$

However, the capillary number rarely exceeds  $10^{-4}$  in microfluidics and the Bretherton results of the previous section are usually adequate.

Bretherton finds his film thickness prediction to be smaller than the measured values at low  $Ca$ , exactly where the matched asymptotic analysis is most valid. This is confirmed by a series of experiments summarized by Ratulowski and Chang (1990), who attribute the deviation to Marangoni effects of surfactant contaminants that are most pronounced at the thin films of low  $Ca$ . The film thickness is determined only by how the front cap lays down a thin film by its capillary pressure. In this region, the film interface is stretched considerably and the interfacial surfactant concentration decreases from the cap to the film. The film surface tension is then larger than the cap and this Marangoni traction drags additional liquid into the film to thicken it.

For soluble surfactants, a complex model involving bulk-interface transport must be constructed to account for this new mechanism. For insoluble surfactants, however, a simple correction can be obtained almost trivially. In the limit of very small  $Ca$ , this traction approaches infinity and the free surface in the transition region can be treated as a deformable but rigid interface that is laid onto the stagnant film. The velocity at the rigid interface vanishes and the parabolic velocity of Eq. (11.1) simply becomes:

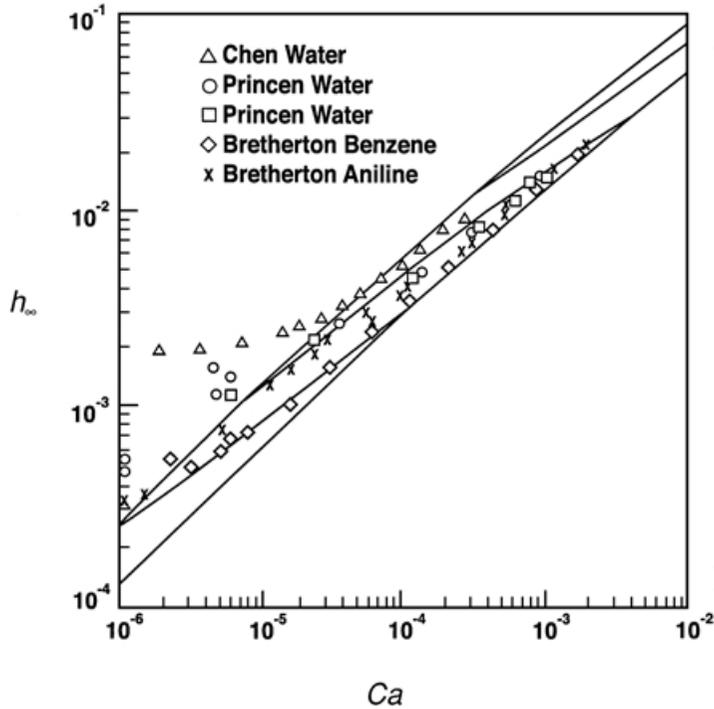

$$u(y) = -\frac{\sigma}{\mu} \frac{\partial^3 h}{\partial x^3} \left( \frac{y^2}{2} - \frac{yh}{2} \right) \quad (11.13)$$

The flow rate  $q$  is then corrected by the factor of 4 due to the interface traction. The same correction yields a factor of 4 to the left-hand side of the Bretherton equation, Eq. (11.3). As a result, one simply scales  $Ca$  by 4 and the same dimensionless Eq. (11.4) results. Hence, in the limit of low  $Ca$ , soluble surfactants will correct the film thickness by a factor of  $4^{2/3}$ . This asymptote is clearly approached by the experimental data in Figure 11.2 at low  $Ca$ . Ratulowski and Chang show that these asymptotic values at infinite traction are also the maximum values attainable for other more complex surfactant transport at low  $Ca$ . The correction to pressure drop is more intricate as it requires the resolution of the entire bubble. Because the surfactants accumulate at the back cap (or near a stagnation point near the back cap), correction requires a model for surfactant accumulation. Such a model was constructed by Park (1992) who then showed that the pressure drop across the bubble now has a  $Ca^{1/3}$  scaling due to the accumulation. The pressure drop, then, increases by a factor of  $Ca^{1/3}$  in the presence of surfactants.

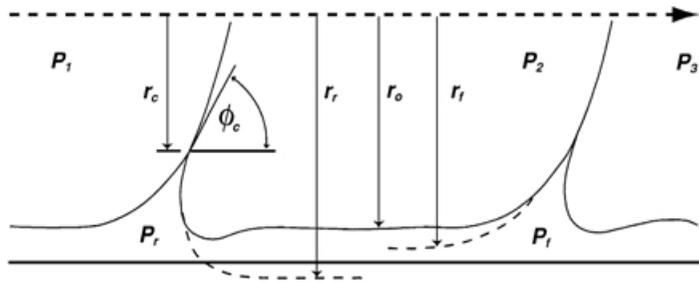

One particularly interesting phenomenon concerning Marangoni effect is remobilization [Stebe et al., 1991] at high bulk surfactant concentrations when the entire interface can saturate even as it is being stretched. As such, the Marangoni traction vanishes and the mobile limit is again attained. Still, this strategy only reduces the pressure drop by a factor of order unity and does not change the basic scalings.

For bubble trains whose bubbles are separated by thin lamellae instead of spherical caps (see Figure 11.3), Ratulowski and Chang (1989) show that the pressure drop remains constant to the leading order, while the film thickness decreases as adjacent bubbles are compressed (larger contact radius  $r_c$  in Figure 11.3). It is clear from geometric considerations that a larger compression between adjacent bubbles will decrease the film thickness. In fact, an expansion of the Laplace–Young equation for the lamellae about zero contact radius shows that the film thickness is related to the free bubble thickness at  $r_c = 0$  by:

$$h_\infty(r_c) = (1 - r_c)h_\infty(0) \quad (11.14)$$

**FIGURE 11.2** The film thickness of a bubble translating in various surfactant solutions. The capillary number  $Ca$  is a dimensionless speed and the film thickness is scaled by the capillary radius. The theoretical curves correspond to different surfactant equilibrium constants between the interface and the bulk. At low  $Ca$ , they all approach the same asymptote derived in the text.

**FIGURE 11.3** Schematic of a bubble train. The contact radius  $r_c$  represents the degree of compression.

What is less apparent is that, because the lamella is a constant curvature axisymmetric surface, its contribution to the curvatures of both asymptotes of the thin annular film is identical. As a result, the pressure drop across the bubble is independent of the contact radius.

Schwartz et al. (1986) examine drop transport and find that the thickness and pressure drop increase monotonically with respect to the viscosity ratio between the drop and the wetting fluid. The maximum occurs at infinitely large viscosity, corresponding to a solid drop, and it is found to be larger than Bretherton's result by a factor of  $2^{2/3}$ . The difference in this correction factor from the Marangoni correction is because the latter corresponds to a stationary rigid film while the former is a translating one. The Bretherton scaling results are hence very robust estimates for circular capillaries. They are only slightly corrected by Marangoni tractions due to surfactants, drop viscosity and even bubble spacing.

The Bretherton scaling arguments break down, however, for channels with noncircular channels. Ratulowski and Chang (1989) examined the square channel numerically. Because the bubble caps of isolated bubbles are axisymmetric, contact must be made with the wall at low  $Ca$ . This is estimated to be at  $Ca = 0.04$ , below which contact lines are expected and the liquid does not wet the channel wall. Thus, favorable operating conditions only exist for  $Ca$  larger than 0.04 and the numerical results show that the film thickness and pressure drop show peculiar scaling:

$$h_{\infty} = 0.69 - 0.10 \ln Ca \quad \Delta p/(\sigma/R) = 3.14Ca^{0.14} \quad (11.15)$$

The radius  $R$  corresponds to a cylindrical capillary with the same cross-section area.

Estimates for other channel geometries have not been computed but the formulation by Ratulowski and Chang can still be used. In essence, one must solve the following two-dimensional unit cell equation for each dimensionless bubble radius  $r$ , scaled with respect to  $R$ :

$$\nabla^2 \psi = -1 \quad (11.16)$$

This fundamental solution is solved within a cross section of the straight capillary with a Dirichlet boundary condition at the capillary wall and Neumann condition at the circular interface with the dimensionless radius  $r$ . The flow rate–capillary pressure relation then becomes:

$$q = -K \frac{\partial p}{\partial x} = K(r) \frac{\partial^3 r}{\partial x^3} \quad (11.17)$$

The permeability constant  $K(r)$  is the cross-section average of the fundamental solution above multiplied by the factor  $\sigma R^4/\mu$ . A higher order version of the curvature can be used in place of the second derivative of  $r$ . To avoid contact between bubble and capillary, the capillary cross-section geometry must be nearly axisymmetric. As such, one does not expect the pressure drop to be significantly different from Bretherton's estimate for circular capillaries, despite the difference in  $Ca$  scaling.

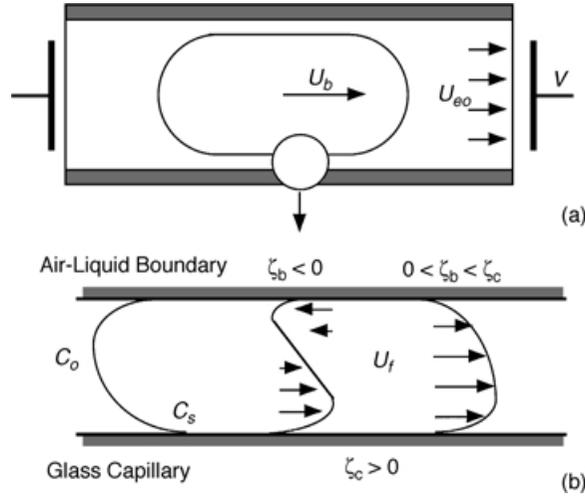

## 11.4 Bubble Transport by Electrokinetic Flow

The large pressure drop required to drive multiphase microchannel flow immediately suggests the electrokinetic driving force is more desirable. If the electrokinetic flow behind the bubble or drop is larger than that of the surrounding film, a high-pressure region can build up behind the bubble/drop to drive it with the same capillary pressure mechanism as before. As will be shown below, it is much easier to build pressure with electrokinetic flow than pressure-driven flow behind the bubble. As such, the required driving force is not as large as that of pressure-driven flow. The task is then to reduce the flow around the bubble/drop without shorting the current required to drive the fluid.

This design consideration requires some knowledge of electrokinetic flow [Russel et al., 1989; Probstein, 1994]. Electrokinetic flow occurs when the dielectric channel wall contains some surface charges that attract co-ions of opposite charge in the solution to a thin double layer of thickness  $\lambda$ , the Debye length, which ranges from 10 nm to microns depending on the bulk electrolyte concentration. The counter-ion concentration increases from the bulk value toward the wall within this double layer, while the co-ion decreases from its bulk value. Both bulk values are identical due to charge neutrality so there is a net charge within the thin double layer. The total amount of this charge is determined through ionization equilibrium by the surface charge on the capillary.

Within the double layer, the potential  $\phi$  is governed by the Poisson equation:

$$\frac{\partial^2 \phi}{\partial y^2} = \frac{F\rho}{\epsilon} \quad (11.18)$$

**FIGURE 11.4** Electrokinetically driven bubble transport. The electrolyte ion concentration profile  $C_o$  is shown below with the velocity profiles  $U_f$  for both negative and positive zeta potentials at the bubble interface. The bubble translates with bubble speed  $U_b$  and the liquid with electrokinetic velocity  $U_{eo}$ .

The charge density is  $\rho$  and the potential is set to zero at the bulk when  $y$  approaches infinity. The potential at the surface is called the *zeta potential*  $\zeta$ . Due to the Boltzmann distributions of the co-ion and counter-ion, the counter-ion concentration increases much faster than the co-ion concentration decreases toward the wall. As a result, the total ion concentration in the double layer exceeds that in the bulk by a factor of  $\exp(\zeta/kT)$ , as seen in Figure 11.4. Consequently, the charge density  $\rho$  also increases from zero at the bulk to a value at the wall equal to the bulk concentration multiplied by  $\exp(\zeta/kT)$ . Hence, at low  $\zeta/kT$ , Eq. (11.18) indicates that the scaling for  $\lambda$  is inversely proportional to the square root of the bulk ion concentration. Moreover, by integrating Eq. (11.18) over the double layer, its total charge is seen to scale linearly with respect to the potential gradient at the wall. The latter quantity scales as  $\zeta/\lambda$  and one concludes that, for a given capillary–electrolyte pair, the zeta potential  $\zeta$  scales as  $\lambda$ , inversely as the square root of the bulk electrolyte concentration.

In the presence of a tangential electric field  $E$ , there is a net body force on the electrolyte that scales as  $E\rho$ . This body force vanishes in the neutral bulk but accelerates the ions in the double layer to large speeds. These streaming ions then drag the entire fluid body in the capillary along with them. Because the body force is concentrated in the thin double layer, it acts like a surface force and the entire bulk liquid translates rigidly with a uniform tangential velocity. The momentum transfer in  $y$  for the tangential velocity field involves the viscous dissipation term  $\mu d^2u/d^2y$  balanced by the body force  $E\rho$ . Because this is in the same form as the Poisson equation, one sees that  $u$  scales linearly with respect to the electric potential  $\phi$  but approaches a constant value away from the double layer. This asymptote is called the *electrokinetic velocity*:

$$u_c = -\frac{\epsilon_0 \epsilon \zeta_c E}{\mu} \quad (11.19)$$

The constants  $\epsilon_0$  and  $\epsilon$  are the dielectric permittivities that we have omitted in the above scaling arguments.

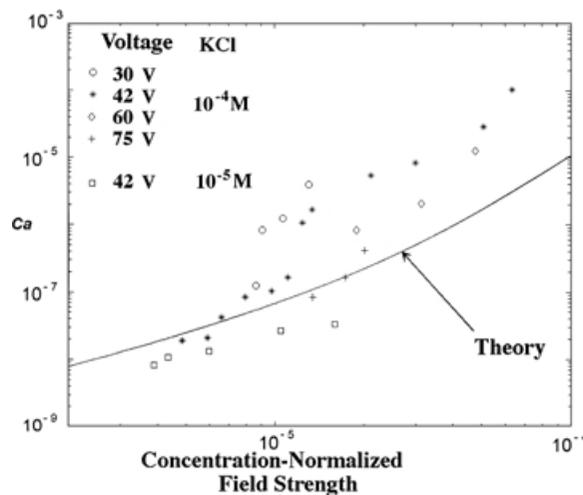

Because the electrokinetic velocity is flat away from the thin double layer (see Figure 11.4), the flowrate scales as the cross-section area, or  $R^2$ . In contrast, for pressure-driven flow the flow rate scales as the square of the area, or  $R^4$ . For the small dimensions of microchannels, one can then obtain much larger flow rates with electrokinetic flow. Even in microchannels that are microns in width and depth, electrokinetic velocity of an electrolyte solution can often exceed 0.1 mm/sec. Similarly, it is easier to

build up back pressure behind bubbles and drops with electrokinetic flow than with pressure-driven flow, if one can reduce the film flow.

Unfortunately, the same flat electrokinetic velocity profile now serves to prevent cessation of film flow. By simple current-voltage calculation in the longitudinal direction, the local electric field  $E$  is easily shown to scale as the inverse of the cross-section area of the electrolyte across the capillary. By Eq. (11.19), the electrokinetic velocity scales the same way. However, the flowrate scales as the electrokinetic velocity times the cross-section area and hence is independent of the cross-section area! The flowrate behind the bubble is the same as that in its surrounding film. As a result, there is no back pressure buildup and the electrolyte simply flows around the bubble. This is indeed observed when air bubbles are driven electrokinetically in a  $\text{KCl}/\text{H}_2\text{SO}_4$  electrolyte (about  $10^{-2}$  and  $10^{-6}$  mol/L each) in a 5-cm-long glass capillary with a 1.0-mm inner diameter and with a voltage drop of 30 to 70 V [Takhistov et al., 2000]. At these conditions, the electrokinetic velocity of the electrolyte is at a healthy 0.1 to 1.0 mm/sec. Nevertheless, the bubble remains stationary as the electrolyte flows past it.

There are several possible means of breaking the above flowrate invariance to cross-section area to reduce the film flow. One can endow the interface with traction, by using finite viscosity drops or interfacial surfactants such that the film profile is no longer flat. The film electric field can also be reduced by reducing the electrolyte concentration such that the high ion concentration within the thickened double layer can increase the film conductivity. More intriguingly, one can use an ionic surfactant to endow a double layer at the interface that has a different charge from the capillary double layer. In this manner, the velocity at the interface is not zero in the moving frame but is negative (see Figure 11.4). This could effectively reduce the film flow to zero.

Because the glass capillary surface of Takhistov et al.'s experiment has a positive charge such that its double layer contains a negative charge, an anionic surfactant, sodium dodecyl sulfate (SDS), is employed to test the above idea. Most glass surfaces are negatively charged but the charge has been reversed through chemical treatment to allow an interfacial double layer of the opposite charge. About  $10^{-5}$  mol/L of such surfactants is added and, after some equilibration time, the bubbles indeed begin to move. In Figure 11.5, the measured bubble speed  $Ca$  is recorded as a function of the electrolyte concentration, applied field and the surfactant concentration. The last quantity is presented as a concentration-normalized field strength obtained from an electrokinetic theory [Takhistov et al., 2000]. Bubble speeds approaching the liquid electrokinetic velocity (without bubble) of  $Ca = 10^{-4}$  are observed, indicating a complete cessation of film flow. A more specific set of data is shown in Figure 11.6 in dimensional quantities, showing a robust 0.14-mm/sec bubble speed.

**FIGURE 11.5** Electrokinetically driven bubble speed as a function of a concentration-normalized electric field for the KCl electrolyte of indicated concentrations. The unnormalized data scatter over 5 decades and are collapsed by the theory.

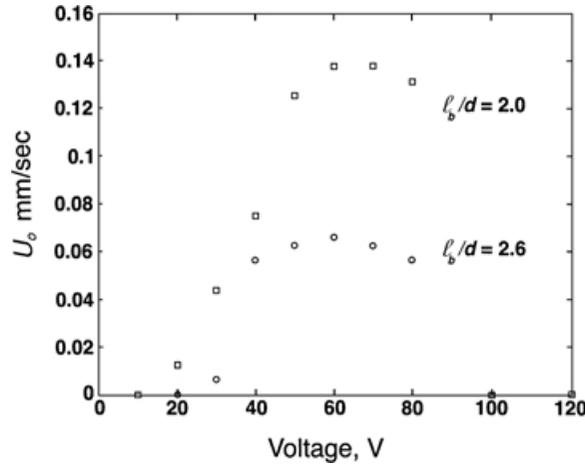

FIGURE 11.6 Raw bubble speed data  $u_0$  as a function of applied voltage and bubble length  $l_b$  normalized by the capillary diameter  $d$ . The bubble speed approaches that of the electrolyte electrokinetic velocity without bubble before dropping to zero abruptly at a critical voltage of 80 V.

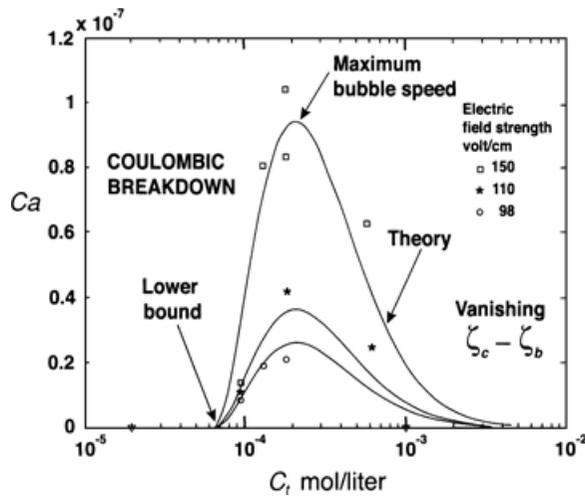

FIGURE 11.7 The window of total ion concentration  $C_i$  where bubble motion is possible.

There are, however, limitations to such electrokinetically driven bubble flow in microchannels. The interfacial zeta potential endowed by the surfactants is a strong function of the electrolyte concentration due to the strong screening effects near the anions of the surfactants [Schultz, 1984]. At high concentrations, the interface double layer can become negligibly thin such that again the film velocity profile approaches a flat one and the bubble speed approaches zero. At very low bulk electrolyte concentrations, on the other hand, the Debye thickness approaches the film thickness. As a result, the ion concentration and conductivity in the film can increase by a factor of  $\exp(\zeta/kT)$ . Because  $\zeta$  is large at low concentration, by the arguments presented before, a significant increase in the film conductivity can occur at low concentrations. This reduces the field strength  $E$  and further reduces the film flow. However, because the interfacial and capillary double layers are oppositely charged, their increased thickness leads to significant Coulombic attraction between the two and will eventually collapse the entire film. These limits are observed in our experimental data for different KCl concentrations shown in Figure 11.7. The fact that the bubble speed approaches

zero at high concentrations suggests that interfacial traction provided by the surfactants is negligible. There is, then, a wide but finite window of electrolyte concentration through which multiphase microfluidic flow can be achieved with an electrokinetic driving force.

The Bretherton analysis can be extended to electrokinetic flow [Takhistov et al., 2000]. The theory now includes the electrolyte concentration dependence of the zeta potential and the important interfacial double layer. The resulting theoretical predictions collapse the data in Figure 11.5 and provide accurate estimates of the data in Figures 11.6 and 11.7. Also included in the theory are the transients necessary to establish a steadily translating bubble. Surfactant adsorption equilibration at the interface and capillary double-layer equilibration are just some of the important transients that must be considered for the design of microdevices.

## 11.5 Future Directions

---

It appears from the above arguments that electrokinetic flow is the only means of overcoming the large capillary forces involved in transporting bubbles and drops in microchannels. Electrokinetic flow in a circular capillary is possible only within certain windows of operation. For noncircular channels, current and flow leakage at the corners are additional concerns. Such leaks must be prevented to have complete cessation of film flow. Further complications arise at channel junctions or constrictions where bubbles and drops may break up or coalesce. Jet streaming of small drops from the front tip of a bubble being sheared in front of a constriction has also been observed. Most of these phenomena must be carefully avoided in the device design. However, the rapid ion motion in the double layers of electrokinetic flow can have certain desirable applications. We have observed charge separation along the bubble that is sufficient to break up the bubble. This may suggest a means of electrophoretic bubble motion and bubble breakup in microreactors. The same polarization can also induce bubble coalescence. Streaming potentials with opposite flows is another possibility but a rather difficult task because of the capillary pressure again. Evaporation and condensation phenomena are also profoundly different in microchannels due to capillary forces. Biological cells with internal and external charges and of the same dimension as the microchannels exhibit a rich spectrum of electrophoretic, electrokinetic and stress-induced adsorption dynamics in microfluidics. These and other known and new phenomena of ionic flow await future studies for applications in microdevice designs.

### 12.1 Introduction

---

This chapter reviews the fundamentals of linear and nonlinear control. This topic is particularly important in microelectromechanical systems (MEMS) applications for two reasons. First, as electromechanical systems, MEMS devices often must be controlled in order to be utilized in an effective manner. Second, important applications of MEMS technology are controls-related because of the utility of MEMS devices in sensor and actuator technologies. Because the area of control is far too vast to be entirely presented in one self-contained chapter, the approach adopted for this chapter is to outline a variety of techniques used for control system synthesis and analysis, provide at least a brief description of their mathematical foundation, discuss the advantages and disadvantages of each of the techniques and provide sufficient references so that the reader can find a starting point in the literature to fully implement any described techniques. The material varies from the extremely basic (e.g., root locus design) to relatively advanced material (e.g., sliding mode control) to cutting-edge research (hybrid systems). Some examples are provided; additionally, many references to the literature are provided to help the reader find further examples of a particular analysis or synthesis technique.

This chapter is divided into three sections, each of which considers both the stability and performance of a control system. The term *performance* includes both the qualitative nature of any transient response of the system, reference signal tracking properties of the system and the long-term or steady-state performance of the system. The first section considers “classical control,” which is the study of single-input, single-output (SISO) linear control systems, which relies heavily upon mathematical techniques from complex variable theory. The material in this section outlines what is typically covered in an elementary undergraduate controls course. The second section considers so-called “modern control” which is the study of multi-input, multi-output (MIMO) control systems in state space. Included in this section is

what is sometimes called “post-modern control” (Zhou, 1996) which is a study of robust system performance and stability in the presence of unmodeled system dynamics. Finally, the third section considers nonlinear control techniques. Not considered in this chapter are model-free control techniques based upon concepts from soft computing, which are outlined in Chapter 14. Also not considered in this chapter are nonlinear, open-loop control techniques (for recent advances in this area, the reader is referred to Lafferriere and Sussmann [1993]; Bullo et al. [2000]; Goodwine and Burdick [2000]).

## 12.2 Classical Linear Control

Classical linear control relies heavily upon mathematical techniques from complex variable theory. This is apparently an historical consequence of the importance of frequency analyses of feedback amplifiers, which motivated much of the development of classical control theory, as well as a consequence of the fact that convolution in the time domain is simple multiplication in the frequency domain which greatly simplifies the analysis of the natural input/output and “block diagram” structure of many control systems. This topic is typically thoroughly covered in undergraduate controls courses. Good references include Dorf (1992), Franklin et al. (1994), Gajec and Lelic (1996), Kuo (1995), Ogata (1997), Raven (1995) and Shinnars (1992).

### 12.2.1 Mathematical Preliminaries

The main tool is the Laplace transform, which transforms the linear ordinary differential equation (ODE) into an algebraic equation, thus reducing the task of solving an ODE into simple algebra. The Laplace transform of a function,  $f(t)$ , is defined as:

$$L[f(t)] = F(s) = \int_0^{\infty} e^{-st} f(t) dt \quad (12.1)$$

and the inverse Laplace transform of  $F(s)$  as:

$$L^{-1}[F(s)] = f(t) = \frac{1}{2\pi j} \int_{c-j\omega}^{c+j\omega} F(s) e^{st} ds, \quad \text{for } t > 0 \quad (12.2)$$

A discussion of extremely important mathematical details concerning convergence and the proper lower limit of integration is found in Ogata (1997). As a practical matter, evaluating the integrals in the definition of the Laplace transform and the inverse Laplace transform is rarely necessary as extensive tables of Laplace transform pairs are readily available. A few Laplace transform pairs for typical functions are listed in Table 12.1. More complete tables can be found in any undergraduate text on classical control theory such as the references listed previously.

Important properties of the Laplace transform are as follows:

1. Real differentiation:  $L\left[\frac{d}{dt}f(t)\right] = sF(s) - f(0)$ .
2. Linearity:  $L[\alpha f_1(t) \pm \beta f_2(t)] = \alpha F_1(s) \pm \beta F_2(s)$ .
3. Convolution:  $L\left[\int_0^t f_1(t-\tau)f_2(\tau) d\tau\right] = F_1(s)F_2(s)$ .
4. Final value theorem: If all the poles of  $sF(s)$  are in the left half of the complex plane, then  $\lim_{t \rightarrow \infty} f(t) = \lim_{s \rightarrow 0} sF(s)$ .

A basic result from the first three properties is that to solve a linear ordinary differential equation, one can take the Laplace transform of each side of the equation, which converts the differential equation into an algebraic equation in  $s$ , then algebraically solve the expression for the Laplace transform of the dependent variable, and then take the inverse Laplace transform of the resulting function.

**TABLE 12.1** Laplace Transform Pairs for Basic Functions

	$F(t)$	$F(s)$
1	Unit impulse, $\delta(t)$	1
2	Unit step, $1(t)$	$\frac{1}{s}$
3	$t$	$\frac{1}{s^2}$
4	$t^n, n = 1, 2, 3, \dots$	$\frac{n!}{s^{n+1}}$
5	$e^{-at}$	$\frac{1}{s+a}$
6	$t^n e^{-at}$	$\frac{n!}{(s+a)^{n+1}}$
7	$\sin \omega t$	$\frac{\omega}{s^2 + \omega^2}$
8	$\cos \omega t$	$\frac{s}{s^2 + \omega^2}$
9	$e^{-at} \cos bt$	$\frac{s+a}{(s+a)^2 + b^2}$
8	$e^{-at} \sin bt$	$\frac{b}{(s+a)^2 + b^2}$

**Example**

As a simple example, consider the differential equation:

$$\begin{aligned} \ddot{x} + x &= 0 \\ x(0) &= 0 \\ \dot{x}(0) &= 1 \end{aligned} \tag{12.3}$$

Taking the Laplace transform of the equation yields:

$$s^2 X(s) - sx(0) - \dot{x}(0) + X(s) = 0 \tag{12.4}$$

Algebraic manipulation gives:

$$X(s) = \frac{1}{s^2 + 1} \tag{12.5}$$

consequently, from the table of Laplace transform pairs:

$$x(t) = \sin(t) \tag{12.6}$$

For more examples, see Ogata (1997), Raven (1995), Kuo (1995), Franklin et al. (1994) etc.

Due to the convolution property of Laplace transforms, a convenient representation of a linear control system is the block diagram representation illustrated in [Figure 12.1](#). In such a block diagram representation, each block contains the Laplace transform of the differential equation representing that component of the control system that relates the input to the block to its output. Arrows between blocks indicate that the output from the preceding block is transferred to the input of the subsequent block. The output of the preceding block multiplies the contents of the block to which it is an input. Simple algebra will yield the overall transfer function of a block diagram representation for a system.

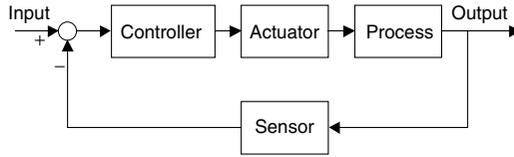

FIGURE 12.1 Typical block diagram representation of a control system.

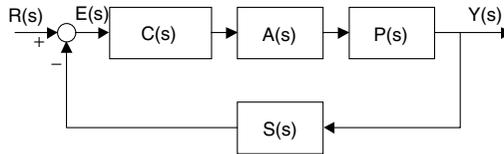

FIGURE 12.2 Generic block diagram including transfer functions.

### Example

The transfer function for the system illustrated in Figure 12.2 can be computed by observing that:

$$E(s) = R(s) - Y(s)S(s) \quad (12.7)$$

and

$$Y(s) = E(s)C(s)A(s)P(s) \quad (12.8)$$

which can be combined to yield

$$\frac{Y(s)}{R(s)} = \frac{C(s)A(s)P(s)}{1 + C(s)A(s)P(s)S(s)} \quad (12.9)$$

A more complete exposition on block diagram algebra can be found in any of the previously cited undergraduate texts. Note that the numerator and denominator of the transfer function will typically be polynomials in  $s$ . The denominator is called the *characteristic equation* for the system. From the table of Laplace transform pairs, it should be clear that if the characteristic polynomial has any roots with a positive real part, then the system will be unstable, as it will correspond to an exponentially increasing solution (see entry 5 in Table 12.1). Given a reference input,  $R(s)$ , determining the response of the system is straightforward: Multiply the transfer function by the reference input, perform a partial fraction expansion (i.e., expand):

$$Y(s) = \frac{R(s)C(s)A(s)P(s)}{1 + C(s)A(s)P(s)S(s)} = \frac{C_1}{s - p_1} + \frac{C_2}{s - p_2} + \dots + \frac{C_n}{s - p_n} \quad (12.10)$$

where each term in the sum on the right-hand side of the equation is something in the form of one of the entries in Table 12.1. In this manner, the contribution to the response of each individual term can be determined by referring to a Laplace transform table and can be superimposed to determine the overall solution:

$$y(t) = y_1(t) + y_2(t) + \dots + y_n(t) \quad (12.11)$$

where each term in the sum is the inverse Laplace transform of the corresponding term in the partial fraction expansion.

**Example**

For the block diagram in Figure 12.2 if  $C(s) = \frac{1}{s}$ ,  $A(s) = 1$ ,  $P(s) = \frac{\omega_n^2}{s + 2\zeta\omega_n}$ ,  $S(s) = 1$  and  $R(s) = \frac{1}{s}$  (a unit step input), then:

$$\begin{aligned}
 Y(s) &= \frac{\omega_n^2}{s(s^2 + 2\zeta\omega_n s + \omega_n^2)} \\
 &= \frac{1}{s} - \frac{s + 2\zeta\omega_n}{s^2 + 2\zeta\omega_n s + \omega_n^2} \\
 &= \frac{1}{s} - \frac{s + \zeta\omega_n}{(s + \zeta\omega_n)^2 + \omega_d^2} - \frac{\zeta\omega_n}{(s + \zeta\omega_n)^2 + \omega_d^2} \\
 &= \frac{1}{s} - \frac{s + \zeta\omega_n}{(s + \zeta\omega_n)^2 + \omega_d^2} - \frac{\zeta\omega_n}{\omega_d} \frac{\omega_d}{(s + \zeta\omega_n)^2 + \omega_d^2}
 \end{aligned} \tag{12.12}$$

where  $\omega_d = \omega_n \sqrt{1 - \zeta^2}$ . Referring to the table of Laplace transform pairs (Table 12.1), and assuming that  $\zeta < 1$ ,

$$y(t) = 1 - e^{-\zeta\omega_n t} \left( \cos(\omega_d t) + \frac{\zeta}{\sqrt{1 - \zeta^2}} \sin(\omega_d t) \right) \tag{12.13}$$

**12.2.2 Control System Analysis and Design**

Control system analysis and design considers primarily stability and performance. One approach to the former is briefly dispensed with first. The stability of a system with the closed-loop transfer function (note that in such a case a controller has already been specified):

$$T(s) = \frac{b_0 s^m + b_1 s^{m-1} + \dots + b_m}{s^n + a_1 s^{n-1} + \dots + a_n} \tag{12.14}$$

is determined by the roots of the denominator, or characteristic equation. In fact, it is possible to determine whether or not the system is stable without actually computing the roots of the characteristic equation. A *necessary condition* for stability is that each of the coefficients  $a_i$  appearing in the characteristic equation be positive. Because this is only a necessary condition, if any of the  $a_i$  are negative, then the system is unstable, but the converse is not necessarily true: Even if all the  $a_i$  are positive, the system may still be unstable. Routh (1975) devised a method to check *necessary and sufficient* conditions for stability.

The method is to construct the Routh array, defined as follows:

Row $n$	$s^n$ :	1	$a_2$	$a_4$	...
Row $n-1$	$s^{n-1}$ :	$a_1$	$a_3$	$a_5$	...
Row $n-2$	$s^{n-2}$ :	$b_1$	$b_2$	$b_3$	...
Row $n-3$	$s^{n-3}$ :	$c_1$	$c_2$	$c_3$	...
$\vdots$	$\vdots$	$\vdots$	$\vdots$	$\vdots$	$\vdots$
Row 2	$s^2$ :	*	*		
Row 1	$s^1$ :	*			
Row 0	$s^0$ :	*			

in which the  $a_i$  are from the denominator of Eq. (12.14);  $b_i$  and  $c_i$  are defined as:

$$b_1 = -\frac{\det \begin{bmatrix} 1 & a_2 \\ a_1 & a_3 \end{bmatrix}}{a_1} \quad b_2 = -\frac{\det \begin{bmatrix} 1 & a_4 \\ a_1 & a_5 \end{bmatrix}}{a_1} \quad b_3 = -\frac{\det \begin{bmatrix} 1 & a_6 \\ a_1 & a_7 \end{bmatrix}}{a_1}$$

$$c_1 = -\frac{\det \begin{bmatrix} a_1 & a_3 \\ b_1 & b_2 \end{bmatrix}}{b_1} \quad c_2 = -\frac{\det \begin{bmatrix} a_1 & a_5 \\ b_1 & b_3 \end{bmatrix}}{b_1} \quad c_3 = -\frac{\det \begin{bmatrix} a_1 & a_7 \\ b_1 & b_4 \end{bmatrix}}{b_1}.$$

The basic result is that the number of poles in the right-half plane (i.e., unstable solutions) is equal to the number of sign changes among the elements in the first column of the Routh array. If they are all positive, then the system is stable. When a zero is encountered, it should be replaced with a small positive constant,  $\epsilon$ , which will then be propagated to lower rows in the array. Then, the result can be obtained by taking the limit as  $\epsilon \rightarrow 0$ .

### Example

Construct the Routh array and determine the stability of the system described by the transfer function:

$$\frac{Y(s)}{R(s)} = \frac{1}{s^4 + 4s^3 + 9s^2 + 10s + 8} \quad (12.15)$$

The Routh array is

$$\begin{array}{r} s^4: \quad \quad \quad 1 \quad \quad \quad 9 \quad \quad 8 \\ s^3: \quad \quad \quad 4 \quad \quad \quad 10 \quad \quad 0 \\ s^2: \quad \frac{-(10-36)}{1} = 26 \quad \frac{-(0-32)}{1} = 32 \quad 0 \\ s^1: \quad \frac{-(128-260)}{4} = 33 \quad \quad \quad 0 \quad \quad 0 \\ s^0: \quad \frac{-(0-1056)}{26} = 40.6 \quad \quad \quad 0 \quad \quad 0 \end{array} \quad (12.16)$$

so the system is stable, as there are no sign changes in the elements in the first column of the array.

One aspect of performance concerns the steady-state error exhibited by the system. For example, from the time-domain solution from the example above, it is clear that as  $t \rightarrow \infty$ ,  $y(t) \rightarrow 1$ . However, the final value theorem can be utilized to determine this without actually solving for the time domain solution.

### Example

Determine the steady-state value for the time-domain function,  $y(t)$ , if its Laplace transform is given by  $Y(s) = \frac{\omega_n^2}{s(s^2 + 2\zeta\omega_n s + \omega_n^2)}$ . Because all the solutions of  $s^2 + 2\zeta\omega_n s + \omega_n^2 = 0$  have a negative real part, all the poles of  $sY(s)$  lie in the left half of the complex plane. Therefore, the final value theorem can be applied to yield:

$$\lim_{t \rightarrow \infty} y(t) = \lim_{s \rightarrow 0} sY(s) = \lim_{s \rightarrow 0} s \frac{\omega_n^2}{s(s^2 + 2\zeta\omega_n s + \omega_n^2)} = 1 \quad (12.17)$$

which clearly is identical to the limit of the time domain solution as  $t \rightarrow \infty$ .

FIGURE 12.3 Robot arm model.

### 12.2.2.1 Proportional–Integral–Derivative (PID) Control

Perhaps the most common control implementation is so-called PID control, where the commanded control input (the output of the “controller” box in Figures 12.1 and 12.2) is equal to the sum of three terms: one term proportional to the error signal (the input to the “controller” box in Figures 12.1 and 12.2), the next term proportional to the derivative of the error signal and the third term proportional to the time integral of the error signal. In this case, from Figure 12.2,  $D(s) = K_p + \frac{K_I}{s} + K_d s$ , where  $K_p$  is the *proportional gain*,  $K_I$  is the *integral gain* and  $K_d$  is the *derivative gain*. A simple analysis of a second-order system shows that increasing  $K_p$  and  $K_I$  generally increases the speed of the response at the cost of generally reducing stability; whereas, increasing  $K_d$  generally increases damping and stability of the response. With  $K_I = 0$ , there may be a nonzero steady-state error, but when  $K_I$  is nonzero the effect of the integral control effort is to typically eliminate steady-state error.

#### Example—PID Control of a Robot Arm

Consider a robot arm illustrated in Figure 12.3. Linearizing the equations of motion about  $\theta = 0$  (the configuration in Figure 12.3) gives:

$$I\ddot{\theta} + mg\theta = u \quad (12.18)$$

where  $I$  is the moment of inertia of the arm,  $m$  is the mass of the arm,  $\theta$  is the angle of the arm and  $u$  is a torque applied to the arm. For PID control,

$$u = K_p(\theta_{\text{desired}} - \theta_{\text{actual}}) + K_d(\dot{\theta}_{\text{desired}} - \dot{\theta}_{\text{actual}}) + K_I \int_0^t (\theta_{\text{desired}} - \theta_{\text{actual}}) dt \quad (12.19)$$

If we set  $I = 1$  and  $m = 1/g$ , the block diagram representation for the system is illustrated in Figure 12.4. Thus, the closed-loop transfer function is

$$T(s) = \frac{K_d s^2 + K_p s + K_I}{s^3 + K_d s^2 + (K_p + 1)s + K_I} \quad (12.20)$$

Figure 12.5 illustrates the step response of the system for proportional control ( $K_p = 1, K_I = 0, K_d = 0$ ), PD control ( $K_p = 1, K_I = 0, K_d = 1$ ) and PID control ( $K_p = 1, K_I = 1, K_d = 1$ ). Note that for proportional

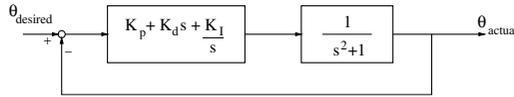

FIGURE 12.4 Robot arm block diagram.

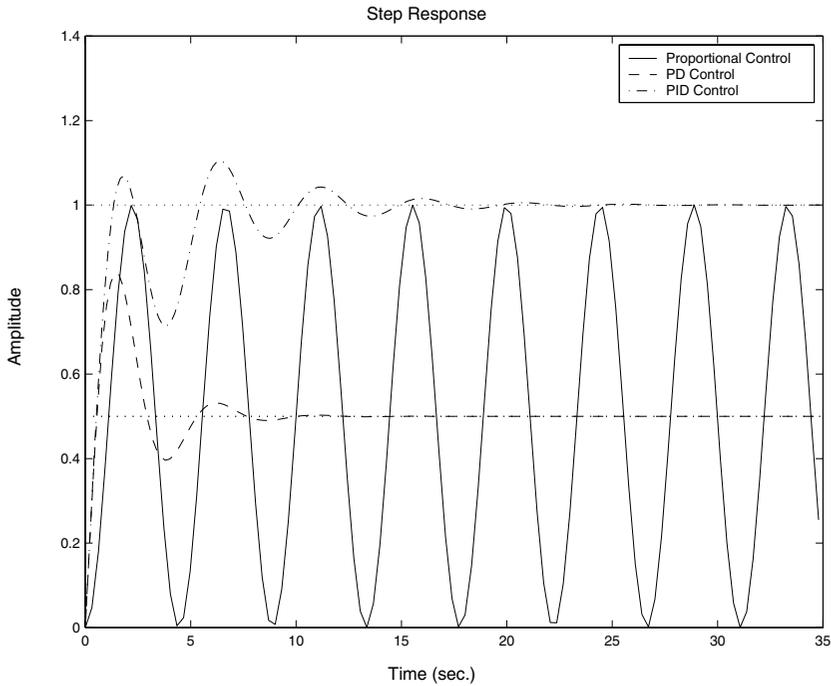

FIGURE 12.5 PID control response.

control and PD controls, there is a final steady-state error, which is eliminated with PI control (also note that both of these facts could be verified analytically using the final value theorem). Finally, note that the system response for pure proportional control is oscillatory, whereas with derivative control the response is much more damped.

The subjects contained in the subsequent sections consider controller synthesis issues. For PID controllers, tuning methods exist and the interested reader is directed to the undergraduate texts cited previously or the papers by Ziegler and Nichols (1942; 1943).

### 12.2.2.2 The Root Locus Design Method

Although, as mentioned above in the discussion of PID control, various rules of thumb can be determined to relate system performance to changes in gains, a systematic approach is clearly more desirable. Because pole locations determine the characteristics of the response of the system (recall the partial fraction expansion), one natural design technique is to plot how pole locations change as a system parameter or control gain is varied [Evans, 1948; 1950]. Because the real part of the pole corresponds to exponential solutions, if all the poles are in the left-half plane, the poles closest to the  $j\omega$ -axis will dominate the system response. In particular, if we focus a second-order system of the form:

$$H(s) = \frac{\omega_n^2}{s^2 + 2\zeta\omega_n s + \omega_n^2} \quad (12.21)$$

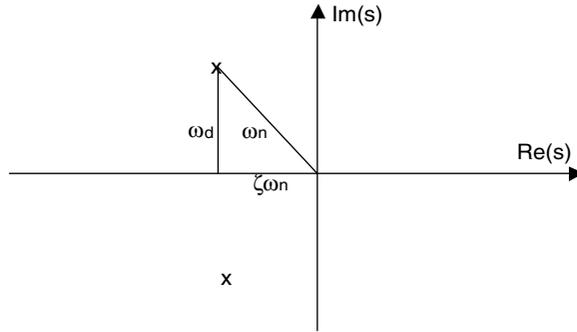

FIGURE 12.6 Complex conjugate poles, natural frequency, damped natural frequency and damping ratio.

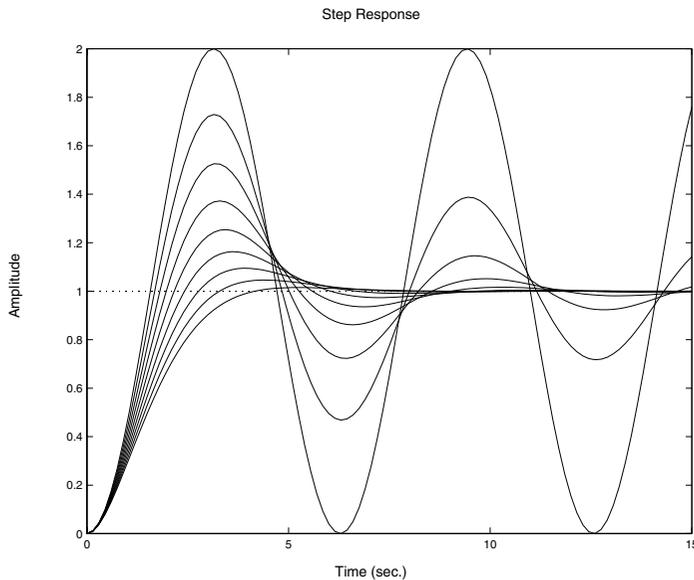

FIGURE 12.7 Step response for various damping factors.

the poles of the system are as illustrated in Figure 12.6. The terms  $\omega_n$ ,  $\omega_d$  and  $\zeta$  are the *natural frequency*, the *damped natural frequency* and the *damping ratio*, respectively. Multiplying  $H(s)$  by  $\frac{1}{s}$  (unit step) and performing a partial fractions expansion give:

$$Y(s) = \frac{1}{s} - \frac{s + \zeta\omega_n}{(s + \zeta\omega_n)^2 + \omega_n^2(1 - \zeta^2)} - \frac{\zeta\omega_n}{(s + \zeta\omega_n)^2 + \omega_n^2(1 - \zeta^2)} \quad (12.22)$$

so the time response for the system is

$$y(t) = 1 - e^{-\zeta\omega_n t} \left( \cos\omega_d t + \frac{\zeta}{\sqrt{1 - \zeta^2}} \sin\omega_d t \right) \quad (12.23)$$

where  $\omega_d = \omega_n\sqrt{1 - \zeta^2}$  and  $0 \leq \zeta < 1$ . Plots of the response for various values of  $\zeta$  are illustrated in Figure 12.7. Clearly, referring to the previous equation and Figure 12.7, if the damping ratio is increased, the oscillatory nature of the response is increasingly damped.

Because the natural frequency and damping are directly related to the location of the poles, one effective approach to designing controllers is to pick control gains based upon desired pole locations. A *root locus*

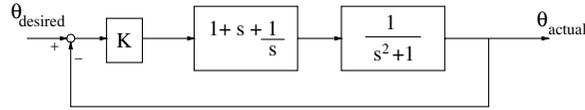

FIGURE 12.8 Robot arm block diagram.

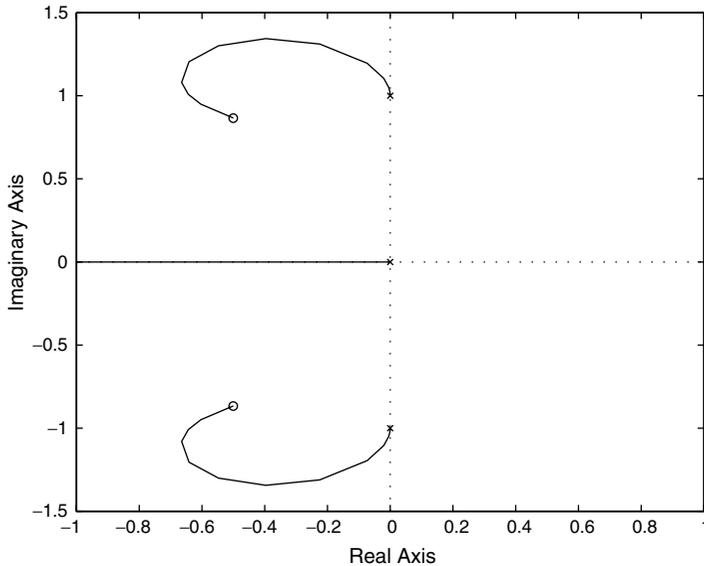

FIGURE 12.9 Root locus for robot arm PID controller.

plot is a plot of pole locations as a system parameter or controller gain is varied. Once the root locus has been plotted, it is straightforward to pick the location on the root locus with the desired pole locations to give the desired system response. There is a systematic procedure to plot the root locus by hand (refer to the cited undergraduate texts), and computer packages such as Matlab (using the `rlocus()` and `rlocfind()` functions) make it even easier. Figure 12.9 illustrates a root locus plot for the robot arm above with the block diagram as the single gain  $K$  is varied from 0 to  $\infty$  as illustrated in Figure 12.8. Note that for the usual root locus plot, only one gain can be varied at a time. In the above example, the ratio of the proportional, integral and derivative gains was fixed, and a multiplicative scaling factor is what is varied in the root locus plot.

Because the roots of the characteristic equation start at each pole when  $K = 0$  and approach each 0 of the characteristic equation as  $K \rightarrow \infty$ , the desired  $K$  can be determined from the root locus plot by finding the part of the locus that most closely matches the desired natural frequency  $\omega_n$  and damping ratio  $\zeta$  (recall Figure 12.7).

Typically, control system performance is specified in terms of *time-domain specifications*, such as *rise time*, *maximum overshoot*, *peak time* and *settling time*, each of which is illustrated in Figure 12.10. Rough estimates of the relationship between the time domain specifications and the natural frequency and damping ratio are given in Table 12.2 [Franklin et al., 1994].

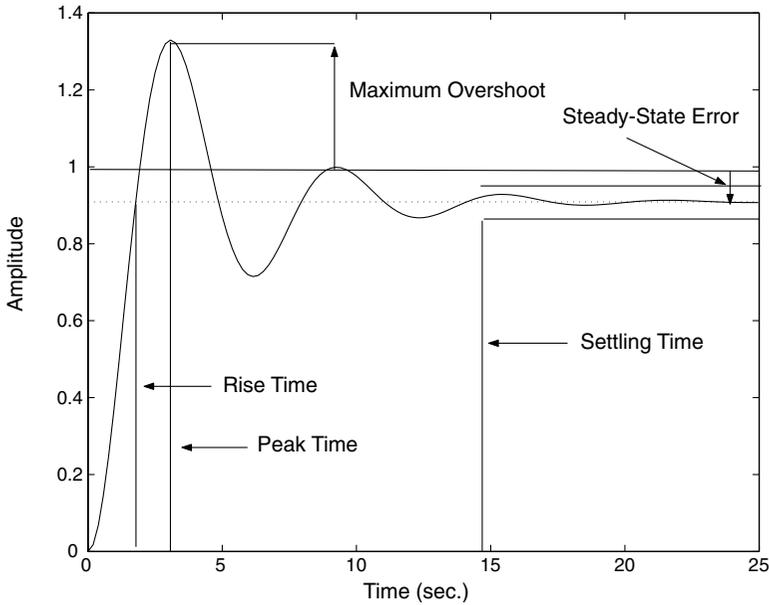

### Example

Returning to the robot arm example, assume that the desired system performance is to have the system rise time be less than 1.4 sec, the maximum overshoot less than 30%, and the 1% settling time less than 10 sec. From the first row in Table 12.2, the natural frequency must be greater than 1.29, and from the third and fourth rows the damping ratio should be greater than approximately 0.4. Figure 12.11 illustrates the root locus plot along with the pole locations and corresponding gain, and  $K(\text{rlocfind}())$  is the

**TABLE 12.2** Time-Domain Specifications as a Function of Natural Frequency, Damped Natural Frequency and Damping Ratio

Rise time:	$t_r \cong \frac{1.8}{\omega_n}$
Peak time:	$t_p \cong \frac{\pi}{\omega_d}$
Overshoot:	$M_p = e^{-\pi\zeta/\sqrt{1-\zeta^2}}$
Settling time (1%):	$t_s = \frac{4.6}{\zeta\omega_n}$

Note: Results are from Franklin et al., 1994.

**FIGURE 12.10** Time domain control specifications.

Matlab command for retrieving the gain value for a particular location on the root locus), which provide a damping ratio of approximately .45 and a natural frequency of approximately 1.38. Figure 12.12 illustrates the step response of the system to a unit step input verifying these system parameters.

### 12.2.2.3 Frequency Response Design Methods

An alternative approach to controller design and analysis is the so-called *frequency response methods*. Frequency response controller design techniques have two main advantages: They provide good controller design even with uncertainty with respect to high-frequency plant characteristics and using experimental data for controller design purposes is straightforward. The two main tools are *Bode* and *Nyquist plots* (see Bode [1945] and Nyquist [1932] for first-source references) and stability analyses are considered first.

A Bode plot is a plot of two curves. The first curve is the logarithm of the magnitude of the response of the *open-loop* transfer function with respect to unit sinusoidal inputs of frequency  $\omega$ . The second curve is the phase of the open-loop transfer function response as a function of input frequency  $\omega$ . The Bode plot for the transfer function:

$$G(s) = \frac{1}{s^3 + 25s^2 + s} \tag{12.24}$$

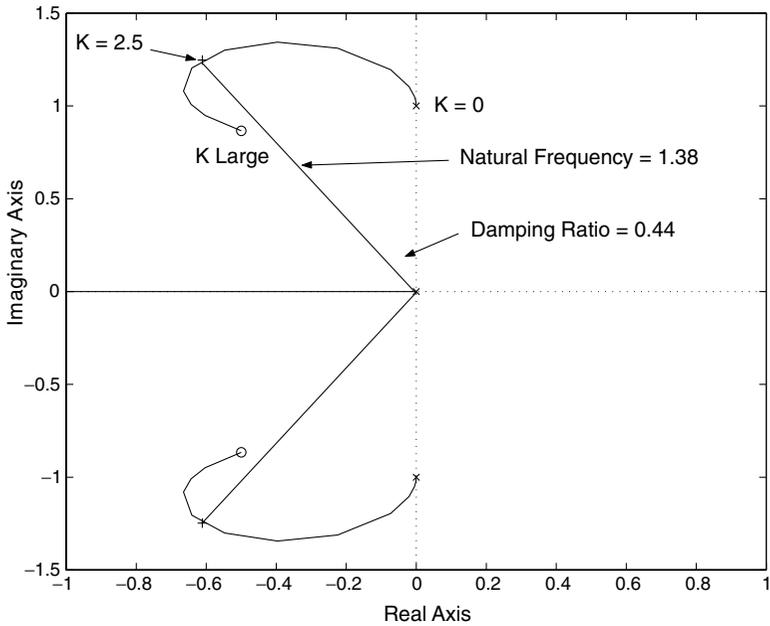

FIGURE 12.11 Selecting pole locations for a desired system response.

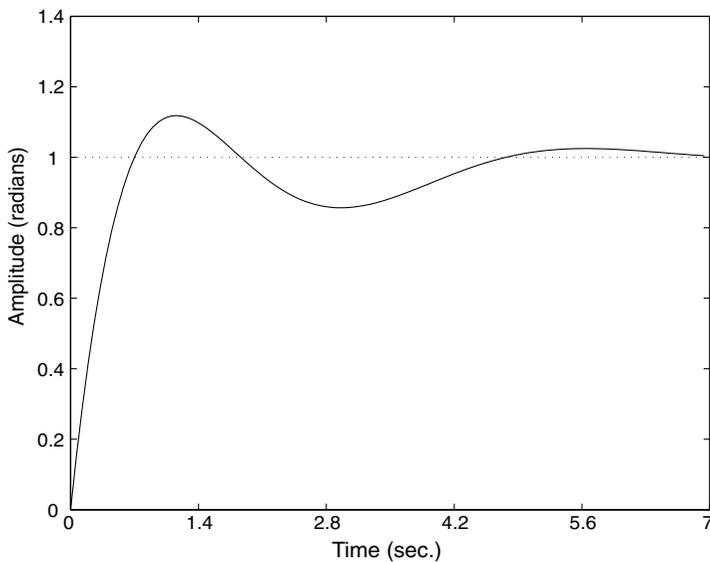

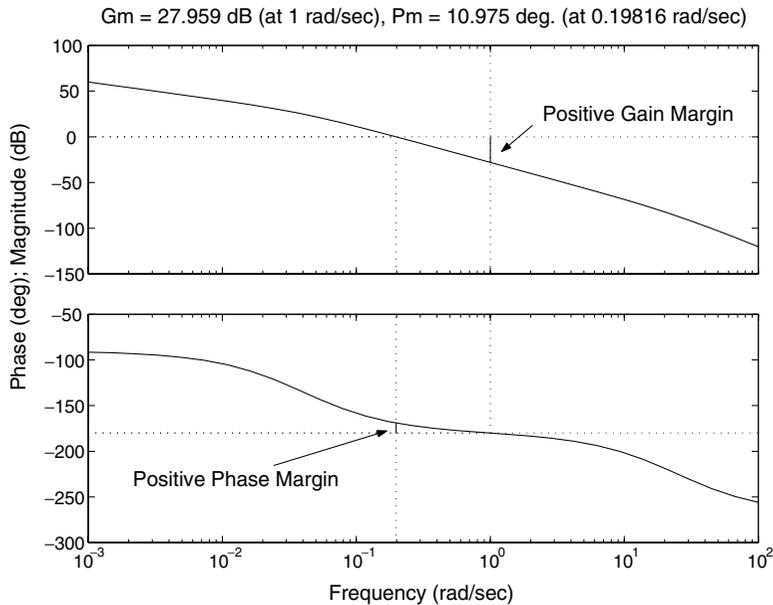

FIGURE 12.12 Robot arm step response.

is illustrated in Figure 12.13. Clearly, as the frequency of the sinusoidal input is increased, the magnitude of the system response decreases. Additionally, the phase difference between the sinusoidal input and system response starts near  $-90^\circ$  and approaches  $-270^\circ$  as the input frequency becomes large.

An advantage of Bode plots is that they are easy to sketch by hand. Because the magnitude of the system response is plotted on a logarithmic scale, the contributions to the magnitude of the response due to individual factors in the transfer function simply add together. Similarly, due to basic facts related to the polar representation of complex numbers, the phase contributions of each factor simply add as well.

**FIGURE 12.13** Bode plot.

Recipes for sketching Bode plots by hand can be found in any undergraduate controls text, such as Franklin et al. (1994), Raven (1995), Ogata (1997) and Kuo (1995).

For systems where the magnitude of the response passes through the value of 1 only one time and for systems where *increasing* the transfer function gain leads to instability (the most common, but not exclusive scenario), the *gain margin* and *phase margin* can be determined directly from the Bode plot to provide a measure of system stability under unity feedback. Figure 12.13 also illustrates the definition of gain and phase margin. Positive gain and phase margins indicate stability under unity feedback; conversely, negative gain and phase margins indicate instability under unity feedback. The class of systems for which Bode plots can be used to determine stability are called *minimum phase systems*. A system is minimum phase if all of its open-loop poles and zeros are in the left-half plane.

Bode plots also provide a means to determine the steady-state error under unity feedback for various types of reference inputs (steps, ramps etc.). In particular, if the low-frequency asymptote of the magnitude plot has a slope of zero and if the value of this asymptote is denoted by  $K$ , then the steady-state error of the system under unity feedback to a step input is

$$\lim_{t \rightarrow \infty} e = \frac{1}{1 + K} \quad (12.25)$$

If the slope of the magnitude plot at low frequencies is  $-20$  dB/decade and if the value where the asymptote intersects the vertical line  $\omega = 1$  is denoted by  $K$ , then the steady-state error to a ramp input is

$$\lim_{t \rightarrow \infty} e = \frac{1}{K} \quad (12.26)$$

### Example

Consider the system illustrated in Figure 12.2 where  $C(s) = A(s) = S(s) = 1$  and  $P(s) = \frac{1/2}{s+1}$ . The Bode plot for the open-loop transfer function  $P(s) = \frac{1/2}{s+1}$  is illustrated in Figure 12.14. The low-frequency asymptote is approximately at  $-6$ , so  $20 \log K = -6 \Rightarrow K \approx 0.5012 \Rightarrow y_{ss} \approx 0.6661$ , where  $y_{ss} = \lim_{t \rightarrow \infty} p(t)$ . Figure 12.15 illustrates the unity feedback closed-loop step response of the system, verifying that the steady-state value for  $y(t)$  is as computed from the Bode plot.

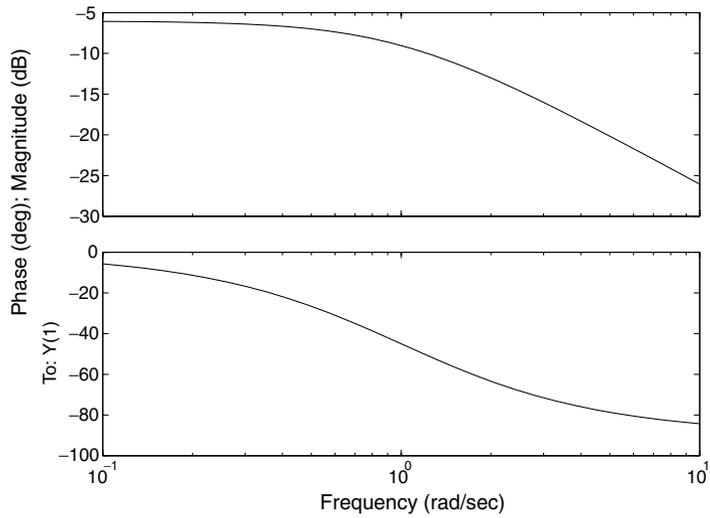

FIGURE 12.14 Bode plot for example problem.

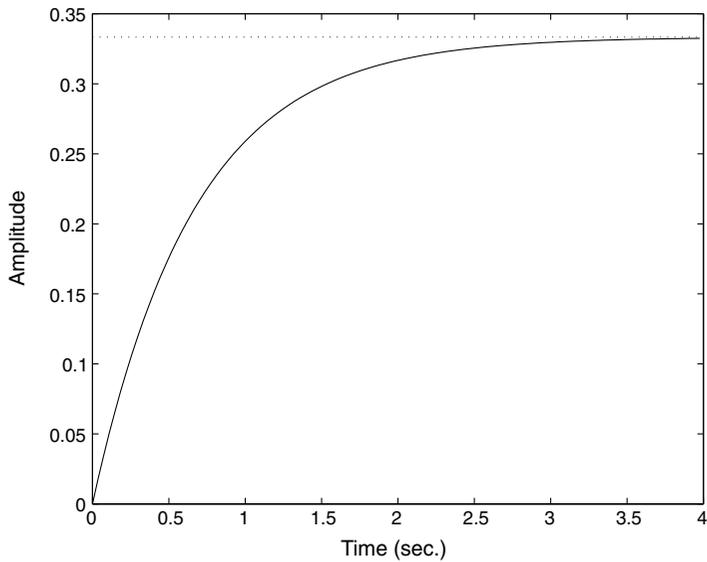

FIGURE 12.15 Step response for example problem.

A Nyquist plot is a more sophisticated means to determine stability and is not limited to cases where only increasing gain leads to system instability. It is based on the well-known result from complex variable theory called the *principle of the argument*. Consider the (factored) transfer function:

$$G(s) = \frac{\prod_i (s + z_i)}{\prod_j (s + p_j)} \quad (12.27)$$

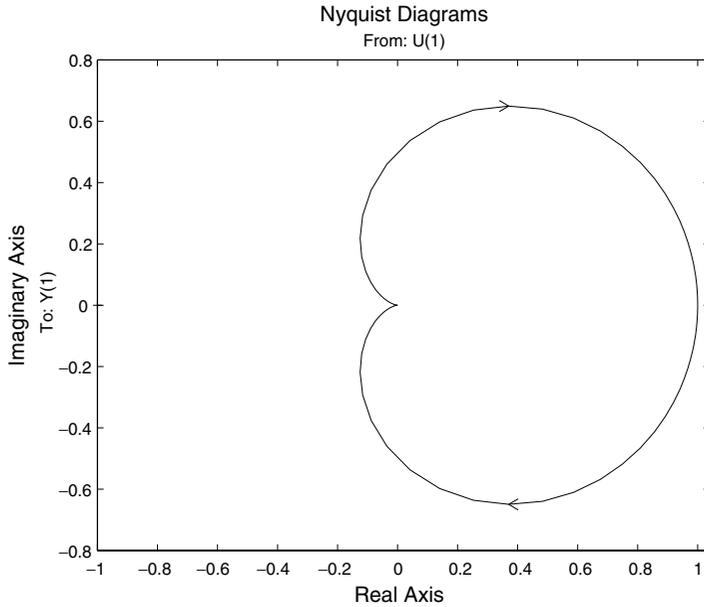

FIGURE 12.16 Nyquist plot for a stable system.

By basic complex variable theory,  $\angle G(s) = \sum_i \theta_i - \sum_j \phi_j$ , where  $\theta_i$  are the angles between  $s$  and the zeros  $z_i$ , and the  $\phi_j$  are the angles between  $s$  and the poles  $p_j$ . Thus, a plot of  $G(s)$  as  $s$  follows a closed contour (in the clockwise direction) in the complex plane will encircle the origin in the clockwise direction the same number of times that there are zeros of  $G(s)$  within the contour minus the number of times that there are poles of  $G(s)$  within the contour. Thus, an easy check for stability is to plot the *open loop*  $G(s)$  on a contour that encircles the entire left-half complex plane. Assuming that  $G(s)$  has no right-half plane poles (poles of  $G(s)$  *itself*, in contrast to poles of the closed-loop transfer function), an encirclement of  $-1$  by the plot will indicate a right-half plane zero of  $1 + G(s)$ , which is an unstable right-half plane pole of the unity feedback closed-loop transfer function:

$$\frac{G(s)}{1 + G(s)} \tag{12.28}$$

The Nyquist plot for a unity feedback system with open-loop transfer function given by:

$$G(s) = \frac{1}{(s + 1)(s + 1)} \tag{12.29}$$

which is stable under unity feedback is illustrated in [Figure 12.16](#), and a Nyquist plot for a system that is unstable under unity feedback is illustrated in [Figure 12.17](#).

#### 12.2.2.4 Lead-Lag Compensation

Lead-lag controller design is another extremely popular compensation technique. In this case, the compensator (the  $C(s)$  block in [Figure 12.2](#)) is of the form:

$$C(s) = K\beta \frac{As + 1}{\alpha As + 1} \frac{Bs + 1}{\beta Bs + 1} \tag{12.30}$$

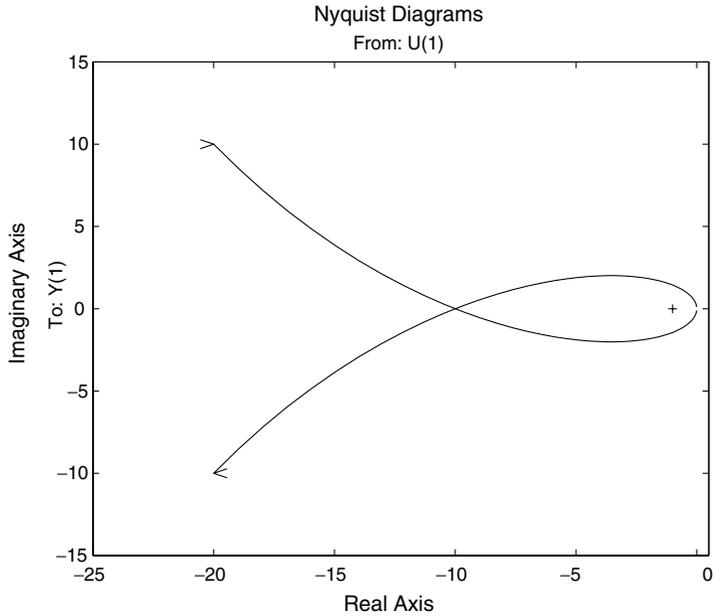

FIGURE 12.17 Nyquist plot of an unstable system.

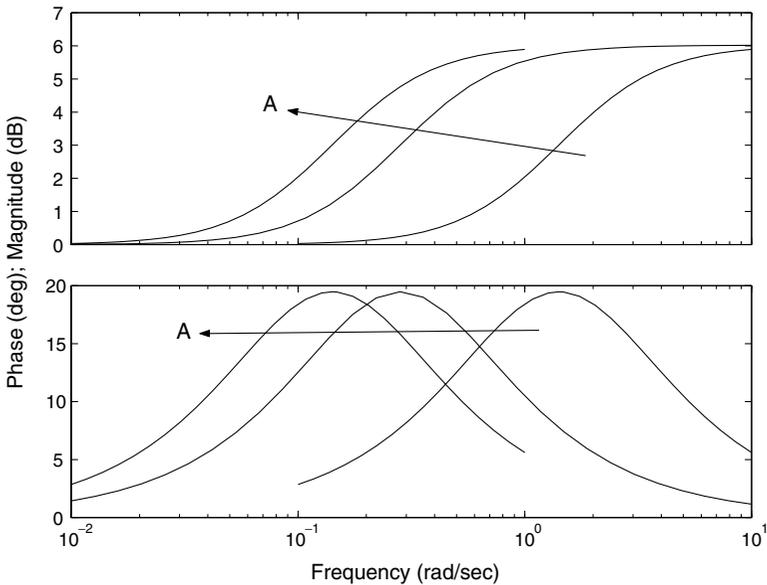

FIGURE 12.18 Bode plots of various lead compensators.

where  $\alpha < 1$  and  $\beta > 1$ . The first fraction is the lead portion of the compensator and can provide increased stability with an appropriate choice for  $A$ . The second term is the lag compensator and provides decreased steady-state error. To understand the first of these assertions, Figure 12.18 plots the Bode plot for a lead compensator for various values of the parameter  $A$ . Because the lead compensator shifts the phase plot up, by an appropriate choice of the parameter  $A$ , the crossover point where the magnitude plot crosses through the value of 0 dB can be shifted to the right, increasing the gain margin.

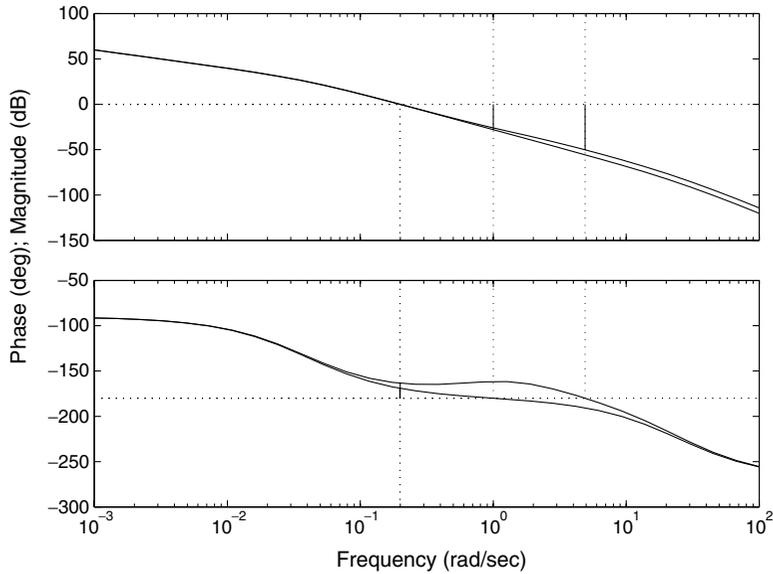

FIGURE 12.19 Lead compensated example system.

### Example

Figure 12.19 plots the bode plot for the compensated system:

$$G(s) = \frac{As + 1}{\alpha As + 1} \frac{1}{s^3 + 25s^2 + s} \quad (12.31)$$

where  $A = 0, 1$  and  $\alpha = 0.5$ . As can be seen, the magnitude crossover point has been shifted to the left, increasing the gain margin. In a similar manner, unstable systems (which would originally have negative gain and phase margins) can possibly be stabilized.

Lag compensation works in a very similar manner to increase the magnitude plot for low frequencies, which decreases the steady-state error for the system. Lead and lag controllers can be used in series to both increase stability as well as decrease steady-state error. Systematic approaches for determining the parameters,  $\alpha$ ,  $\beta$ ,  $A$  and  $B$  can be found in the references, particularly Franklin et al. (1994).

### 12.2.3 Other Topics

Various other topics are typically considered in classical control but will not be outlined here due to space limitations. Such topics include, but are not limited to, systematic methods for tuning PID regulators, lead-lag compensation and techniques for considering and modeling time delay. Interested readers should consult the references, particularly Franklin et al. (1994), Ogata (1997), Kuo (1995) and Raven (1995).

## 12.3 “Modern” Control

In contrast to classical control, which is essentially a complex-variable, frequency-based approach for SISO systems, modern control is a time-domain approach that is amenable to MIMO systems. The basic tools are from the theory of ordinary differential equations and matrix algebra. The topics outlined in this section are the *pole placement* and *linear quadratic regulator* (LQR) problems. Additionally, the basics of robust control are outlined.

### 12.3.1 Pole Placement

First, a multistate but single-input control system will be examined. Consider a control system written in state space:

$$\dot{\mathbf{x}} = \mathbf{A}\mathbf{x} + \mathbf{B}u \quad (12.32)$$

where  $\mathbf{x}$  is the  $1 \times n$  state vector,  $u$  is the scalar input,  $\mathbf{A}$  is an  $n \times n$  constant matrix and  $\mathbf{B}$  is an  $n \times 1$  constant matrix. If we assume that the control input  $u$  can be expressed as a combination of the current state variables (called full state feedback), we can write:

$$u = -k_1x_1 - k_2x_2 - \dots - k_nx_n = -\mathbf{K}\mathbf{x} \quad (12.33)$$

where  $\mathbf{K}$  is a row vector comprised of each of the gains  $k_i$ . Then, the state-space description of the system becomes:

$$\dot{\mathbf{x}} = (\mathbf{A} - \mathbf{B}\mathbf{K})\mathbf{x} \quad (12.34)$$

so that the solution of this equation is

$$\mathbf{x}(t) = e^{(\mathbf{A} - \mathbf{B}\mathbf{K})t}\mathbf{x}(0) \quad (12.35)$$

where  $e^{(\mathbf{A} - \mathbf{B}\mathbf{K})t}$  is the *matrix exponential* of the matrix  $\mathbf{A} - \mathbf{B}\mathbf{K}$  defined by:

$$e^{(\mathbf{A} - \mathbf{B}\mathbf{K})t} = \mathbf{I} + (\mathbf{A} - \mathbf{B}\mathbf{K})t + \frac{(\mathbf{A} - \mathbf{B}\mathbf{K})^2t^2}{2!} + \frac{(\mathbf{A} - \mathbf{B}\mathbf{K})^3t^3}{3!} + \dots \quad (12.36)$$

Basic theory from linear algebra and ordinary differential equations [Hirsch and Smale, 1974] indicates that the stability and characteristics of the transient response will be determined by the eigenvalues of the matrix  $\mathbf{A} - \mathbf{B}\mathbf{K}$ . In fact, if

$$\text{rank}[\mathbf{B}|\mathbf{A}\mathbf{B}|\mathbf{A}^2\mathbf{B}|\mathbf{A}^3\mathbf{B}|\dots|\mathbf{A}^{n-1}\mathbf{B}] = n \quad (12.37)$$

then it can be shown that the eigenvalues of  $\mathbf{A} - \mathbf{B}\mathbf{K}$  can be placed arbitrarily as a function of the elements of  $\mathbf{K}$ . Techniques to solve the problem by hand by way of a similarity transformation exist (see the standard undergraduate controls books), and Matlab has functions for the computations as well.

#### Example—Pole Placement for Inverted Pendulum System

Consider the cart/pendulum system illustrated in [Figure 12.20](#). In state-space form, the equations of motion are

$$\frac{d}{dt} \begin{bmatrix} x \\ \dot{x} \\ \theta \\ \dot{\theta} \end{bmatrix} = \begin{bmatrix} 0 & 1 & 0 & 0 \\ 0 & 0 & \frac{-gm}{M} & 0 \\ 0 & 0 & 0 & 1 \\ 0 & 0 & \frac{-(m+M)g}{lM} & 0 \end{bmatrix} \begin{bmatrix} x \\ \dot{x} \\ \theta \\ \dot{\theta} \end{bmatrix} + \begin{bmatrix} 0 \\ \frac{1}{M} \\ 0 \\ \frac{-1}{lM} \end{bmatrix} u \quad (12.38)$$

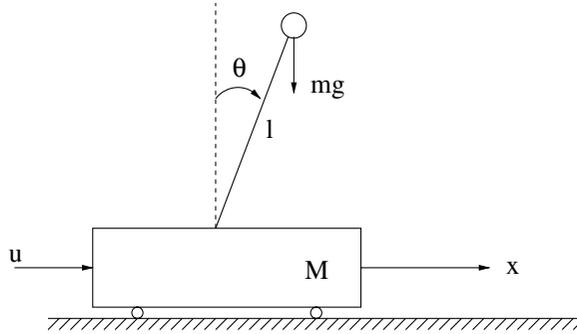

FIGURE 12.20 Cart and pendulum system.

Setting  $M = 10$ ,  $m = 1$ ,  $g = 9.81$  and  $l = 1$  and letting  $u = -k_1x + k_2\dot{x} + k_3\theta + k_4\dot{\theta}$  if the desired pole locations for the system are at

$$\begin{aligned}\lambda_1 &= -1 - i \\ \lambda_2 &= -1 + i \\ \lambda_3 &= -8 \\ \lambda_4 &= -9\end{aligned}\tag{12.39}$$

the Matlab function `place()` can be used to compute the values for the corresponding  $k_i$ . For this problem, the gain values are

$$\begin{aligned}k_1 &= 122.32 \\ k_2 &= 151.21 \\ k_3 &= -849.77 \\ k_4 &= -38.79\end{aligned}\tag{12.40}$$

With initial conditions  $x(0) = 0.25$ ,  $\dot{x}(0) = 0$ ,  $\theta(0) = 0.25$  and  $\dot{\theta}(0) = 0$ , the response of the system is illustrated in Figure 12.21. Note that the cart position,  $x$ , initially moves in the “wrong” direction in order to compensate for the pendulum position.

### 12.3.2 The Linear Quadratic Regulator

The LQR problem is not limited to scalar input problems and seeks to find a control input,

$$\mathbf{u} = -\mathbf{K}\mathbf{x}(t)\tag{12.41}$$

for the system:

$$\dot{\mathbf{x}} = \mathbf{A}\mathbf{x} + \mathbf{B}\mathbf{u}\tag{12.42}$$

that minimizes the *performance index*:

$$J = \int_0^{\infty} (\mathbf{x}^T \mathbf{Q} \mathbf{x} + \mathbf{u}^T \mathbf{R} \mathbf{u}) dt\tag{12.43}$$

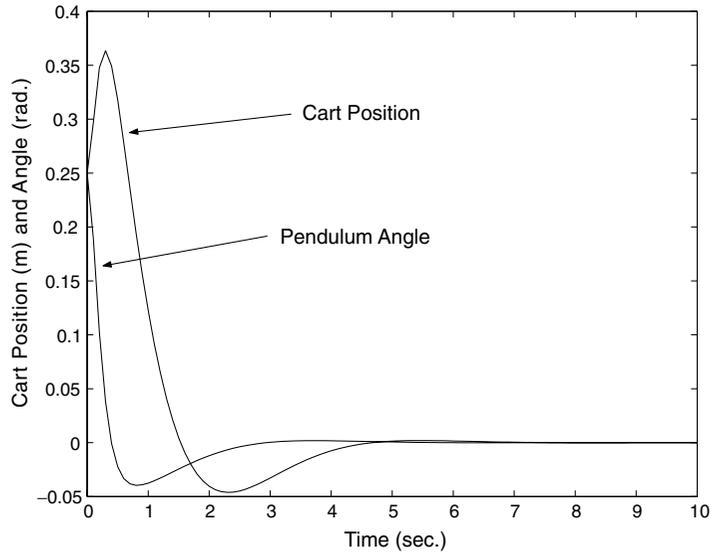

FIGURE 12.21 Cart and pendulum system pole placement response.

where  $\mathbf{Q}$  and  $\mathbf{R}$  are positive definite, real symmetric matrices. By the second method of Lyapunov [Khalil, 1996; Sastry, 2000], the control input that minimizes the performance index is

$$u = -\mathbf{R}^{-1} \mathbf{B}^T \mathbf{P} \mathbf{x}(t) \quad (12.44)$$

where  $\mathbf{R}$  and  $\mathbf{B}$  are from the performance index and equations of motion, respectively, and  $\mathbf{P}$  satisfies the *reduced matrix Riccati equation*:

$$\mathbf{A}^T \mathbf{P} + \mathbf{P} \mathbf{A} - \mathbf{P} \mathbf{B} \mathbf{R}^{-1} \mathbf{B}^T \mathbf{P} + \mathbf{Q} = \mathbf{0} \quad (12.45)$$

### Example—LQR for Inverted Pendulum System

For the same cart and pole system as in the previous example with

$$\mathbf{Q} = \begin{bmatrix} 1 & 0 & 0 & 0 \\ 0 & 1 & 0 & 0 \\ 0 & 0 & 1 & 0 \\ 0 & 0 & 0 & 1 \end{bmatrix} \quad (12.46)$$

(which weights all the states equally), and  $R = 0.001$ , the optimal gains (computed via the Matlab `lqr()` function) are

$$\begin{aligned} k_1 &= 31.62 \\ k_2 &= 145.75 \\ k_3 &= -95.53 \\ k_4 &= -21.65 \end{aligned} \quad (12.47)$$

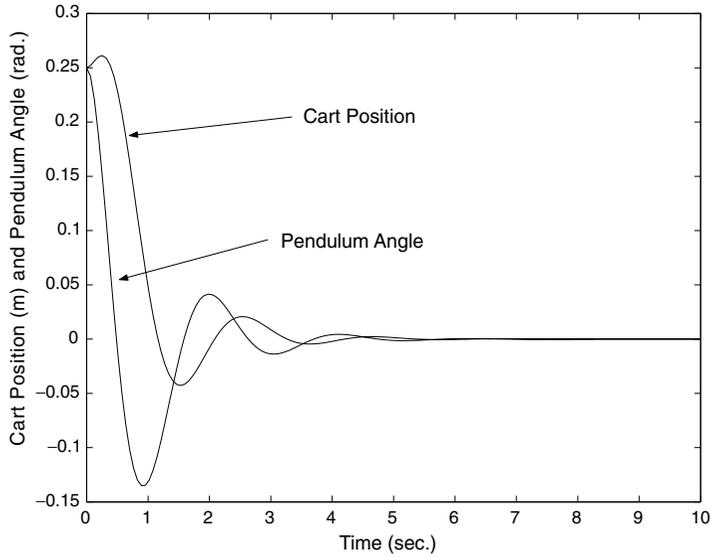

FIGURE 12.22 Cart and pendulum LQR response.

and the response of the system with initial conditions  $x(0) = 0.25$ ,  $\dot{x}(0) = 0$ ,  $\theta(0) = 0.25$  and  $\dot{\theta}(0) = 0$  is illustrated in Figure 12.22. If the  $Q$  matrix is modified to provide a heavy weighting for the  $\theta$  state,

$$Q = \begin{bmatrix} 1 & 0 & 0 & 0 \\ 0 & 1 & 0 & 0 \\ 0 & 0 & 100 & 0 \\ 0 & 0 & 0 & 1 \end{bmatrix} \quad (12.48)$$

the system response is illustrated in Figure 12.23. Note that the pendulum angle goes to zero very rapidly, but at the “expense” of a slower response and greater deviation for the cart position.

### 12.3.3 Basic Robust Control

The main idea motivating modern robust control techniques is to incorporate explicitly plant uncertainty representations into system modeling and control synthesis methods. The basic material here outlines the presentation in Doyle et al. (1992), and the more advanced material is from Zhou (1996). Modern robust control is a very involved subject and only the briefest outline can be provided here.

Consider the unity feedback SISO system illustrated in Figure 12.24, where  $P$  and  $C$  are the plant and controller transfer functions;  $R(s)$  is the reference signal;  $Y(s)$  is the output;  $D(s)$  and  $N(s)$  are external disturbances and sensor noise, respectively;  $E(s)$  is the error signal; and  $U(s)$  is the control input.

Now, define the *loop transfer function*,  $L = CP$ , and the *sensitivity function*:

$$S = \frac{1}{1 + L} \quad (12.49)$$

which is the transfer function from the reference input  $R(s)$  to the error  $E(s)$  which provides a measure of the sensitivity of the closed loop (or *complementary sensitivity*) transfer function:

$$T = \frac{PC}{1 + PC} \quad (12.50)$$

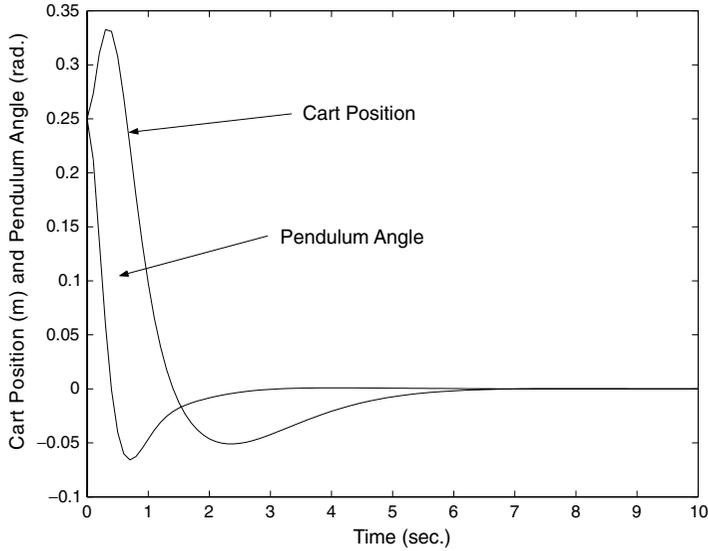

FIGURE 12.23 Cart and pendulum LQR response with large pendulum angle weighting.

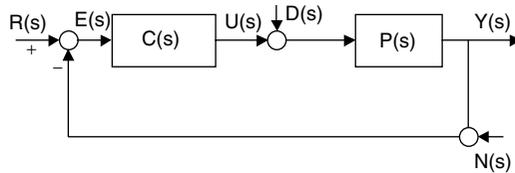

FIGURE 12.24 Robust control feedback block diagram.

to infinitesimal variations in the plant  $P$ . Now, given a (frequency-dependent) weighting function  $W_1(s)$ , a natural *performance specification* (relating tracking error to classes of reference signals) is

$$\|W_1 S\|_\infty < 1 \tag{12.51}$$

where  $\|\cdot\|_\infty$  denotes the infinity norm. An easy graphical test for the performance specification is that the Nyquist plot of  $L$  must always lie outside a disk of radius  $|W_1|$  centered at  $-1$ .

To incorporate plant uncertainty into the model, consider a nominal plant  $P$  and perturbed plant  $\tilde{P}$  where  $P$  and  $\tilde{P}$  differ by some multiplicative or other type of uncertainty. Let  $W_2$  be a stable transfer function and  $\Delta$  be a variable stable transfer function satisfying  $\|\Delta\|_\infty \leq 1$ . Then, common uncertainty models can be constructed by appropriate combinations of  $P$ ,  $\Delta$  and  $W$ . It can be shown that the system is *internally stable* (this is a stronger definition than simple I/O stability; see Doyle [1992]) for the conditions shown in Table 12.3.

Recall that the nominal performance condition was  $\|W_1 S\|_\infty < 1$ . Not surprising, then, the *robust performance* condition is a combination of the two (for the  $(1 + \Delta W_2)P$  perturbation):

$$\| |W_1 S| + |W_2 T| \|_\infty < 1 \tag{12.52}$$

Other robust performance measures for various types of uncertainty can be found in Doyle et al. (1992) and Zhou (1996).

Recall that  $W_1$  is the performance specification weighting function and  $W_2$  is the plant uncertainty transfer function. Consider the following facts:

**TABLE 12.3** Internal Stability Conditions

Perturbation	Condition
$(1 + \Delta W_2)P$	$\ W_2 T\ _\infty < 1$
$P + \Delta W_2$	$\ W_2 CS\ _\infty < 1$
$\frac{P}{1 + \Delta W_2 P}$	$\ W_2 PS\ _\infty < 1$
$\frac{P}{1 + \Delta W_2}$	$\ W_2 S\ _\infty < 1$

1. Plant uncertainty is greatest for high frequencies.
2. It is only reasonable to demand high performance for low frequencies.

Typically, then,

$$|W_1| > 1 > |W_2| \quad (12.53)$$

for low frequencies, and

$$|W_1| < 1 < |W_2| \quad (12.54)$$

for high frequencies (it can be shown that the magnitude of either  $W_1$  or  $W_2$  must be less than 1). Now, by considering the relationship between  $L$ ,  $S$  and  $T$ , the following can be derived:

$$|W_1| \gg 1 > |W_2| \Rightarrow |L| > \frac{|W_1|}{1 - |W_2|} \quad (12.55)$$

and

$$|W_1| < 1 \ll |W_2| \Rightarrow |L| < \frac{1 - |W_1|}{|W_2|} \quad (12.56)$$

*Loopshaping* [Bower and Schultheiss, 1961; Horowitz, 1963] controller design is the task of determining an  $L$  (and hence  $C$ ) that satisfies the low-frequency performance criterion as well as the high-frequency robustness criterion. Hence, the task is to design  $C$  so that the magnitude versus frequency plot of  $L$  appears as in [Figure 12.25](#). In the figure, the indicated low-frequency performance bound is a plot of:

$$\frac{|W_1|}{1 - |W_2|} \quad (12.57)$$

for low frequencies, and the high-frequency stability bound is a plot of:

$$\frac{1 - |W_1|}{|W_2|} \quad (12.58)$$

for high frequencies.

Two more aspects of this problem have been developed in recent years. The first concerns optimality and the second concerns multivariable systems. For both aspects of these recent developments, interested readers are referred to the comprehensive book by Zhou (1996).

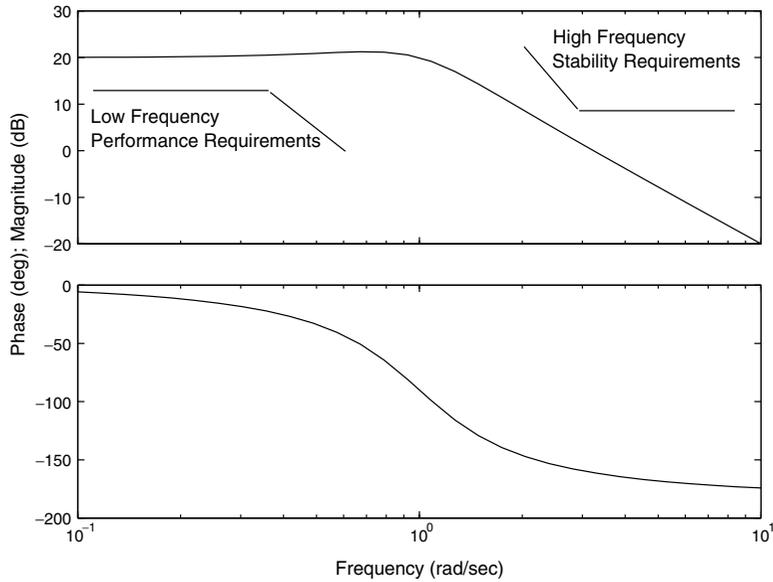

FIGURE 12.25 Loopshaping concepts.

## 12.4 Nonlinear Control

Aside from the developments of robust optimal control briefly outlined in the previous section, the area of most recent development in control theory has been nonlinear control, where, in contrast to ignoring nonlinear effects via linearization, the nonlinearities in the control system are either expressly recognized or are even exploited for control purposes. Much, but not all, development in nonlinear control has utilized tools from differential geometry. While the control techniques will be outlined here, the basics of differential geometry will not, and the interested reader is referred to Abraham et al. (1988), Boothby (1986), Isidori (1996) and Nijmeijer and van der Schaft (1990) for details.

The general nonlinear model considered here is of the form:

$$\dot{\mathbf{x}} = \mathbf{f}(\mathbf{x}) + \sum_{i=1}^n \mathbf{g}_i(\mathbf{x}) u_i \quad (12.59)$$

where  $\mathbf{x}$  is a  $1 \times n$  vector, the  $\mathbf{f}(\mathbf{x})$  and  $\mathbf{g}_i(\mathbf{x})$  are smooth vector fields, and the  $u_i$  are scalar control inputs. Note that this is not the most general form for nonlinear systems, as the  $u_i$  are assumed to enter the equations in an affine manner (i.e., they simply multiply the  $\mathbf{g}_i(\mathbf{x})$  vector fields). For some aerodynamic problems, for example, this assumption may not be true.

### 12.4.1 SISO Feedback Linearization

In contrast to the standard Jacobian linearization of a nonlinear control system, feedback linearization is a technique to construct a nonlinear change of coordinates which converts a nonlinear system in the original coordinates to a linear system in the new coordinates. Thus, whereas the Jacobian linearization is an approximation of the original system, a feedback linearized system is still exactly the original system. For clarity of presentation, SISO systems will be considered first, followed by MIMO systems. Excellent references for feedback linearization are Isidori (1996), Nijmeijer and van der Schaft (1990), Krener (1987), Khalil (1996) and Sastry (2000). Developmental papers or current research in this area are considered

in Slotine and Hedrick (1993), Brockett (1978), Dayawansa et al. (1985), Isidori et al. (1981a; 1981b) and Krener (1987).

Consider the nonlinear system:

$$\begin{aligned}\dot{\mathbf{x}} &= \mathbf{f}(\mathbf{x}) + \mathbf{g}(\mathbf{x})u \\ y &= h(\mathbf{x})\end{aligned}\tag{12.60}$$

where the function  $h(\mathbf{x})$  is called the *output function*. Let  $L_{\mathbf{f}}h$  denote the *Lie derivative* of the function  $h$  with respect to the vector field  $\mathbf{f}$ , which is defined in coordinates as:

$$L_{\mathbf{f}}h(\mathbf{x}) = \sum_{i=1}^n \frac{\partial h}{\partial x_i}(\mathbf{x})f_i(\mathbf{x})\tag{12.61}$$

where

$$\mathbf{x} = \begin{bmatrix} x_1 \\ x_2 \\ \vdots \\ x_{n-1} \\ x_n \end{bmatrix} \quad \text{and} \quad \mathbf{f} = \begin{bmatrix} f_1(\mathbf{x}) \\ f_2(\mathbf{x}) \\ \vdots \\ f_{n-1}(\mathbf{x}) \\ f_n(\mathbf{x}) \end{bmatrix}\tag{12.62}$$

so it is simply the directional derivative of  $h$  along  $\mathbf{f}$ . Now, because the system evolves according to the state equations, the time derivative of the output function  $\dot{y}$  is simply the directional derivative of the output function along the control system:

$$\dot{y} = \dot{h} = \frac{\partial h}{\partial \mathbf{x}}\dot{\mathbf{x}} = \frac{\partial h}{\partial \mathbf{x}}(\mathbf{f}(\mathbf{x}) + \mathbf{g}(\mathbf{x})u) = L_{\mathbf{f}+\mathbf{g}u}h = L_{\mathbf{f}}h + L_{\mathbf{g}}hu\tag{12.63}$$

The *relative degree* of a system is defined as follows: A SISO nonlinear system is said to have *strict relative degree*  $\gamma$  at the point  $x$  if:

$$1. \quad L_{\mathbf{g}}L_{\mathbf{f}}^i h(x) \equiv 0 \quad i = 0, 1, 2, \dots, \gamma - 2\tag{12.64}$$

$$2. \quad L_{\mathbf{g}}L_{\mathbf{f}}^{\gamma-1} h(x) \neq 0\tag{12.65}$$

In the case where  $\gamma = n$ , the system is *full state feedback linearizable*, and it is possible to construct the following change of coordinates where the original coordinates  $x_i$  are mapped to a new set of coordinates  $\xi_i$  as follows:

$$\begin{aligned}\xi_1 &= h(x) \\ \xi_2 &= \dot{\xi}_1 = \dot{h} = L_{\mathbf{f}}h \\ \xi_3 &= \dot{\xi}_2 = \ddot{h} = L_{\mathbf{f}}^2 h \\ &\vdots \\ \xi_n &= \dot{\xi}_{n-1} = L_{\mathbf{f}}^{\gamma-1} h\end{aligned}\tag{12.66}$$

Computing derivatives, the control system becomes:

$$\begin{aligned}
 \dot{\xi}_1 &= \xi_2 \\
 \dot{\xi}_2 &= \xi_3 \\
 &\vdots \\
 \dot{\xi}_{n-1} &= \xi_n \\
 \dot{\xi}_n &= L_f^\gamma h + L_g L_f^{\gamma-1} h u
 \end{aligned} \tag{12.67}$$

or, setting

$$u = \frac{1}{L_g L_f^{\gamma-1} h} (-L_f^\gamma h + v) \tag{12.68}$$

the system is

$$\begin{aligned}
 \dot{\xi}_1 &= \xi_2 \\
 \dot{\xi}_2 &= \xi_3 \\
 &\vdots \\
 \dot{\xi}_{n-1} &= \xi_n \\
 \dot{\xi}_n &= v
 \end{aligned} \tag{12.69}$$

which is both linear and in controllable canonical form. At this point, it is simple to determine an appropriate  $v$  to stabilize the system or track desired values of  $h(x)$ . One approach is pole placement; that is,  $v = -\mathbf{K}\xi$ . Note that the overall approach was to determine an output function  $h$  that could be differentiated  $n$  times before the control input appeared. This essentially constructs a system known as a *chain of integrators*, as the derivative of the  $i$ th state in the  $\xi$  variables is equal to the  $(i + 1)$ th state variable.

There are two main limitations to feedback linearization approaches. The first is that not all systems are feedback linearizable, although analytical tests exist to determine whether a particular system is linearizable. Second, determining the output function,  $h(x)$  involves solving a system of partial differential equations (generally, not easy to do).

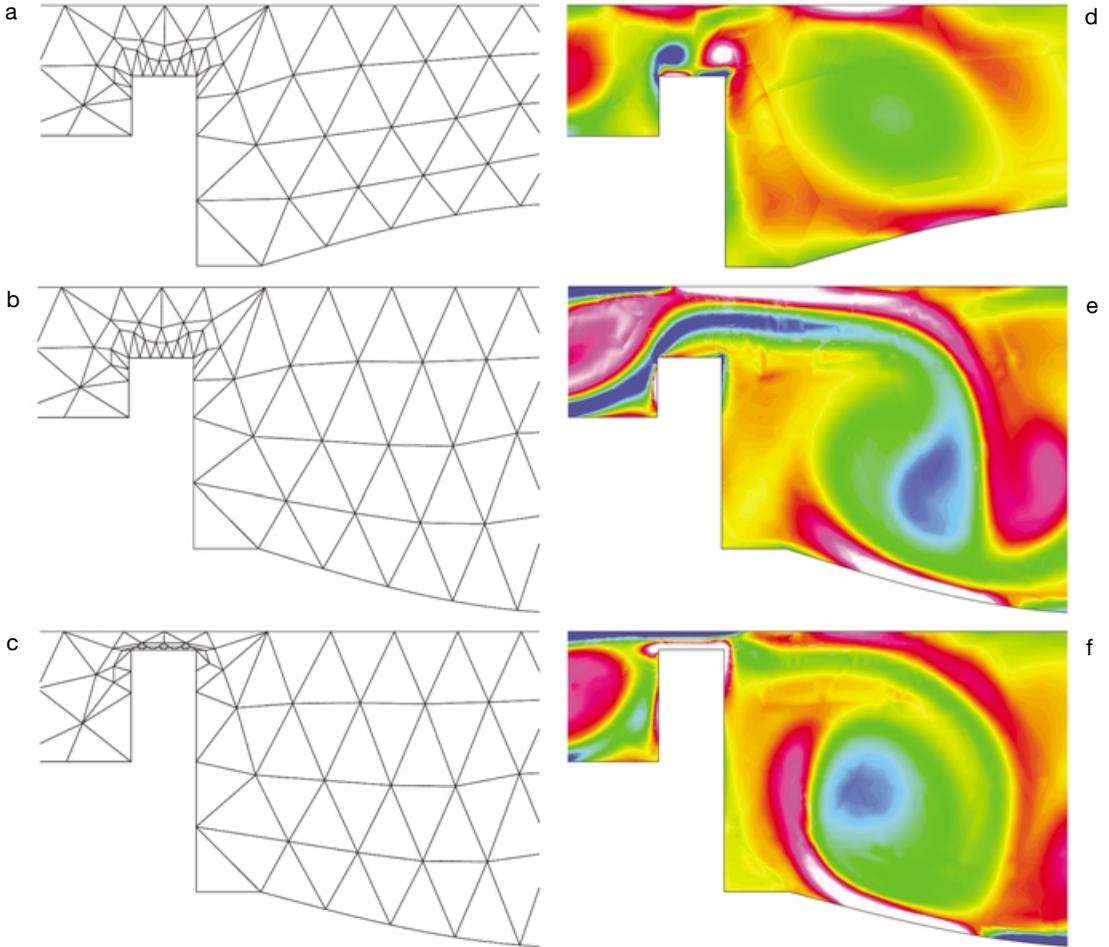

### Example—SISO Full State Feedback Linearization

Consider, as a mathematical example of the computations involved in feedback linearization, the system:

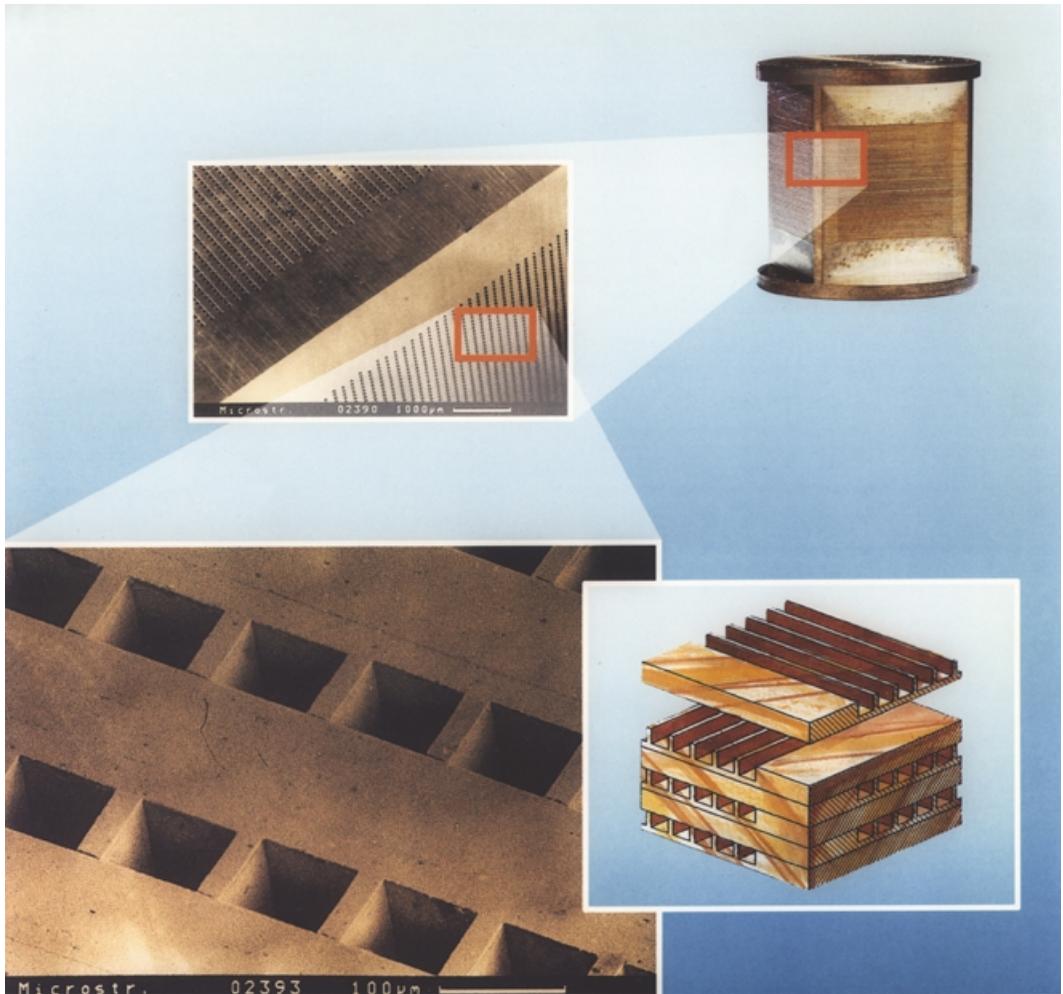

$$\begin{bmatrix} \dot{x}_1 \\ \dot{x}_2 \\ \dot{x}_3 \\ \dot{x}_4 \end{bmatrix} = \begin{bmatrix} x_3 \\ x_4 \\ x_1 + x_2 + x_3 \\ x_1 - x_3 \end{bmatrix} + \begin{bmatrix} 0 \\ 0 \\ 0 \\ 1 \end{bmatrix} u = f(x) + g(x)u \tag{12.70}$$

with output function,  $y = h(x) = x_1$ . The system has a relative degree equal to 4, so the system is full state feedback linearizable and the coordinate transformation is given by:

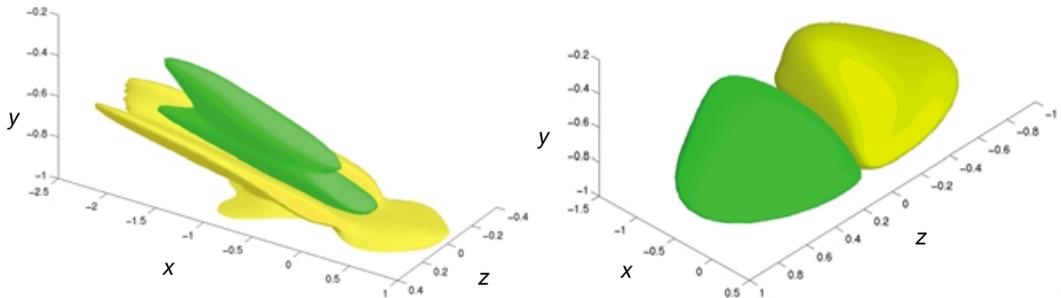

$$\begin{aligned}
 \xi_1 &= h(x) = x_1 \\
 \xi_2 &= L_f h(x) = x_3 \\
 \xi_3 &= L_f^2 h(x) = x_1 + x_2 + x_3 \\
 \xi_4 &= L_f^3 h(x) = x_1 + x_2 + 2x_3 + x_4
 \end{aligned} \tag{12.71}$$

**COLOR FIGURE 13.11** Visualization of the coherent structures of uncontrolled near-wall turbulence at  $Re_\tau = 180$ . Despite the geometric simplicity of this flow (see [Figure 13.1](#)), it is phenomenologically rich and is characterized by a large range of length scales and time scales over which energy transport and scalar mixing occur. The relevant spectra characterizing these complex nonlinear phenomena are continuous over this large range of scales, thus such flows have largely eluded accurate description via dynamic models of low state dimension. The nonlinearity, the distributed nature and the inherent complexity of their dynamics make turbulent flow systems particularly challenging for successful application of control theory. (Simulation by Bewley et al. (2001). Reprinted with permission of Cambridge University Press.)

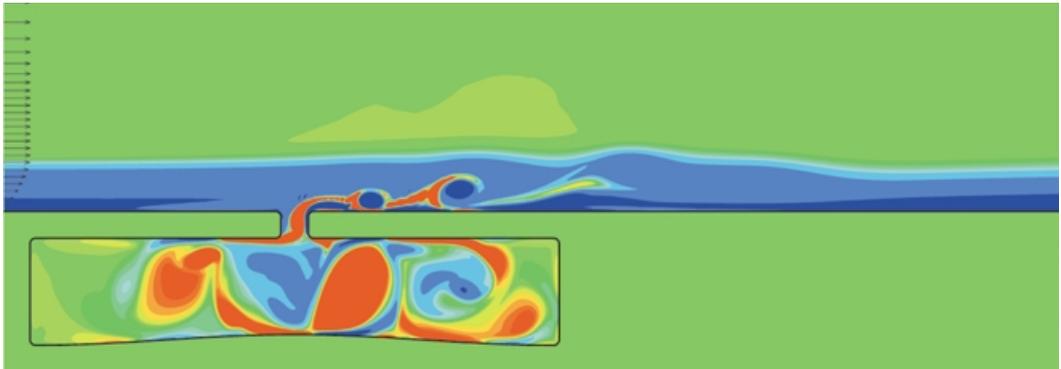

**COLOR FIGURE 13.12** Example of the spectacular failure of linear control theory to stabilize a simple nonlinear chaotic convection system governed by the Lorenz equation. Plotted are the regions of attraction to the desired stationary point (blue) and to an undesired stationary point (red) in the linearly controlled nonlinear system, and typical trajectories in each region (black and green, respectively). The cubical domain illustrated is  $\Omega = (-25, 25)^3$  in all subfigures; for clarity, different viewpoints are used in each subfigure. (Reprinted from Bewley, T.R. (1999) *Phys. Fluids* **11**, 1169–1186. Copyright 1999, American Institute of Physics. With permission.)

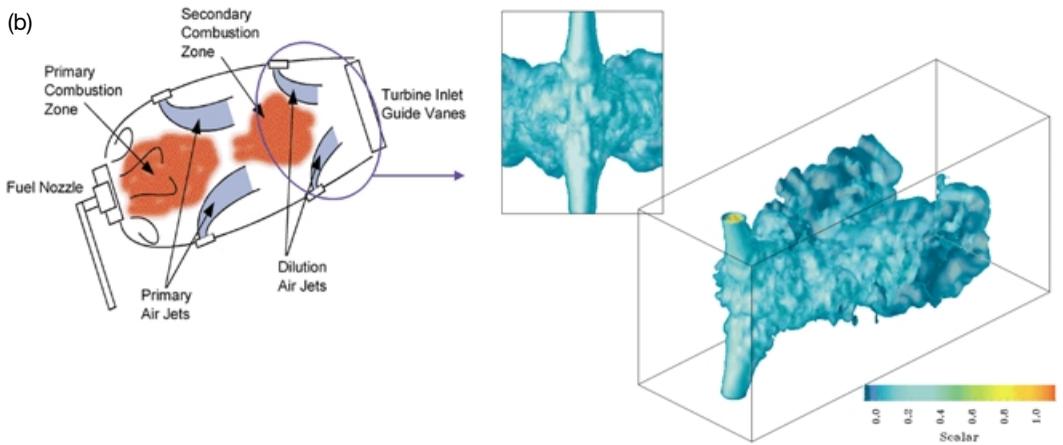

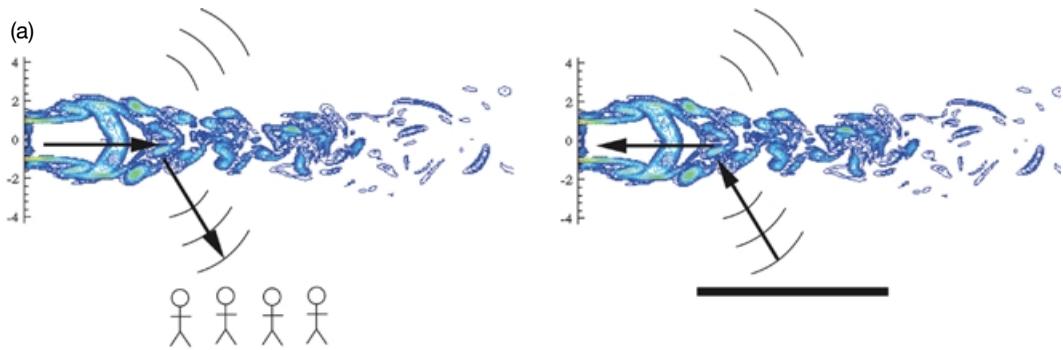

**COLOR FIGURE 13.14** Performance of optimized blowing/suction controls for formulations based on minimizing  $T_0(\phi)$ , case *c* (see Section 13.9.1.2), as a function of the optimization horizon  $T^*$ . The direct numerical simulations of turbulent channel flow reported here were conducted at  $Re_\tau = 100$ . For small optimization horizons ( $T^* = O(1)$ , sometimes called the “suboptimal approximation”), approximately 20% drag reduction is obtained, a result that can be obtained with a variety of other approaches. For sufficiently large optimization horizons ( $T^* \geq 25$ ), the flow is returned to the region of stability of the laminar flow, and the flow relaminarizes with no further control effort required. No other control algorithm tested in this flow to date has achieved this result with this type of flow actuation. (From Bewley, T.R., Moin, P., and Temam, R., *J. Fluid Mech.*, to appear. (a) 45.4% of input waveform, flap deflection =  $-0.3 \mu\text{m}$

(a) 65.4% of input waveform, flap deflection =  $-22.5 \mu\text{m}$

**COLOR FIGURE 35.38** Phase-averaged streamline plots at different phases of the forcing cycle.

The above equations and the fact that the system has a relative degree of 4 is verified by the following detailed calculations:

$$\begin{aligned}
 L_g h(x) &= L_g x_1 = \begin{bmatrix} 1 & 0 & 0 & 0 \end{bmatrix} \begin{bmatrix} 0 \\ 0 \\ 0 \\ 1 \end{bmatrix} = 0, \\
 L_g L_f h(x) &= L_g L_f x_1 = L_g \begin{bmatrix} 1 & 0 & 0 & 0 \end{bmatrix} \begin{bmatrix} x_3 \\ x_4 \\ x_1 + x_2 + x_3 \\ x_1 - x_3 \end{bmatrix} = L_g x_3 = \begin{bmatrix} 0 & 0 & 1 & 0 \end{bmatrix} \begin{bmatrix} 0 \\ 0 \\ 0 \\ 1 \end{bmatrix} = 0, \\
 L_g L_f^2 h(x) &= L_g L_f^2 x_1 = L_g L_f x_3 = L_g \begin{bmatrix} 0 & 0 & 1 & 0 \end{bmatrix} \begin{bmatrix} x_3 \\ x_4 \\ x_1 + x_2 + x_3 \\ x_1 - x_3 \end{bmatrix} \\
 &= L_g(x_1 + x_2 + x_3) = \begin{bmatrix} 1 & 1 & 1 & 0 \end{bmatrix} \begin{bmatrix} 0 \\ 0 \\ 0 \\ 1 \end{bmatrix} = 0, \\
 L_g L_f^3 h(x) &= L_g L_f^3 x_1 = L_g L_f(x_1 + x_2 + x_3) = L_g \begin{bmatrix} 1 & 1 & 1 & 0 \end{bmatrix} \begin{bmatrix} x_3 \\ x_4 \\ x_1 + x_2 + x_3 \\ x_1 - x_3 \end{bmatrix} \\
 &= L_g(x_1 + x_2 + 2x_3 + x_4) = \begin{bmatrix} 1 & 1 & 2 & 1 \end{bmatrix} \begin{bmatrix} 0 \\ 0 \\ 0 \\ 1 \end{bmatrix} = 1
 \end{aligned} \tag{12.72}$$

Therefore, a controller of the form:

$$\begin{aligned}
 u &= \frac{1}{L_g L_f^3 h} (-L_f^4 h + v) \\
 &= (-(3x_1 + 2x_2 + 2x_3 + x_4) + k_1 x_1 + k_2 x_3 + k_3(x_1 + x_2 + x_3) + k_4(x_1 + x_2 + 2x_3 + x_{er4})) \tag{12.73}
 \end{aligned}$$

with the gains  $k_i$  picked via pole placement, for example, will allow the system to track trajectories of the output function  $h(x) = x_1$ .

So far, this section has considered full state feedback linearization where the relative degree of a system is equal to the dimension of its state space. Partial feedback linearization is also possible where the relative

degree is less than the dimension of the state space; however, for such systems an analysis of the stability of the *zero dynamics* is necessary. In particular, if the relative degree  $\gamma < n$ , then the change of coordinates is typically expressed in the form:

$$\begin{aligned}
 \xi_1 &= h(x) \\
 \xi_2 &= \dot{\xi}_1 = \dot{h} = L_f h \\
 \xi_3 &= \dot{\xi}_2 = \ddot{h} = L_f^2 h \\
 &\vdots \\
 \xi_\gamma &= \dot{\xi}_{\gamma-1} = L_f^{\gamma-1} h \\
 \eta_1 &= \eta_1(x) \\
 \eta_2 &= \eta_2(x) \\
 &\vdots \\
 \eta_{n-\gamma} &= \eta_{n-\gamma}(x)
 \end{aligned} \tag{12.74}$$

where the  $\eta_i$  are chosen so that the matrix:

$$\begin{bmatrix} dh(x) \\ dL_f h(x) \\ \vdots \\ dL_f^{\gamma-1} h(x) \\ d\eta_1(x) \\ \vdots \\ d\eta_{n-\gamma}(x) \end{bmatrix} \tag{12.75}$$

is full rank. The dynamics of the system in the new coordinates will be of the form:

$$\begin{aligned}
 \dot{\xi}_1 &= \xi_2 \\
 \dot{\xi}_2 &= \xi_3 \\
 &\vdots \\
 \dot{\xi}_\gamma &= b(\xi, \eta) + a(\xi, \eta)u \\
 \dot{\eta}_1 &= q_1(\xi, \eta) \\
 &\vdots \\
 \dot{\eta}_{n-\gamma} &= q_{n-\gamma}(\xi, \eta)
 \end{aligned} \tag{12.76}$$

The zero dynamics are the dynamics expressed by the  $\eta$  equations, the stability of which must be considered independently of the linearized  $\xi$  equations. The interested reader is referred to texts by Isidori (1996), Khalil (1996), Nijmeijer and van der Schaft (1990) and Sastry (2000) for the relevant details.

## 12.4.2 MIMO Full-State Feedback Linearization

The MIMO feedback linearization is a slight extension of the SISO feedback linearization by which the SISO linearization construction is repeated for  $m$  output functions for a system with  $m$  control inputs:

$$\begin{aligned}\dot{\mathbf{x}} &= \mathbf{f}(\mathbf{x}) + \mathbf{g}_1(\mathbf{x})u_1 + \mathbf{g}_2(\mathbf{x})u_2 + \cdots + \mathbf{g}(\mathbf{x})_m u_m \\ y_1 &= h_1(\mathbf{x}) \\ y_2 &= h_2(\mathbf{x}) \\ &\vdots \\ y_m &= h_m(\mathbf{x})\end{aligned}\tag{12.77}$$

Now, the vector relative degree is defined as a combination of relative degrees for each of the output functions. Considering the  $j$ th output  $y_j$ ,

$$\dot{y}_j = L_f h_j + L_{g_1} h_j u_1 + L_{g_2} h_j u_2 + \cdots + L_{g_m} h_j u_m\tag{12.78}$$

If  $L_{g_i} h_j \equiv 0$  for each  $i$ , then the inputs do not appear in the derivative. Now let  $\gamma_j$  be the smallest integer such that  $L_{g_i} L_f^{\gamma_j - 1} h_j \neq 0$  for at least one  $i$ . Define the matrix:

$$A(x) = \begin{bmatrix} L_{g_1} L_f^{\gamma_1 - 1} h_1 & \cdots & L_{g_m} L_f^{\gamma_1 - 1} h_1 \\ \vdots & \ddots & \vdots \\ L_{g_1} L_f^{\gamma_m - 1} h_m & \cdots & L_{g_m} L_f^{\gamma_m - 1} h_m \end{bmatrix}\tag{12.79}$$

Now, the system has vector relative degree  $\gamma_1, \gamma_2, \dots, \gamma_m$  at  $x$  if  $L_{g_i} L_f^k h_i \equiv 0 \ 0 \leq k \leq \gamma_i - 2$  for  $i = 1, \dots, m$  and the matrix  $A(x)$  is nonsingular.

## 12.4.3 Control Applications of Lyapunov Stability Theory

Lyapunov theory for autonomous differential equations states that if  $x = 0$  is an equilibrium point for a differential equation  $\dot{x} = f(x)$ , and there exists a continuously differentiable function,  $V(x) > 0$  except for  $V(0) = 0$  and  $\dot{V}(x) < 0$  and in some domain containing zero where:

$$\dot{V}(x) = \sum_{i=1}^n \frac{\partial V}{\partial x_i} \dot{x}_i = \sum_{i=1}^n \frac{\partial V}{\partial x_i} f_i(x)\tag{12.80}$$

then the point  $x = 0$  is an asymptotically stable equilibrium point for the differential equation. The utility of Lyapunov theory in control is that controller synthesis techniques can be designed to ensure the negative definiteness of a Lyapunov function to ensure stability or boundedness of the system trajectories.

As fully described in Khalil (1996), the main applications of Lyapunov stability theory to control system design are *Lyapunov redesign*, *backstepping*, *sliding mode control* and *adaptive control*. Due to space limitations, the basic concepts of each will only be briefly outlined here.

Lyapunov redesign is an instance of nonlinear robust control design; however, there is a severe restriction upon how the uncertainties are expressed in the equations of motion with a corresponding restriction on the types of systems that are amenable to this technique. In particular, consider the system:

$$\dot{x} = f(t, x) + G(t, x)u + G(t, x)\delta(t, x, u)\tag{12.81}$$

where  $f$  and  $G$  are known,  $\delta$  is unknown but is bounded by a known, but not necessarily small, function. The main restriction here is that the uncertainty enters the system in exactly the same manner as the

control input. In order to use Lyapunov redesign, a stabilizing control law exists for the nominal system (ignoring  $\delta$ ) and a Lyapunov function for the nominal system must be known. (Note that one nice aspect of the feedback linearization discussed previously is that if a controller is designed using that technique, a Lyapunov function is straightforward to determine due to the simple form of the equations of motion after the nonlinear coordinate transformation.) Due to the way that the uncertainty enters the system, it is easy to modify the nominal control law to compensate for the uncertainty to ensure that  $\dot{V}(x) < 0$ . References concerning Lyapunov redesign include Corless (1993), Corless and Heitmann (1981), Barmish et al. (1983) and Spong and Vidyasager (1989).

Backstepping is a recursive controller design procedure where the entire control system is decomposed into smaller, simpler subsystems for which it may be easier to design a stabilizing controller. By considering the appropriate way to modify a Lyapunov function after each smaller subsystem is designed, a stabilizing controller for the full system may be obtained. The main restriction for this technique is a limitation on the structure of the equations of motion (a type of hierarchical structure is required). Extensions of this procedure to account for certain system uncertainties have also been developed. For references, see Krstic et al. (1995), Qu (1993) and Slotine and Hedrick (1993).

The basic idea in sliding mode control is to drive the system in finite time to a certain submanifold of the configuration space, called the *sliding manifold*, upon which the system should indefinitely evolve. Because the sliding manifold has a lower dimension than the full state space for the system, a lower order model can describe the evolution of the system on the sliding manifold. If a stabilizing controller can be designed for the sliding manifold, the problem reduces to designing a controller to drive the system to the sliding manifold. The advantage of sliding mode control is that it is very robust with respect to system uncertainties. One disadvantage is that it is a bit mathematically quirky as there are discontinuities in the control law when switching from the full state of the system to the sliding manifold. Additionally, “chattering,” wherein the system constantly alternates between the two sides of the submanifold, is a common problem. See Utkin (1992) and DeCarlo et al. (1988) for overviews of the approach.

Finally, there is a vast literature in the area of adaptive control. In adaptive control, some system performance index is measured and the adaptive controller modifies adjustable parameters in the controller in order to maintain the performance index of the control system close to a desired value (or set of desired values). This is clearly desirable in cases where system parameters are unknown or change with time. Representative references concerning adaptive control include Anderson et al. (1986), Ioannou and Sun (1995), Krstic et al. (1995), Landau et al. (1998), Narendra and Annaswamy (1989) and Sastry and Bodson (1989).

#### 12.4.4 Hybrid Systems

*Hybrid systems* are systems characterized by both continuous as well as discrete dynamics. Examples of hybrid systems include, but certainly are not limited to, digital computer-controlled systems, distributed control systems governed by a hierarchical logical interaction structure, multi-agent systems (such as the air traffic management system [Tomlin, 1998]) and systems characterized by intermittent physical contact [Goodwine, 2000]. Recent papers considering modeling and control synthesis methods for such complicated systems include Alur and Henzinger (1996), Antsaklis et al. (1995; 1997), Branicky et al. (1998), Henzinger and Sastry (1998) and Lygeros et al. (1999).

### 12.5 Parting Remarks

---

This chapter provided a brief overview of the fundamental concepts in analysis and design of control systems. Included was an outline of “classical linear control,” including stability concepts (the Routh array) and controller design techniques (root locus and lead-lag synthesis). Additionally, more recent advances in control including pole placement, the linear quadratic regulator and the basic concepts from robust control were outlined and examples were provided. Finally, recent developments in nonlinear

control, including feedback linearization (for both single-input, single-output and multi-input, multi-output systems), were outlined along with basic approaches utilizing Lyapunov stability theory.

## Defining Terms

**Adaptive control:** A controller design technique wherein typically some parameter in the controller is varied or changed in response to variations in the controlled system.

**Backstepping:** A nonlinear controller design technique based upon Lyapunov stability theory.

**Block diagram:** A graphical representation of a differential equation describing a linear control system.

**Bode plot:** A plot of the magnitude of the response of a system to sinusoidal inputs vs. the frequency of the inputs and a plot of the phase difference between the sinusoidal input and response of the system.

**Characteristic equation:** The equation obtained by equating the denominator of a transfer function with zero. Analysis of the characteristic equation yields insight into the stability of a transfer function.

**Feedback linearization:** A nonlinear controller design technique based upon determining a nonlinear change of coordinates which transform the differential equations describing the system into a simple, canonical and controllable form.

**Gain margin:** A measure of stability or instability of a control system which can be determined from a Bode plot by considering the magnitude of the system response when the phase difference between the input and system response is  $-180^\circ$ .

**Laplace transform:** A mathematical transformation useful to transform ordinary differential equations into algebraic equations.

**Loopshaping:** A controller design method based upon obtaining a desired “shape” for the Bode plot of a system.

**LQR control:** An optimal control design technique based upon minimizing a cost function defined as a combination of the magnitude of the system response and the control effort. LQR is an acronym for linear quadratic regulator.

**Lyapunov redesign:** A nonlinear robust controller design technique based upon Lyapunov stability theory.

**Lyapunov stability theory:** The analysis of the stability of (nonlinear) differential equations based upon the time derivative of a Lyapunov function.

**Nonlinear control:** The design and analysis of control systems described by nonlinear differential equations.

**Nyquist plot:** A contour plot in the complex plane of a transfer function as the dependent variable encircles the entire right-half complex plane.

**Phase margin:** A measure of stability or instability of a control system which can be determined from a Bode plot by considering the magnitude of the phase difference between the input and system response when the magnitude of the response is equal to 0 dB.

**PID control:** A very common control law wherein the input to the system is proportional to the error, the derivative of the error and the time integral of the error. PID is an acronym for proportional–integral–derivative control.

**Poles:** Roots of the denominator of a transfer function.

**Pole placement:** A state-space controller design technique based upon specifying certain eigenvalues for the system.

**Robust control:** The design and analysis of control systems which explicitly account for unmodeled system dynamics and disturbances.

**Root locus:** A controller synthesis technique wherein the poles of the transfer function of a control system are plotted as a parameter (usually a controller gain) is varied.

**Routh array:** A technique to determine the number of roots of a polynomial that have a positive real part without having to factor the polynomial. This is used to determine the stability of a transfer function based upon its characteristic equation.

**Sliding mode control:** A nonlinear controller design technique based upon Lyapunov stability theory with the goal of driving the system to a center manifold upon which the dynamics of the system are simpler and easily controlled.

**Transfer function:** The algebraic expression relating the Laplace transform of the input to the output of a control system.

**Zeros:** Roots of the numerator of a transfer function.

## For Further Information

Most of the material covered in the chapter is thoroughly covered in textbooks. For the section on classical control, the undergraduate texts by Dorf (1992), Franklin et al. (1994), Kuo (1995), Ogata (1997) and Raven (1995) provide a complete mathematical treatment of root locus design, PID control, lead-lag compensation and basic state-space methods. Textbooks for linear, robust control include Doyle et al. (1992) and Zhou (1996).

The standard textbooks for geometric nonlinear control are Isidori (1996) and Nijmeijer and van der Schaft (1990). Additional material concerning the mathematical basis for differential geometry is found in Abraham et al. (1988) and Boothby (1986). Sastry (2000) provides an overview of differential geometric techniques but also considers Lyapunov-based methods and nonlinear dynamical systems in general. Khalil (1996) focuses primarily on Lyapunov methods and includes a chapter on differential geometric techniques.

As traditional scientific disciplines individually grow towards their maturity, many new opportunities for significant advances lie at their intersection. For example, remarkable developments in control theory in the last few decades have considerably expanded the selection of available tools which may be applied to regulate physical and electrical systems. When combined with microelectromechanical (MEMS) techniques for distributed sensing and actuation, as highlighted elsewhere in this handbook, these techniques hold great promise for several applications in fluid mechanics, including the delay of transition and the regulation of turbulence. Such applications of control theory require a very balanced perspective, in which one considers the relevant flow physics when designing the control algorithms and, conversely, takes into account the requirements and limitations of control algorithms when designing both reduced-order flow models and the fluid-mechanical systems to be controlled themselves. Such a balanced perspective is elusive, however, as both the research establishment in general and universities in particular are accustomed only to the dissemination and teaching of component technologies in isolated fields. To advance, we must not toss substantial new interdisciplinary questions over the fence for fear of them being “outside our area;” rather, we must break down these very fences that limit us and attack these challenging new questions with a Renaissance approach. In this spirit, this chapter surveys a few recent attempts at bridging the gaps between the several scientific disciplines comprising the field of flow control, in an attempt to clarify the author’s perspective on how recent advances in these constituent disciplines fit together in a manner that opens up significant new research opportunities.

## 13.1 Introduction

---

Flow control is perhaps the most difficult Grand Challenge application area for MEMS technology. Potentially, it is also one of the most rewarding, as a common feature in many fluid systems is the existence of natural instability mechanisms by which a small input, when coordinated correctly, can lead to a large response in the overall system. As one of the key driving application areas for MEMS, it is thus appropriate to survey recent developments in the fundamental framework for flow control in this handbook.

The area of flow control plainly resides at the intersection of disciplines, incorporating essential and nontrivial elements from control theory, fluid mechanics, Navier–Stokes mathematics, numerical methods and, of course, fabrication technology for “small” (millimeter-scale), self-contained, durable devices which can integrate the functions of sensing, actuation and control logic. Recent developments in the integration of these disciplines, while grounding us with appropriate techniques to address some fundamental open questions, hint at the solution of several new questions which are yet to be asked. To follow up on these new directions, it is essential to have a clear vision of how recent advances in these fields fit together and to know where the significant unresolved issues at their intersection lie.

This chapter will attempt to elucidate the utility of an interdisciplinary perspective to this type of problem by focusing on the control of a prototypical and fundamental fluid system: plane channel flow. The control of the flow in this simple geometry embodies a myriad of complex issues and interrelationships whose understanding requires us to draw from a variety of traditional disciplines. Only when these issues and perspectives are combined is a complete understanding of the state of the art achieved and a vision of where to proceed next identified.

Though plane channel flow will be the focus problem we will discuss here, the purpose of this work goes well beyond simply controlling this particular flow with a particular actuator/sensor configuration. At its core, the research effort we will describe is devoted to the development of an integrated, interdisciplinary understanding that will allow us to synthesize the necessary tools to attack a variety of flow control problems in the future. The focus problem of control of channel flow is chosen not simply because

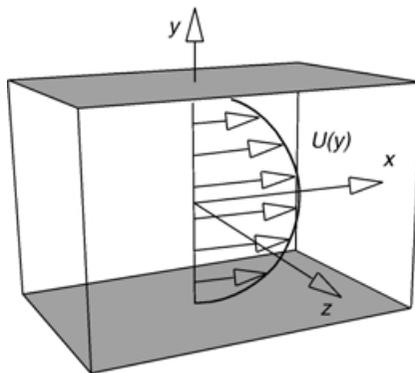

of its technological relevance or fundamental character, but because it embodies many of the important unsolved issues to be encountered in the assortment of new flow control problems that will inevitably follow. The primary objective of this work is to lay a solid, integrated footing upon which these future efforts may be based.

To this end, this chapter will describe mostly the efforts with which the author has been directly involved, in an attempt to weave the story that threads these projects together as part of the fabric of a substantial new area of interdisciplinary research. Space does not permit complete development of these projects; rather, the chapter will survey a selection of recent results that bring the relevant issues to light. The reader is referred to the appropriate full journal articles for all of the relevant details and careful placement of these projects in context with the works of others. Space limitations also do not allow this brief chapter to adequately review the various directions all my friends and colleagues are taking in this field. Rather than attempt such a review and fail, I refer the reader to a host of other recent reviews which, taken together, themselves span only a fraction of the current work being done in this active area of research. For an experimental perspective, the reader is referred to several other chapters in this handbook, and to the recent reviews of Ho and Tai (1996; 1998), McMichael (1996), Gad-el-Hak (1996) and Löfdahl and Gad-el-Hak (1999). For a mathematical perspective, the reader is referred to the recent dedicated volumes compiled by Banks (1992), Banks et al. (1993), Gunzburger (1995), Lagnese et al. (1995) and Sritharan (1998) for a sampling of recent results in this area.

## 13.2 Linearization: Life in a Small Neighborhood

As a starting point for the introduction of control theory into the fluid-mechanical setting, we first consider the linearized system arising from the equation governing small perturbations to a laminar flow. From a physical point of view, such perturbations are quite significant, as they represent the initial stages of the complex process of transition to turbulence, and thus their mitigation or enhancement has a substantial effect on the evolution of the flow.

To be concrete, an enlightening problem that captures the essential physics of many important features of both transition and turbulence in wall-bounded flows is that of plane channel flow, as illustrated in Figure 13.1. Without loss of generality, we assume the walls are located at  $y = \pm 1$ . We begin our study by

**FIGURE 13.1** Geometry of plane channel flow. The flow is sustained by an externally applied pressure gradient in the  $x$  direction. This canonical problem provides an excellent testbed for the study of both transition and turbulence in wall-bounded flows. Note that many of the important flow phenomena in this geometry, in both the linear and nonlinear setting, are fundamentally three dimensional. A nonphysical assumption of periodicity of the flow perturbations in the  $x$  and  $z$  directions is often assumed for numerical convenience, with the box size chosen to be large enough that this nonphysical assumption has minimal effect on the observed flow statistics. It is important to evaluate critically the implications of such assumptions during the process of control design, as discussed in detail in Sections 13.4 and 13.5.

analyzing small perturbations  $\{u, v, w, p\}$  to the (parabolic) laminar flow profile  $U(y)$  in this geometry, which are governed by the linearized incompressible Navier–Stokes equation:

$$\frac{\partial u}{\partial x} + \frac{\partial v}{\partial y} + \frac{\partial w}{\partial z} = 0, \quad (13.1a)$$

$$\dot{u} + U \frac{\partial}{\partial x} u + U' v = -\frac{\partial p}{\partial x} + \frac{1}{\text{Re}} \Delta u, \quad (13.1b)$$

$$\dot{v} + U \frac{\partial}{\partial x} v = -\frac{\partial p}{\partial y} + \frac{1}{\text{Re}} \Delta v, \quad (13.1c)$$

$$\dot{w} + U \frac{\partial}{\partial x} w = -\frac{\partial p}{\partial z} + \frac{1}{\text{Re}} \Delta w. \quad (13.1d)$$

Equation (13.1a), the continuity equation, constrains the solution of Eqs. (13.1b) to (13.1d), the momentum equations, to be divergence free. This constraint is imposed through the  $\nabla p$  terms in the momentum equations, which act as Lagrange multipliers to maintain the velocity field on a divergence-free submanifold of the space of square-integrable vector fields. In the discretized setting, such systems are called *descriptor systems* or *differential-algebraic equations* and, defining a state vector  $\mathbf{x}$  and a control vector  $\mathbf{u}$ , may be written in the generalized state-space form:

$$E \dot{\mathbf{x}} = A \mathbf{x} + B \mathbf{u}. \quad (13.2)$$

Note that if the Navier–Stokes equation (13.1) is put directly into this form,  $E$  is singular. This is an essential feature of the Navier–Stokes equation that necessitates careful treatment in both simulation and control design in order to avoid spurious numerical artifacts. A variety of techniques exist to express the system of equations (13.1) with a reduced set of variables or spatially distributed functions with only two degrees of freedom per spatial location, referred to as a *divergence-free basis*. In such a basis, the continuity equation is applied implicitly, and the pressure is eliminated from the set of governing equations. All three velocity components and the pressure (up to an arbitrary constant) may be determined from solutions represented in such a basis. When discretized and represented in the form of Eq. (13.2), the Navier–Stokes equation written in such a basis leads to an expression for  $E$  that is nonsingular.

For the geometry indicated in [Figure 13.1](#), a suitable choice for this reduced set of variables, which is convenient in terms of the implementation of boundary conditions, is the wall-normal velocity,  $v$ , and the wall-normal vorticity,  $\omega \triangleq \partial u / \partial z - \partial w / \partial x$ . Taking the Fourier transform of Eq. (13.1) in the streamwise and spanwise directions and manipulating these equations and their derivatives leads to the classical Orr–Sommerfeld/Squire formulation of the Navier–Stokes equation at each wavenumber pair  $\{k_x, k_z\}$ :

$$\hat{\Delta} \hat{v} = \{-ik_x U \hat{\Delta} + ik_x U'' + \hat{\Delta}(\hat{\Delta}/\text{Re})\} \hat{v}, \quad (13.3a)$$

$$\hat{\omega} = \{-ik_z U'\} \hat{v} + \{-ik_x U + \hat{\Delta}/\text{Re}\} \hat{\omega}, \quad (13.3b)$$

where the hats ( $\hat{\cdot}$ ) indicate Fourier coefficients and the Laplacian now takes the form  $\hat{\Delta} \triangleq \partial^2 / \partial y^2 - k_x^2 - k_z^2$ . Note that particular care is needed when solving this system; in order to invert the Laplacian on the LHS of Eq. (13.3a), the boundary conditions on  $v$  must be accounted for properly. By manipulation of the governing equations and casting them in a derivative form, we effectively trade one numerical

difficulty (singularity of  $E$ ) for another (a tricky boundary condition inclusion to make the Laplacian on the LHS of Eq. (13.3a) invertible).

Note the spatially invariant structure of the present geometry: every point on each wall is, statistically speaking, identical to every other point on that wall. Canonical problems with this sort of spatially invariant structure in one or more directions form the backbone of much of the literature on flow transition and turbulence. It is this structure that facilitates the use of Fourier transforms to completely decouple the system state  $\{\hat{v}, \hat{\omega}\}$  at each wavenumber pair  $\{k_x, k_z\}$  from the system state at every other wavenumber pair, as indicated in Eq. (13.3). Such decoupling of the Fourier modes of the unforced linear system in the directions of spatial invariance is a classical result upon which much of the available linear theory for the stability of Navier–Stokes systems is based. As noted by Bewley and Agarwal (1996), taking the Fourier transform of both the control variables and the measurement variables maintains this system decoupling in the control formulation, greatly reducing the complexity of the control design problem to several smaller, completely decoupled control design problems at each wavenumber pair  $\{k_x, k_z\}$ , each of which requires spatial discretization in the  $y$  direction only.

Once a tractable form of the governing equation has been selected, in order to pose the flow control problem completely, several steps remain:

- the state equation must be spatially discretized,
- boundary conditions must be chosen and enforced,
- the variables representing the controls and the available measurements must be identified and extracted,
- the disturbances must be modeled, and
- the “control objective” must be precisely defined.

To identify a fundamental yet physically relevant flow control problem, the decisions made at each of these steps require engineering judgment. Such judgment is based on physical insight concerning the flow system to be controlled and how the essential features of such a system may be accurately modeled. An example of how to accomplish these steps is described in some detail by Bewley and Liu (1998). In short, we may choose:

- a Chebyshev spatial discretization in  $y$ ,
- no-slip boundary conditions ( $u = w = 0$  on the walls) with the distribution of  $v$  on the walls (the blowing/suction profile) prescribed as the control,
- skin friction measurements distributed on the walls,
- idealized disturbances exciting the system, and
- an objective of minimizing flow perturbation energy.

As we learn more about the physics of the system to be controlled, there is significant room for improvement in this problem formulation, particularly in modeling the structure of relevant system disturbances and in the precise statement of the control objective.

Once the above-mentioned steps are complete, the present decoupled system at each wavenumber pair  $\{k_x, k_z\}$  may finally be manipulated into the standard state-space form:

$$\begin{aligned}\dot{\mathbf{x}} &= \mathbf{A}\mathbf{x} + B_1\mathbf{w} + B_2\mathbf{u}, \\ \mathbf{y} &= C_2\mathbf{x} + D_{21}\mathbf{w},\end{aligned}\tag{13.4}$$

with

$$B_1 \triangleq (G_1 \ 0), \quad C_2 \triangleq G_2^{-1}C, \quad D_{21} \triangleq (0 \ \alpha I), \quad \mathbf{w} \triangleq \begin{pmatrix} \mathbf{w}_1 \\ \mathbf{w}_2 \end{pmatrix},$$

where  $\mathbf{x}$  denotes the state,  $\mathbf{u}$  denotes the control,  $\mathbf{y}$  denotes the available measurements (scaled as discussed below), and  $\mathbf{w}$  accounts for the external disturbances (including the state disturbances  $\mathbf{w}_1$  and the measurement noise  $\mathbf{w}_2$ , scaled as discussed below). Note that  $C\mathbf{x}$  denotes the raw vector of measured variables, and  $G_1$  and  $\alpha G_2$  represent the square root of any known or expected covariance structure of the state disturbances and measurement noise, respectively. The scalar  $\alpha^2$  is identified as an adjustable parameter that defines the ratio of the maximum singular value of the covariance of the measurement noise divided by the maximum singular value of the covariance of the state disturbances; w.l.o.g., we take  $\bar{\sigma}(G_1) = \bar{\sigma}(G_2) = 1$ . Effectively, the matrix  $G_1$  reflects which state disturbances are strongest, and the matrix  $G_2$  reflects which measurements are most corrupted by noise. Small  $\alpha$  implies relatively high overall confidence in the measurements, whereas large  $\alpha$  implies relatively low overall confidence in the measurements.

Not surprisingly, there is a wide body of theory surrounding how to control a linear system in the standard form of Eq. (13.4). The application of one popular technique (to a related two-dimensional problem), called *proportional–integral (PI) control* and generally referred to as “classical” control design, is presented in Joshi et al. (1997). The application of another technique, called  $\mathcal{H}_\infty$  control and generally referred to as “modern” control design, is laid out in Bewley and Liu (1998), hereafter referred to as BL98. The application of a related modern control strategy (to the two-dimensional problem), called *loop transfer recovery (LTR)*, is presented in Cortezzi and Speyer (1998). More recent publications by these groups further extend these seminal efforts.

It is useful, to some extent, to understand the various theoretical implications of the control design technique chosen. Ultimately, however, flow control boils down to the *design* of a control that achieves the desired engineering objective (transition delay, drag reduction, mixing enhancement, etc.) to the maximum extent possible. The theoretical implications of the particular control technique chosen are useful only to the degree to which they help attain this objective. Engineering judgment, based both on an understanding of the merits of the various control theories and on the suitability of such theories to the structure of the fluid-mechanical problem of interest, guides the selection of an appropriate control design strategy. In the following section, we summarize the  $\mathcal{H}_\infty$  control design approach, illustrate why this approach is appropriate for the structure of the problem at hand, and highlight an important distinguishing characteristic of the present system when controls computed via this approach are applied.

### 13.3 Linear Stabilization: Leveraging Modern Linear Control Theory

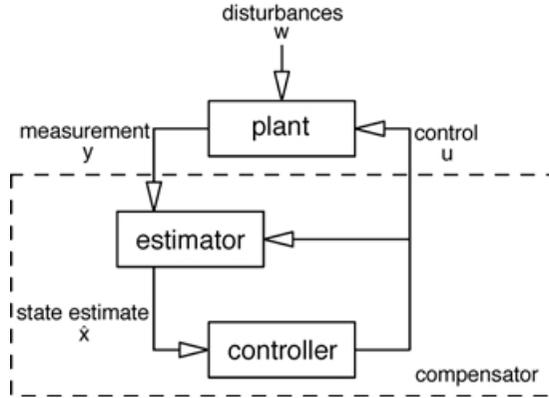

As only a limited number of noisy measurements  $\mathbf{y}$  of the state  $\mathbf{x}$  are available in any practical control implementation, it is beneficial to develop a filter that extracts as much useful information as possible from the available flow measurements before using this filtered information to compute a suitable control. In modern control theory, a model of the system itself is used as this filter, and the filtered information extracted from the measurements is simply an estimate of the state of the physical system. This intuitive framework is illustrated schematically in Figure 13.2. By modeling (or neglecting) the influence of the unknown disturbances in Eq. (13.4), the system model takes the form:

$$\dot{\hat{\mathbf{x}}} = A\hat{\mathbf{x}} + B_1\hat{\mathbf{w}} + B_2\mathbf{u} - \mathbf{v}, \quad (13.5a)$$

$$\hat{\mathbf{y}} = C_2\hat{\mathbf{x}} + D_{21}\hat{\mathbf{w}}, \quad (13.5b)$$

where  $\hat{\mathbf{x}}$  is the state estimate,  $\hat{\mathbf{w}}$  is a disturbance estimate, and  $\mathbf{v}$  is a feedback term based on the difference between the measurement of the state,  $\mathbf{y}$ , and the corresponding quantity in the model,  $\hat{\mathbf{y}}$ , such that:

$$\mathbf{v} = L(\mathbf{y} - \hat{\mathbf{y}}). \quad (13.5c)$$

**FIGURE 13.2** Flow of information in a modern control realization. The plant, forced by external disturbances, has an internal state  $\mathbf{x}$  which cannot be observed. Instead, a noisy measurement  $\mathbf{y}$  is made, with which a state estimate  $\hat{\mathbf{x}}$  is determined. This state estimate is then used to determine the control  $\mathbf{u}$  to be applied to the plant to regulate  $\mathbf{x}$  to zero. Essentially, the full equation for the plant (or a reduced model thereof) is used in the estimator as a filter to extract useful information about the state from the available measurements.

The control  $\mathbf{u}$ , in turn, is based on the state estimate  $\hat{\mathbf{x}}$  such that:

$$\mathbf{u} = K\hat{\mathbf{x}}. \quad (13.6)$$

Equation (13.4) is referred to as the “plant,” (13.5) is referred to as the “estimator,” and (13.6) is referred to as the “controller.” The estimator, Eq. (13.5), and the controller, Eq. (13.6), taken together, will be referred to as the “compensator.” The problem at hand is to compute linear time-invariant (LTI) matrices  $K$  and  $L$  and some estimate of the disturbance,  $\hat{\mathbf{w}}$ , such that:

1. the estimator feedback  $\mathbf{v}$  forces  $\hat{\mathbf{x}}$  towards  $\mathbf{x}$ , and
2. the controller feedback  $\mathbf{u}$  forces  $\mathbf{x}$  towards zero,

even as unknown disturbances  $\mathbf{w}$  both disrupt the system evolution and corrupt the available measurements of the system state.

### 13.3.1 The $\mathcal{H}_\infty$ Approach to Control Design

Several textbooks describe in detail how the  $\mathcal{H}_\infty$  technique determines  $K$ ,  $L$ , and  $\hat{\mathbf{w}}$  for systems of the form Eqs. (13.4) to (13.6) in the presence of structured and unstructured disturbances  $\mathbf{w}$ . The reader is referred to the seminal paper by Doyle et al. (1989), the more accessible textbook by Green and Limebeer (1995), and the more advanced texts by Zhou et al. (1996) and Zhou and Doyle (1998) for derivation and further discussion of these control theories, and to BL98 for an extended discussion in the context of the present problem. To summarize this approach briefly, a cost function  $\mathcal{J}$  describing the control problem at hand is defined that weighs together the state  $\mathbf{x}$ , the control  $\mathbf{u}$ , and the disturbance  $\mathbf{w}$  such that:

$$\mathcal{J} \triangleq E[\mathbf{x}^* Q \mathbf{x} + \ell^2 \mathbf{u}^* \mathbf{u} - \gamma^2 \mathbf{w}^* \mathbf{w}] \triangleq E[\mathbf{z}^* \mathbf{z} - \gamma^2 \mathbf{w}^* \mathbf{w}], \quad (13.7a)$$

where

$$\mathbf{z} \triangleq C_1 \mathbf{x} + D_{12} \mathbf{u}, \quad C_1 \triangleq \begin{pmatrix} Q^{1/2} \\ 0 \end{pmatrix}, \quad D_{12} \triangleq \begin{pmatrix} 0 \\ \ell I \end{pmatrix}. \quad (13.7b)$$

The matrix  $Q$  shaping the dependence on the state in the cost function,  $\mathbf{x}^*Q\mathbf{x}$ , may be selected to numerically approximate any of a variety of physical properties of the flow, such as the flow perturbation energy, its enstrophy, the mean square of the drag measurements, etc. The matrix  $Q$  may also be biased to place extra penalty on flow perturbations in a specific region in space of particular physical significance. The choice of  $Q$  has a profound effect on the final closed-loop behavior, and it must be selected with care. Based on our numerical tests to date, cost functions related to the energy of the flow perturbations have been the most successful for the purpose of transition delay. To simplify the algebra that follows, we have set the matrices  $R$  and  $S$  shaping the  $\mathbf{u}^*R\mathbf{u}$  and  $\mathbf{w}^*S\mathbf{w}$  terms in the cost function equal to  $I$ . As shown in Lauga and Bewley (2000), it is straightforward to generalize this result to other positive-definite choices for  $R$  and  $S$ . Such a generalization is particularly useful when designing controls for a discretization of a partial differential equation (PDE) in a consistent manner such that the feedback kernels converge to continuous functions as the computational grid is refined.

Given the structure of the system defined in Eqs. (13.4) to (13.6) and the control objective defined in Eq. (13.7), the  $\mathcal{H}_\infty$  compensator is determined by simultaneously minimizing the cost function  $\mathcal{J}$  with respect to the control  $\mathbf{u}$  and maximizing  $\mathcal{J}$  with respect to the disturbance  $\mathbf{w}$ . In such a way, a control  $\mathbf{u}$  is found that maximally attains the control objective even in the presence of a disturbance  $\mathbf{w}$  that maximally disrupts this objective. For *sufficiently large*  $\gamma$  and a system that is both *stabilizable* and *detectable* via the controls and measurements chosen,<sup>1</sup> this results in finite values for  $\mathbf{u}$ ,  $\mathbf{v}$ , and  $\mathbf{w}$ , the magnitudes of which may be adjusted by variation of the three scalar parameters  $\ell$ ,  $\alpha$ , and  $\gamma$ , respectively. Reducing  $\ell$ , modeling the “price of the control” in the engineering design, generally results in increased levels of control feedback  $\mathbf{u}$ . Reducing  $\alpha$ , modeling the “relative level of corruption” of the measurements by noise, generally results in increased levels of estimator feedback  $\mathbf{v}$ . Reducing  $\gamma$ , modeling the “price” of the disturbance to Nature (in the spirit of a noncooperative game), generally results in increased levels of disturbances  $\mathbf{w}$  of maximally disruptive structure to be accounted for during the design of the compensator.

The  $\mathcal{H}_\infty$  control solution [Doyle et al., 1989] may be described as follows: a compensator that minimizes  $\mathcal{J}$  in the presence of that disturbance which simultaneously maximizes  $\mathcal{J}$  is given by:

$$K = -\frac{1}{\ell^2}B_2^*X, \quad L = -\frac{1}{\alpha^2}ZYC_2^*, \quad \hat{\mathbf{w}} = \frac{1}{\gamma^2}B_1^*X\hat{\mathbf{x}}, \quad (13.8)$$

where

$$X = \text{Ric} \begin{pmatrix} A & \frac{1}{\gamma^2}B_1B_1^* - \frac{1}{\ell^2}B_2B_2^* \\ -C_1^*C_1 & -A^* \end{pmatrix},$$

$$Y = \text{Ric} \begin{pmatrix} A^* & \frac{1}{\gamma^2}C_1^*C_1 - \frac{1}{\alpha^2}C_2^*C_2 \\ -B_1B_1^* & -A \end{pmatrix},$$

$$Z = \left(1 - \frac{YX}{\gamma^2}\right)^{-1},$$

where  $\text{Ric}(\cdot)$  denotes the positive-definite solution of the associated Riccati equation [Laub, 1991].<sup>2</sup> The simple structure of the above solution, and its profound implications in terms of the performance and

<sup>1</sup> Further description of these important technical requirements for solvability of the control problem is deferred to the above-mentioned texts. These requirements are easily met in many practical settings.

<sup>2</sup> Note that, for the control problem to be soluble,  $\gamma$  must be sufficiently large so that: (a)  $X$  and  $Y$  may be found that are positive definite, and (b)  $\rho(XY) < \gamma^2$ , where  $\rho(\cdot)$  denotes the spectral radius. An approximate lower bound on  $\gamma$  that meets these conditions, denoted  $\gamma_0$ , may be determined by trial and error.

robustness of the resulting closed-loop system, is one of the most elegant results of linear control theory. We comment below on a few of the more salient features of this result.

Algebraic manipulation of Eqs. (13.4) to (13.8) leads to the closed-loop form:

$$\begin{aligned}\dot{\tilde{\mathbf{x}}} &= \tilde{A}\tilde{\mathbf{x}} + \tilde{B}\mathbf{w}, \\ \mathbf{z} &= \tilde{C}\tilde{\mathbf{x}},\end{aligned}\tag{13.9}$$

where

$$\begin{aligned}\tilde{\mathbf{x}} &= \begin{pmatrix} \mathbf{x} \\ \mathbf{x} - \hat{\mathbf{x}} \end{pmatrix}, \\ \tilde{A} &= \begin{pmatrix} A + B_2K & -B_2K \\ -\gamma^{-2}B_1B_1^* & A + LC_2 + \gamma^{-2}B_1B_1^* \end{pmatrix}, \\ \tilde{B} &= \begin{pmatrix} B_1 \\ B_1 + LD_{21} \end{pmatrix}, \\ \tilde{C} &= (C_1 + D_{12}K \quad -D_{12}K).\end{aligned}$$

Taking the Laplace transform of Eq. (13.9), it is easy to define the transfer function  $T_{zw}(s)$  from  $\mathbf{w}(s)$  to  $\mathbf{z}(s)$  (the Laplace transforms of  $\mathbf{w}$  and  $\mathbf{z}$ ) such that:

$$\mathbf{z}(s) = \tilde{C}(sI - \tilde{A})^{-1}\tilde{B}\mathbf{w}(s) \triangleq T_{zw}(s)\mathbf{w}(s).$$

Norms of the system transfer function  $T_{zw}(s)$  quantify how the system output of interest,  $\mathbf{z}$ , responds to disturbances  $\mathbf{w}$  exciting the closed-loop system.

The expected value of the root mean square (rms) of the output  $\mathbf{z}$  over the rms of the input  $\mathbf{w}$  for disturbances  $\mathbf{w}$  of maximally disruptive structure is denoted by the  $\infty$ -norm of the system transfer function,

$$\|T_{zw}\|_{\infty} \triangleq \sup_{\omega} \bar{\sigma}[T_{zw}(j\omega)].$$

$\mathcal{H}_{\infty}$  control is often referred to as “robust” control, as  $\|T_{zw}\|_{\infty}$ , reflecting the worst-case amplification of disturbances by the system from the input  $\mathbf{w}$  to the output  $\mathbf{z}$ , is in fact bounded from above by the value of  $\gamma$  used in the problem formulation. Subject to this  $\infty$ -norm bound,  $\mathcal{H}_{\infty}$  control minimizes the expected value of the rms of the output  $\mathbf{z}$  over the rms of the input  $\mathbf{w}$  for white Gaussian disturbances  $\mathbf{w}$  with identity covariance, denoted by the 2-norm of the system transfer function:

$$\|T_{zw}\|_2 \triangleq \left( \frac{1}{2\pi} \int_{-\infty}^{\infty} \text{trace}[T_{zw}(j\omega)^* T_{zw}(j\omega)] d\omega \right)^{1/2}.$$

Note that  $\|T_{zw}\|_2$  is often cited as a measure of performance of the closed-loop system, whereas  $\|T_{zw}\|_{\infty}$  is often cited as a measure of its robustness. Further motivation for consideration of control theories related to these particular norms is elucidated by Skogestad and Postlethwaite (1996). Efficient numerical algorithms to solve the Riccati equations for  $X$  and  $Y$  in the compensator design and to compute the transfer function norms  $\|T_{zw}\|_2$  and  $\|T_{zw}\|_{\infty}$  quantifying the closed-loop system behavior are well developed, and are discussed further in the standard texts.

Note that, for high-dimensional discretizations of infinite dimensional systems, it is not feasible to perform a parametric variation on the individual elements of the matrices defining the control problem. The control design approach taken here represents a balance of engineering judgment in the construction

of the matrices defining the structure of the control problem,  $\{B_1, B_2, C_1, C_2\}$ , and parametric variation of the three scalar parameters involved,  $\{\ell, \alpha, \gamma\}$ , in order to achieve the desired trade-offs between performance, robustness, and the control effort required. This approach retains a sufficient but not excessive degree of flexibility in the control design process. In general, intermediate values of the three parameters  $\{\ell, \alpha, \gamma\}$  are found to lead to the most suitable control designs.

$\mathcal{H}_2$  control (also known as linear quadratic Gaussian control, or LQG) is an important limiting case of  $\mathcal{H}_\infty$  control. It is obtained in the present formulation by relaxing the bound  $\gamma$  on the infinity norm of the closed-loop system, taking the limit as  $\gamma \rightarrow \infty$  in the controller formulation. Such a control formulation focuses solely on performance (i.e., minimizing  $\|T_{zw}\|_2$ ). As LQG does not provide any guarantees about system behavior for disturbances of particularly disruptive structure ( $\|T_{zw}\|_\infty$ ), it is often referred to as “optimal” control. Though one might confirm *a posteriori* that a particular LQG design has favorable robustness properties, such properties are not guaranteed by the LQG control design process. When designing a large number of compensators for an entire array of wavenumber pairs  $\{k_x, k_z\}$  via an automated algorithm, as is necessary in the current problem, it is useful to have a control design tool that inherently builds in system robustness, such as  $\mathcal{H}_\infty$ . For isolated low-dimensional systems, as often encountered in many industrial processes, *a posteriori* robustness checks on hand-tuned LQG designs are often sufficient.

It is also interesting to note that certain favorable robustness properties may be assured by the LQG approach by strategies involving either:

1. setting  $B_1 = (B_2 \ 0)$  and taking  $\alpha \rightarrow 0$ , or
2. setting  $C_1 = (C_2 \ 0)$  and taking  $\ell \rightarrow 0$ .

These two approaches are referred to as loop transfer recovery (LQG/LTR), and are further explained in Stein and Athans (1987). Such a strategy is explored by Cortezzi and Speyer (1998) in the two-dimensional setting of the current problem. In the present system, both  $B_2$  and  $C_2$  are very low rank, as there is only a single control variable and a single measurement variable at each wall in the Fourier-space representation of the physical system at each wavenumber pair  $\{k_x, k_z\}$ . However, the state itself is a high-dimensional approximation of an infinite-dimensional system. It is beneficial in such a problem to allow the modeled state disturbances  $\mathbf{w}_1$  to input the system, via the matrix  $B_1$ , at more than just the actuator inputs, and to allow the response of the system  $\mathbf{x}$  to be weighted in the cost function, via the matrix  $C_1$ , at more than just the sensor outputs. The LQG/LTR approach of assuring closed-loop system robustness, however, requires us to sacrifice one of these features in the control formulation, in addition to taking  $\alpha \rightarrow 0$  or  $\ell \rightarrow 0$ , in order to apply one of the two strategies listed above. It is noted here that the  $\mathcal{H}_\infty$  approach, when soluble, allows for the design of compensators with inherent robustness guarantees without such sacrifices of flexibility in the definition of the control problem of interest, thereby giving significantly more latitude in the design of a “robust” compensator.

The names  $\mathcal{H}_2$  and  $\mathcal{H}_\infty$  are derived from the system norms  $\|T_{zw}\|_2$  and  $\|T_{zw}\|_\infty$  that these control theories address, with the symbol  $\mathcal{H}$  denoting the particular “Hardy space” in which these transfer function norms are well defined. It deserves mention that the difference between  $\|T_{zw}\|_2$  and  $\|T_{zw}\|_\infty$  might be expected to be increasingly significant as the dimension of the system is increased. Neglecting, for the moment, the dependence on  $\omega$  in the definition of the system norms, the matrix Frobenius norm,  $(\text{trace}[T^*T])^{1/2}$ , and the matrix 2–norm,  $\bar{\sigma}[T]$ , are “equivalent” up to a constant. Indeed, for scalar systems these two matrix norms are identical, and for low-dimensional systems their ratio is bounded by a constant related to the dimension of the system. For high-dimensional discretizations of infinite-dimensional systems, however, this norm equivalence is relaxed, and the differences between these two matrix norms may be substantial. The temporal dependence of the two system norms  $\|T_{zw}\|_2$  and  $\|T_{zw}\|_\infty$  distinguishes them even for low-dimensional systems; the point here is only that, for high-dimensional systems, the important differences between these two system norms is even more pronounced, and control techniques such as  $\mathcal{H}_\infty$  that account for both such norms might prove to be beneficial. Techniques (such as  $\mathcal{H}_\infty$ ) that bound  $\|T_{zw}\|_\infty$  are especially appropriate for the present problem, as transition is often associated with the triggering of a “worst-case” phenomenon, which is well characterized by this measure.

### 13.3.2 Advantages of Modern Control Design for Non-Normal Systems

Matrices  $A$  arising from the discretization of systems in fluid mechanics are often highly “non-normal,” which means that the eigenvectors of  $A$  are highly nonorthogonal. This is especially true for transition in a plane channel. Important characteristics of this system, such as  $O(1000)$  transient energy growth and large amplification of external disturbance energy in stable flows at subcritical Reynolds numbers, cannot be explained by examination of its eigenvalues alone. Discretizations of Eq. (13.3), when put into the state-space form of Eq. (13.4), lead to system matrices of the form:

$$A = \begin{pmatrix} L & 0 \\ C & S \end{pmatrix}. \quad (13.10)$$

For certain wavenumber pairs (specifically, those with  $k_x \approx 0$  and  $k_z = O(1)$ ), the eigenvalues of  $A$  are real and stable, the matrices  $L$  and  $S$  are quite similar in structure, and  $\bar{\sigma}(C)$  is disproportionately large.

In order to illustrate the behavior of a system matrix with such structure, consider a reduced system matrix of the above form but where  $L$ ,  $C$ , and  $S$  are scalars. Specifically, compare the two stable closed-loop system matrices:

$$A_1 = \begin{pmatrix} -0.01 & 0 \\ 0 & -0.011 \end{pmatrix},$$

$$A_2 = \begin{pmatrix} -0.01 & 0 \\ 1 & -0.011 \end{pmatrix}.$$

Both matrices have the same eigenvalues. However, the eigenvectors of  $A_1$  are orthogonal, whereas the eigenvectors of  $A_2$  are

$$\xi_1 = \begin{pmatrix} 0.001 \\ 1.000 \end{pmatrix} \quad \text{and} \quad \xi_2 = \begin{pmatrix} 0 \\ 1.000 \end{pmatrix}.$$

Even though its eigenvalues differ by 10%, the eigenvectors of  $A_2$  are less than  $0.06^\circ$  from being exactly parallel. It is in this sense that we define this system as being “non-normal” or “nearly defective.”<sup>3</sup> This severe nonorthogonality of the system eigenvectors is a direct result of the disproportionately large coupling term  $C$ . Compensators that reduce  $C$  will make the eigenvectors of  $A_2$  closer to orthogonal without necessarily changing the system eigenvalues.

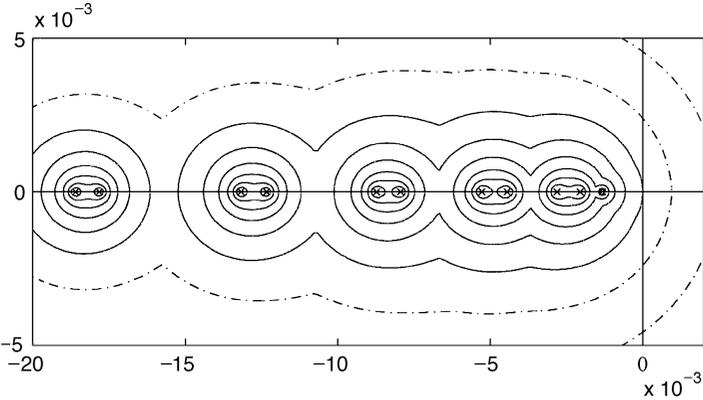

The consequences of nonorthogonality of the system eigenvectors are significant. Though the “energy” (the Euclidean norm) of the state of the system  $\dot{\mathbf{x}} = A_1 \mathbf{x}$  uniformly decreases in time from all initial conditions, the “energy” of the state of the system  $\dot{\mathbf{x}} = A_2 \mathbf{x}$  from the initial condition  $\mathbf{x}(0) = \xi_1 - \xi_2$  grows by a factor of over a thousand before eventually decaying due to the stability of the system. This is referred to as the *transient energy growth* of the stable non-normal system, and is a result of the reduced destructive interference exhibited by the two modes of the solution as they decay at different rates. In fluid mechanics, transient energy growth is thought to be an important linear mechanism leading to transition in subcritical flows, which are linearly stable but nonlinearly unstable [Butler and Farrell, 1992].

The excitation of such systems by external disturbances is well described in terms of the system norms  $\|T_{zw}\|_2$  and  $\|T_{zw}\|_\infty$ , which (as described previously) quantify the rms amplification of Gaussian and worst-case disturbances by the system. For example, consider a closed-loop system of the form of Eq. (13.9) with  $\tilde{B} = \tilde{C} = I$ . Taking the system matrix  $\tilde{A} = A_1$ , the norms of the system transfer function are  $\|T_{zw}\|_2 = 9.8$  and  $\|T_{zw}\|_\infty = 100$ . On the other hand, taking the system matrix  $\tilde{A} = A_2$ , the 2-norm of the

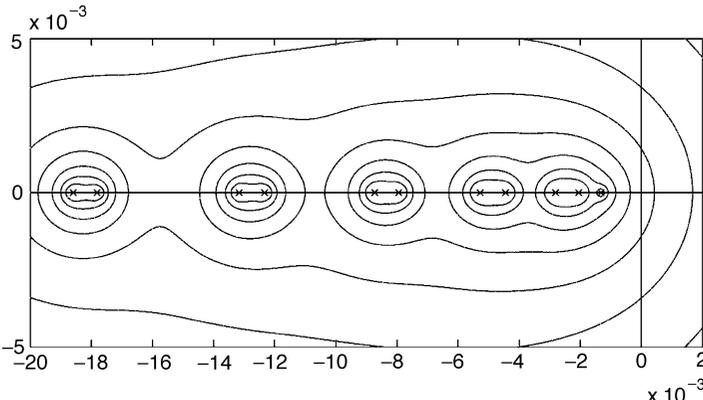

<sup>3</sup>Though this definition is dependent on the coordinate system and norm chosen to define the orthogonality of the eigenvectors, the physical systems we will consider lend themselves naturally to preferred norm definitions motivated by the energetics of the system. In particular, the nonlinear terms of the Navier–Stokes equation (which are neglected in the present linear analysis) are orthogonal only under certain norms related to the kinetic energy of the system at hand, suggesting a natural, physically motivated choice of norm for the systems we will consider.

system transfer function is 48 times larger and the  $\infty$ -norm is 91 times larger, though the two systems have identical closed-loop eigenvalues. Large system-transfer-function norms and large values of maximum transient energy growth are often highly correlated, as they both come about due to nonnormality in a stable system.

Graphical interpretations of  $\|T_{zw}\|_2$  and  $\|T_{zw}\|_\infty$  for the present channel flow system are given in Figures 13.3 and 13.4 by examining contour plots of the appropriate matrix norms of  $T_{zw}(s)$  in the complex plane  $s$ . Recall that  $T_{zw}(s) \triangleq C (sI - \tilde{A})^{-1} \tilde{B}$ , so these contours approach infinity in the neighborhood of each eigenvalue of  $\tilde{A}$ . Contour plots of this type have recently become known as the *pseudospectra* of an input/output system and have become a popular generalization of plots of the eigenvalues of  $A$  in recent efforts to study nonnormality in uncontrolled fluid systems [Trefethen et al., 1993]. For the open-loop systems depicted in these figures, we define  $\tilde{A} = A$ ,  $\tilde{B} = B_1$ , and  $\tilde{C} = C_1$ . The severe non-normality of the present fluid system for Fourier modes with  $k_x \approx 0$  is reflected by the elliptical isolines surrounding each pair of eigenvalues with nearly parallel eigenvectors in these pseudospectra, a feature that is much more pronounced in the system depicted in Figure 13.3 than in that depicted in Figure 13.4. The severe non-normality of the system depicted in Figure 13.3 is also reflected by its much larger value of  $\|T_{zw}\|_\infty$ .

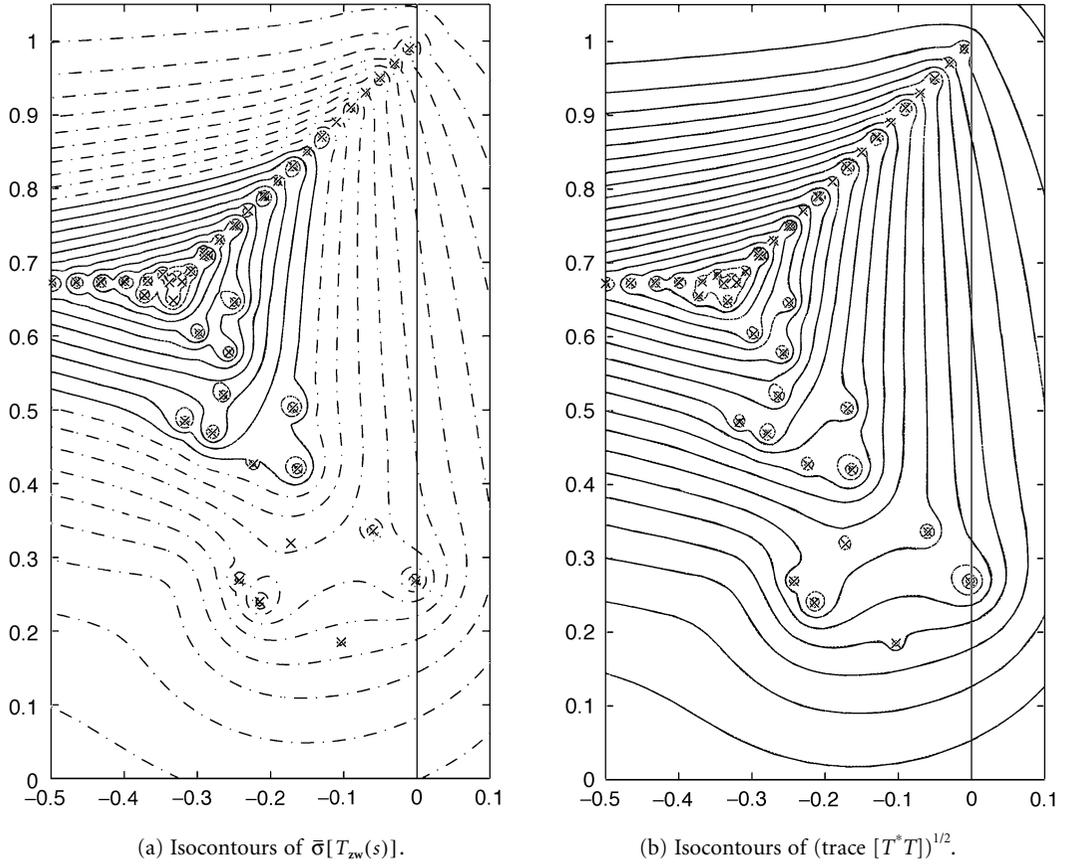

(a) Isocontours of  $\bar{\sigma}[T_{zw}(s)]$  in the complex plane  $s$ . The peak value of this matrix norm on the  $j\omega$  axis is defined as the system norm  $\|T_{zw}\|_\infty$  and corresponds to the solid isoline with the smallest value.

(b) Isocontours of  $(\text{trace}[T^*T])^{1/2}$  in the complex plane  $s$ . The system norm  $\|T_{zw}\|_2$  is related to the integral of the square of this matrix norm over the  $j\omega$  axis.

**FIGURE 13.3** Graphical interpretations (a.k.a. “pseudospectra”) of the transfer function norms  $\|T_{zw}\|_\infty$  (a) and  $\|T_{zw}\|_2$  (b) for the present system in open loop, obtained at  $k_x = 0$ ,  $k_z = 2$ , and  $Re = 5000$ . The eigenvalues of the system matrix  $A$  are marked with an  $\times$ . All isoline values are separated by a factor of 2, and the isolines with the largest value are those nearest to the eigenvalues. For this system,  $\|T_{zw}\|_\infty = 2.6 \times 10^5$ .

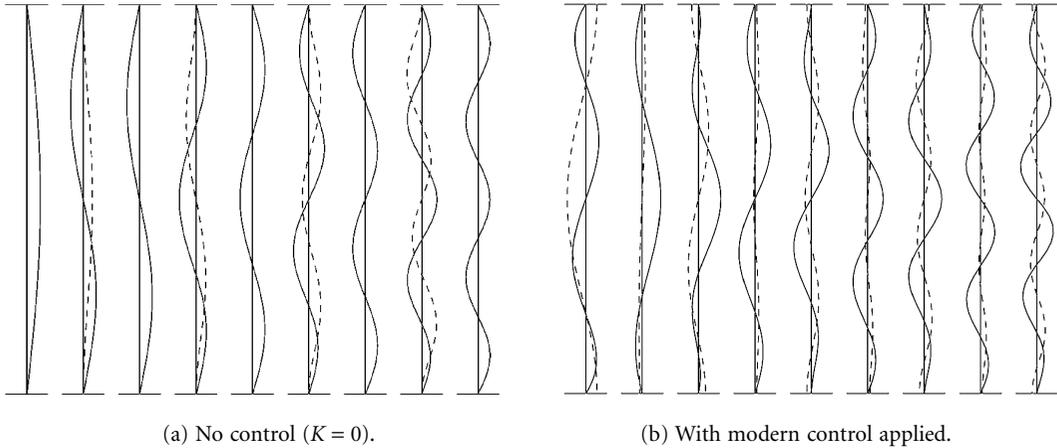

**FIGURE 13.4** Pseudospectra interpretations of  $\|T_{zw}\|_\infty$  (a) and  $\|T_{zw}\|_2$  (b) for the open loop system at  $k_x = -1$ ,  $k_z = 0$ , and  $Re = 5000$ . For plotting details, see Figure 13.3. For this system,  $\|T_{zw}\|_\infty = 1.9 \times 10^4$ .

As  $\{\tilde{A}, \tilde{B}, \tilde{C}\}$  may be defined for either the open-loop or the closed-loop case, this technique for analysis of non-normality extends directly to the characterization of controlled fluid systems.

The  $\mathcal{H}_\infty$  control technique is in fact based on minimizing the 2–norm of the system transfer function while simultaneously bounding the  $\infty$ –norm of the system-transfer function. In the current transition problem, our control objective is to inhibit the (linear) formation of energetic flow perturbations that can lead to nonlinear instability and transition to turbulence. It is natural that control techniques such as  $\mathcal{H}_\infty$ , which are designed upon the very transfer function norms that quantify the excitation of such flow perturbations by external disturbances, will have a distinct advantage for achieving this objective over control techniques that account for the eigenvalues only, such as those based on the analysis of root-locus plots.

### 13.3.3 Effectiveness of Control Feedback at Particular Wavenumber Pairs

The application of the modern control design approach described in Section 13.3.1 to the Orr-Sommerfeld/Squire problem laid out in Section 13.2 was explored extensively in BL98 for two particular wavenumber pairs and Reynolds numbers. The control effectiveness was quantified using several different techniques, including eigenmode analysis, transient energy growth, and transfer function norms. The control was remarkably effective and the trends with  $\{\ell, \alpha, \gamma\}$  were all as expected; the reader is referred to the journal article for complete tabulation of the results. One of the most notable features of this paper is that the application of the control resulted in the closed-loop eigenvectors becoming significantly closer to orthogonal, as illustrated in Figure 13.5; note especially the high degree of correlation between the second

**FIGURE 13.5** The nine least stable eigenmodes of the closed-loop system matrix  $A + B_2K$  for  $k_x = 0$ ,  $k_z = 2$ , and  $Re = 5000$ . Plotted are the nonzero part of the  $\hat{\omega}$  component of the eigenvectors (solid) and the nonzero part of the  $\hat{v}$  component of the eigenvectors (dashed) as a function of  $\gamma$  from the lower wall (bottom) to the upper wall (top). In (a), the dashed line is magnified by a factor of 1000 with respect to the solid line; in (b), the dashed line is magnified by a factor of 300. Note that the eigenvectors become significantly closer to orthogonal by the application of the control. (From Bewley, T.R., and Liu, S. (1998) *J. Fluid Mech.* **365**, 305–349. Reprinted with permission of Cambridge University Press.)

and third eigenvectors of Figure 13.5a, and how this correlation is disrupted in Figure 13.5b. This was accompanied by concomitant reductions in both transient energy growth and the system transfer function norms in the controlled system. Note that the nearly parallel nature of the pairs of eigenvectors  $\{\xi_2, \xi_3\}$ ,  $\{\xi_4, \xi_5\}$ ,  $\{\xi_6, \xi_7\}$ , and  $\{\xi_8, \xi_9\}$  in the uncontrolled case (Figure 13.5a) is also reflected by the elliptical isolines surrounding the corresponding eigenvalues illustrated by the pseudospectra of Figure 13.3.

Note the nonzero value of  $\hat{v}$  at the walls in Figure 13.5b; this reflects the wall blowing/suction applied as the control. Note also that half of the eigenvectors in Figure 13.5a have zero  $\hat{v}$  components. These are commonly referred to as the Squire modes of the system and are decoupled from the perturbations in  $\hat{v}$  because of the block of zeros in the upper-right corner of  $A$ . Such decoupling is not seen in Figure 13.5b, because the closed-loop system matrix  $A + B_2K$  is full.

## 13.4 Decentralization: Designing for Massive Arrays

As illustrated in Figures 13.6 and 13.7, there are two possible approaches for experimental implementation of linear compensators for this problem:

1. a centralized approach, applied in Fourier space, or
2. a decentralized approach, applied in physical space.

Both of these approaches may be used to apply boundary control (such as distributions of blowing/suction) based on wall information (such as distributions of skin friction measurements). Both approaches may be used to implement the  $\mathcal{H}_\infty$  compensators developed in Section 13.3, LQG/LTR compensators, PID feedback, or a host of other types of control designs. However, there are important differences in terms of the applicability of these two approaches to physical systems. The pros and cons of these approaches are now presented.

### 13.4.1 Centralized Approach

The centralized approach is simplest in terms of its derivation, as most linear compensators in this geometry are designed in Fourier space, leveraging the spatially invariant structure of this system mentioned previously and the complete decoupling into Fourier modes which this structure provides [Bewley

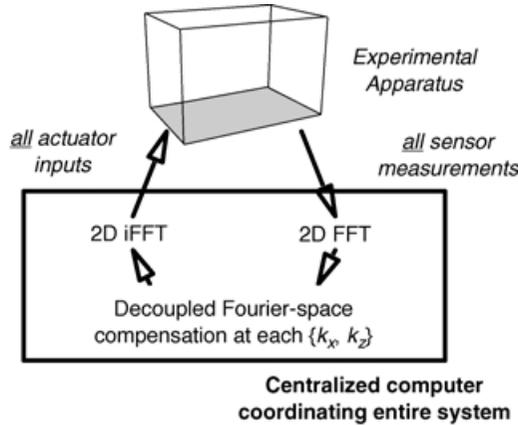

FIGURE 13.6 Centralized approach to the control of plane channel flow in Fourier space.

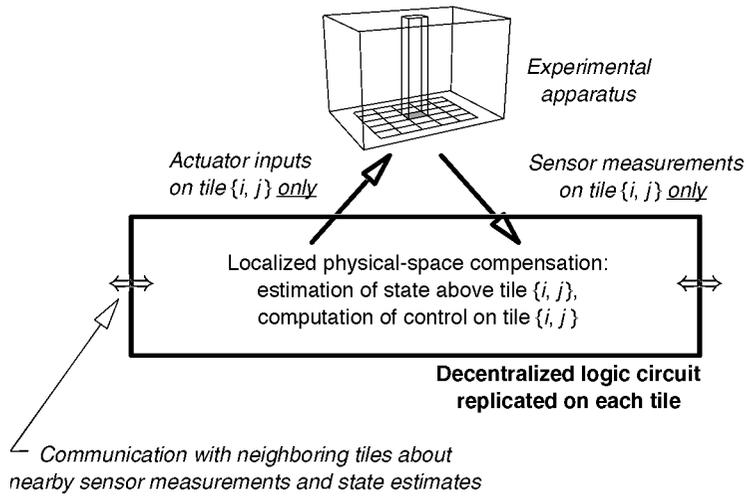

FIGURE 13.7 Decentralized approach to the control of plane channel flow in physical space.

and Agarwal, 1996]. As indicated in Figure 13.6, implementation of this approach is straightforward. This type of experimental realization was recommended by Cortelezzi and Speyer (1998) in related work. There are two major shortcomings of this approach:

1. The approach requires an online two-dimensional fast Fourier transform (FFT) of the entire measurement vector and an online two-dimensional inverse FFT (iFFT) of the entire control vector.
2. The approach assumes spatial periodicity of the flow perturbations.

With regard to point 1, it is important to note that the expense of centralized computations of two-dimensional FFTs and iFFTs will grow rapidly with the size of the array of sensors and actuators; to be specific, the computational expense is proportional to  $N_x N_y \log(N_x N_y)$ . This will rapidly decrease the bandwidth possible as the array size (and the number of Fourier modes) is increased for a fixed speed of the central processing unit (CPU). Communication of signals to and from the CPU is also an important limiting factor as the array size grows. Thus, this approach does not extend well to massive arrays of sensors and actuators.

With regard to point 2, it is important to note that transition phenomena in physical systems, such as boundary layers and plane channels, are not spatially periodic, though it is often useful to characterize

the solutions of such systems with Fourier modes. The application of Fourier-space controllers that assume spatial periodicity in their formulation to physical systems that are not spatially periodic will be corrupted by Gibb's phenomenon, the well-known effect in which a Fourier transform is spoiled across all frequencies when the data one is transforming are not themselves spatially periodic. In order to correct for this phenomenon in formulations based on Fourier-space computations of the control, windowing functions such as the Hanning window are appropriate. Windowing functions filter the signals coming into the compensator such that they are driven to zero near the edges of the physical domain under consideration, thus artificially imposing spatial periodicity on the non-spatially-periodic measurement vector.

### 13.4.2 Decentralized Approach

The decentralized approach, applied in physical space, is not as convenient to derive. Riccati equations of the size of the entire discretized three-dimensional system pictured in Figure 13.1 and governed by Eq. (13.1), represented in physical space appear to be numerically intractable.

However, if such a problem could be solved, one would expect that the controller feedback kernels relating the state estimate  $\hat{\mathbf{x}}$  inside the domain to the control forcing  $\mathbf{u}$  at some point on the wall should decay quickly as a function of distance from the control point, as the control authority of any blowing/suction hole drilled into the wall on the surrounding flow decays rapidly with distance in a distributed viscous system.

Similarly, the estimator feedback kernels relating measurement errors  $(\mathbf{y} - \hat{\mathbf{y}})$  at some point on the wall to the estimator forcing terms  $\mathbf{v}$  on the system model inside the domain should decay quickly as a function of distance from the measurement point, as the correlation of any two flow-perturbation variables is known to decay rapidly with distance in a distributed viscous system.

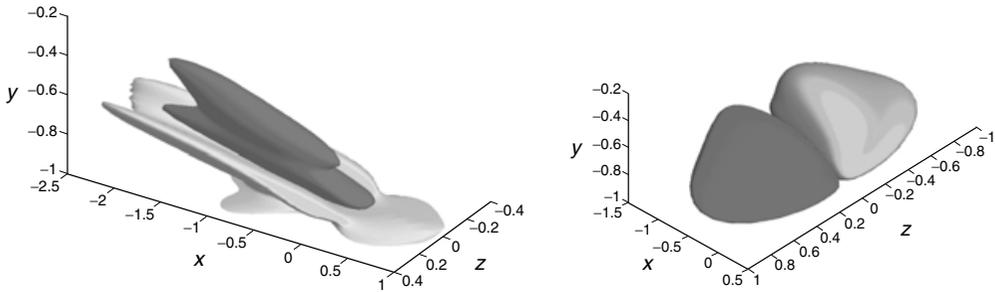

Finally, due to the spatially invariant structure of the problem at hand, the control and estimation kernels for each sensor and actuator on the wall should be identical, though spatially shifted.

In other words, the physical-space kernels sought to determine the control and estimator feedback are spatially localized convolution kernels. If their spatial decay rate is rapid enough (e.g., exponential), then we will be able to truncate them at a finite distance from each actuator and sensor while maintaining a prescribed degree of accuracy in the feedback computation, resulting in spatially compact convolution kernels with finite support.

With such spatially compact convolution kernels, decentralized control of the present system becomes possible, as illustrated in Figure 13.7. In such an approach, several tiles are fabricated, each with sensors, actuators and an identical logic circuit. The computations on each tile are limited in spatial extent, with the individual logic circuit on each tile responsible for the (physical-space) computation of the state estimate only in the volume immediately above that tile. Each tile communicates its local measurements and state estimates with its immediate neighbors, with the number of tiles over which such information propagates in each direction depending on the tile size and spatial extent of the truncated convolution kernels. By replication, we can extend such an approach to arbitrarily large arrays of sensors and actuators. Though additional truncation of the kernels will disrupt the effectiveness of this control strategy near the edges of the array, such edge effects are limited to the edges in this case (unlike Gibb's phenomenon) and should become insignificant as the array size is increased.

## 13.5 Localization: Relaxing Nonphysical Assumptions

As discussed previously, though the physical-space representation of the three-dimensional linear system is intractable in the controls setting, the (completely decoupled) one-dimensional systems at each wave-number pair  $\{k_x, k_z\}$  in the Fourier-space representation of this problem are easily managed. Remarkably, these two representations are completely equivalent. Performing a Fourier transform (which is simply a linear change of variables) of the *entire* three-dimensional system (including the state, the controls, the measurements and the disturbances) block diagonalizes *all* of the matrices involved in the three-dimensional physical-space control problem. With such block-diagonal structure, the constituent  $\mathcal{H}_\infty$  control problems

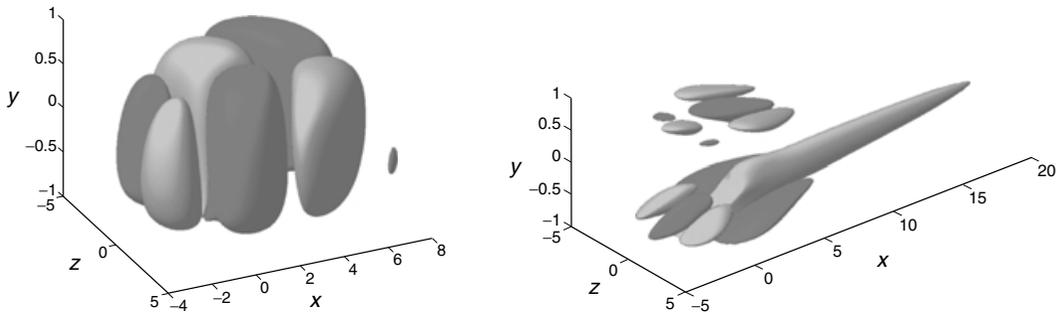

**FIGURE 13.8** (Color figure follows p. 12-26.) Localized controller gains relating the state estimate  $\hat{\mathbf{x}}$  inside the domain to the control forcing  $\mathbf{u}$  at the point  $\{x = 0, y = -1, z = 0\}$  on the wall. Visualized are a positive and negative isosurface of the convolution kernels for (left) the wall-normal component of velocity and (right) the wall-normal component of vorticity. (From Högberg, M., and Bewley, T.R., *Automatica* (submitted). With permission from Elsevier Science.)

at each wavenumber pair  $\{k_x, k_z\}$  may be solved independently and, once solved, reassembled in physical space with an inverse Fourier transform. If the numerics are handled properly, this approach is equivalent to solving the three-dimensional physical-space control problem directly.

Recent theoretical work on this problem by Bamieh et al. (2000), and related work by D’Andrea and Dullerud (2000), further support the notion that an array of  $\mathcal{H}_\infty$  compensators developed at each wavenumber pair, when inverse-transformed back to the physical domain, should in fact result in spatially localized convolution kernels with exponential decay. This exponential decay, in turn, allows truncation of the kernels to any prescribed degree of accuracy. Thus, if the truncated kernels are allowed to be sufficiently large in streamwise and spanwise extent, favorable closed-loop system properties, such as robust stability and reduced system transfer function norms, may be retained. Until very recently, however, it has not been possible to obtain such kernels for Navier–Stokes systems, due to an assortment of numerical challenges.

In Högberg and Bewley (2000), spatially localized convolution kernels for both the control and estimation of plane channel flow have finally been obtained. The technique used was based on that described previously, deriving (in our initial efforts)  $\mathcal{H}_2$  compensation at an array of wavenumber pairs  $\{k_x, k_z\}$  and then inverse-transforming the lot, with special attention paid to the details of the control formulation and the numerical method. In particular, a numerical discretization technique not plagued by spurious eigenvalues was chosen, and the control formulation was slightly modified such that the time derivative of the blowing/suction velocities is penalized in the cost function. The resulting localized kernels are illustrated in Figures 13.8 and 13.9. Such kernels facilitate the decentralized control implementation discussed in Section 13.4.2 and depicted in Figure 13.7, paving the way for experimental implementation with massive arrays of tiles integrating sensing, actuating and the control logic.

Note that the control convolution kernels shown in Figure 13.8 angle away from the wall in the *upstream* direction. Coupled with the mean flow profile indicated in Figure 13.1, this accounts for the convective delay which requires us to anticipate flow perturbations on the interior of the domain with actuation on the wall somewhere downstream. The estimation convolution kernels shown in Figure 13.9, on the other hand, extend well *downstream* of the measurement point. This accounts for the delay between the motions of the convecting flow structures on the interior of the domain and the eventual influence of these motions on the local drag profile on the wall; during this time delay, the flow structures responsible for these motions convect downstream. Note that the upstream bias of the control kernels and the downstream bias of the estimation kernels, though physically tenable, were not prescribed in the problem formulation. A *posteriori* study of the streamwise, spanwise, and wall-normal extent, the symmetry, and the shape of such control and estimation kernels provides us with a powerful new tool with which the fundamental physics of this distributed fluid-mechanical system may be characterized.

**FIGURE 13.9** (Color figure follows p. 12-26.) Localized estimator gains relating the measurement error  $(\mathbf{y} - \hat{\mathbf{y}})$  at the point  $\{x = 0, y = -1, z = 0\}$  on the wall to the estimator forcing terms  $\mathbf{v}$  inside the domain. Visualized are a positive and negative isosurface of the convolution kernels for (left) the wall-normal component of velocity and (right) the wall-normal component of vorticity. (From Högberg, M., and Bewley, T.R., *Automatica* (submitted). With permission from Elsevier Science.)

The localized convolution kernels illustrated in Figures 13.8 and 13.9 are approximately independent of the computational box of the size in which they were computed, so long as this box is sufficiently large. Thus, when implementing these kernels, we may effectively assume that they were derived in an *infinite*-sized box, relaxing the nonphysical assumption of spatial periodicity used in the problem formulation and modeling the physical situation of spatially evolving flow perturbations in a spatially invariant geometry and mean flow.

The localized convolution kernels illustrated in Figures 13.8 and 13.9 are also approximately independent of the computational mesh resolution with which they were computed, so long as this computational mesh is sufficiently fine. Indeed, a computational mesh sufficient to resolve the flow under consideration also adequately resolves these convolution kernels.

### 13.5.1 Open Questions

As we have shown, the framework for decentralized  $\mathcal{H}_\infty$  control of the fully resolved transition problem in the geometry depicted in Figure 13.1 is now established. Obtaining spatial localization of the convolution kernels in physical space was the final remaining conceptual/numerical hurdle to be overcome. This work paves the way for decentralized application of such compensation with massive arrays of identical control tiles integrating sensing, actuation and the control logic (Figure 13.7). Though in some sense “complete,” this effort has also exposed several fundamental open questions, which will now be briefly discussed.

For a given choice of the matrices  $\{B_1, B_2, C_1, C_2\}$  and design parameters  $\{\ell, \alpha, \gamma > \gamma_0\}$  selected, decentralized  $\mathcal{H}_\infty$  compensators may be determined using the procedure described above, and performance and robustness benchmarks may be obtained via simulation. As a final step in the control design process, it is of interest to explore how much the computational effort required by the logic on each tile may be reduced without significant degradation in the closed-loop system behavior. This can lead to a significant reduction in the number of floating point operations per second required by the logic circuit on each tile. However, as will be discussed in Section 13.6, compensator reduction in the decentralized setting remains a significant unsolved problem; standard reduction strategies developed for finite, closed systems are not applicable and new research is motivated.

With the decentralized linear control framework established and prototypical numerical examples solved, we are now in a position to explore the effectiveness of compensators computed via this framework to the finite-amplitude perturbations that actually lead to transition, and to the “large” amplitude perturbations of fully developed turbulence, in the nonlinear equations of fluid motion. An extensive analytical and numerical study within this framework is underway. Issues regarding our preliminary

efforts in this direction are briefly reviewed in Section 13.7. As emphasized in the introduction, such a study should be guided by an interdisciplinary perspective in order to be maximally successful. Specifically, such a study should fully incorporate the known or postulated linear mechanisms leading to transition or, in the case of turbulence, the linear mechanisms thought to be at least partially responsible for sustaining the turbulent cascade of energy. In addition, this effort motivates the development of new analytical tools that might help clarify the types of state disturbances and flow perturbations that are particularly important in such phenomena. Armed with such an understanding, large benefits might be realized in the compensator design, as the modeling of the structure of the state disturbances exciting the system,  $G_1$ , and the weighting on the flow perturbations of interest in the cost function,  $Q$ , are important design criteria. In fact, we fully expect that the transfer of information between our physical understanding of fundamental flow phenomena and our knowledge of how to control such phenomena will be a two-way transfer. Such a strategy promises to provide powerful new tools for obtaining fundamental physical understanding of classical problems in fluid mechanics as we gain new insight in how to modify these phenomena by the action of control feedback.

A host of other canonical flow control problems, including the control of spatially developing boundary layers, bluff-body flows, and free shear layers, should also be amenable to linear control application using the framework outlined here. A few such extensions are discussed briefly in Section 13.8.

## 13.6 Compensator Reduction: Eliminating Unnecessary Complexity

---

Strategies for the development of reduced-order decentralized compensators of the present form remain a key unsolved issue. With the  $\mathcal{H}_2/\mathcal{H}_\infty$  approach, as described previously, a physical-space state estimate in the volume immediately above each tile must be updated online by the logic circuit on each tile as the flow evolves. However, it is not at all necessary for the compensator to compute an accurate state estimate as an intermediate variable; indeed, our only requirement is that, based on whatever filtered information the dynamic compensator does extract from the noisy system measurements, suitable controls may be determined to achieve the desired closed-loop system behavior. It should be possible to reduce substantially the complexity of the dynamic compensator and still achieve this more modest objective.

There are two possible representations in which the complexity of the compensator can be reduced: in Fourier space (where the compensator is designed) or in physical space (where the decentralized compensation is applied).

### 13.6.1 Fourier-Space Compensator Reduction

At any particular wavenumber pair  $\{k_x, k_z\}$ , there is one actuator variable at each wall, one sensor variable at each wall, and a spatial discretization in  $y$  of the state variables across the domain stretching between these walls. Due to the complete decoupling of the control problem into separate Fourier modes, the system model used in the estimator at each particular wavenumber pair is not referenced by the compensator at any other wavenumber pair. Thus, the compensators at each wavenumber pair are completely decoupled and may be reduced independently. At certain wavenumber pairs, it might be important to retain several degrees of freedom in the dynamic compensator, while at other wavenumber pairs, it might be possible to retain significantly fewer degrees of freedom without significant degradation in the closed-loop system behavior. Several existing compensator reduction strategies are well suited to this problem, and their application in this setting is straightforward. Cortelezzi and Speyer (1998) successfully applied the balanced truncation technique of open-loop model reduction in this Fourier-space framework in order to facilitate the design of a reduced-complexity dynamic compensator.

As mentioned earlier, it is the nonorthogonality of the entire set of system eigenvectors that leads to the peculiar (and important) possibilities for energy amplification in these systems, so compensator

reduction techniques mindful of the relevant transfer function norms are necessary. In addition, as eloquently described by Obinata and Anderson (2000), it is most appropriate when designing low-order compensators for high-order plants to reduce the compensator while accounting for how it performs in the closed loop. An assortment of closed-loop compensator reduction techniques are now available and should be tested in future work.

In the setting of designing a decentralized compensator, there is an important shortcoming to performing standard compensator reductions in Fourier space. As the compensator reduction problem is independent at each wavenumber pair, we might be left with a different number of degrees of freedom in the reduced-order compensator at each wavenumber pair, leaving us with a dynamical system model that is impossible to inverse transform back into the physical domain. Even if we restrict the compensator reduction algorithm to reduce to the same number of degrees of freedom at each wavenumber pair (a restrictive assumption that should be unnecessary), there appears to be no appropriate strategy currently available to coordinate this reduction process across all wavenumbers in a consistent manner such that the inverse transform of the reduced dynamic model is spatially localized. Without such coordination, it seems inevitable that the ordering and representation of the various modes of this dynamic model will be scrambled during the process of compensator reduction at each wavenumber pair, resulting in an inverse-transform back in physical space that does not exhibit the spatial localization which is essential to facilitate decentralized control.

### 13.6.2 Physical-Space Compensator Reduction

As an alternative to Fourier-space compensator reduction, one might consider instead the reduction of the physical-space model and its associated localized convolution kernels. This has several advantages linked to the fact that this is the actual compensation to be computed on each tile. The first advantage is that spatial localization will be retained, as compensator reduction is applied after the localized kernels are obtained. Another important advantage is that this setting allows us to keep more degrees of freedom in the dynamical system model to represent streamwise and spanwise fluctuations of the state near the wall than we retain to represent the behavior of the state on the interior of the domain. This effectively relaxes the restrictive assumption referred to in the previous paragraph. Such an emphasis on resolving the state near the wall is motivated by inspection of the convolution kernels plotted in [Figures 13.8](#) and [13.9](#), in which it is clear that the details of the flow near the wall are of increased importance when computing the feedback.

However, note that the system model simulated on each individual tile is not self-contained, due to the interconnections with neighboring tiles indicated in [Figure 13.7](#). Thus, if one reduces the system model above a single tile, all neighboring tiles that reference this state estimate will be affected. As the system model is not self-contained, as it was in the Fourier-space case, existing compensator reduction approaches are not applicable.

An important observation, however, is that the structure of the system model carried by each tile is identical. Due to the repeated structure of the model represented on the array, it is sufficient to optimize the system model carried by a single tile. The repeated structure of the distributed physical-space model should make the compensator reduction problem tractable. This fundamental problem of reducing distributed, interconnected dynamic compensators in the decentralized closed-loop setting remains, as yet, unsolved.

### 13.6.3 Nonspatially Invariant Systems

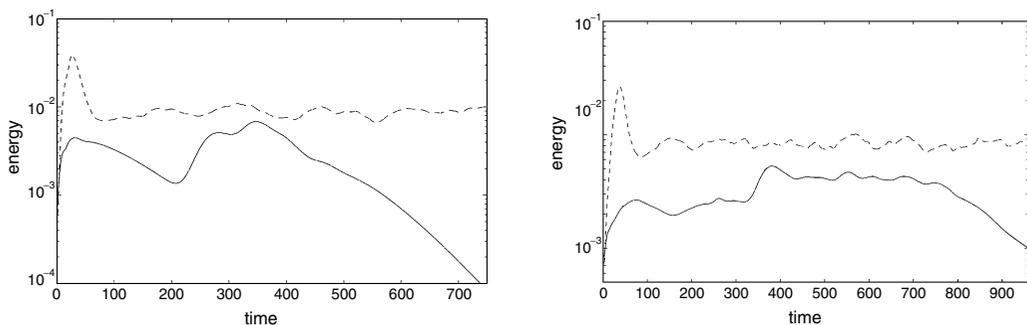

Finally, it should be stated that the Fourier-space decoupling leveraged at the outset of this problem formulation has been one of the key ingredients that have permitted accurate solution of well-resolved canonical flow control problems to date. The linear control technique we have used to solve these control problems involves the solution of matrix Riccati equations, which are accurately soluble for state dimensions only up to  $O(10^3)$ . As we move to more applied flow control problems in which such Fourier-space decoupling is either more restrictive or not available, if we continue to use Riccati-based control approaches,

creative new compensator reduction strategies will be required. We might need to apply “open-loop” model reduction strategies (in advance of computing the control feedback and closing the loop) in order to make manageable the dimension of the Riccati equations to be solved in the compensator formulation. As mentioned earlier, it is most appropriate when designing low-order compensators for high-order plants to reduce the compensator while accounting for how it performs in the closed loop. Unfortunately, extremely high-order discretizations of nonspatially invariant PDE systems will not likely afford us this luxury, as such systems do not decouple (via Fourier transforms) into constituent lower-order control problems amenable to matrix-based compensator design strategies.

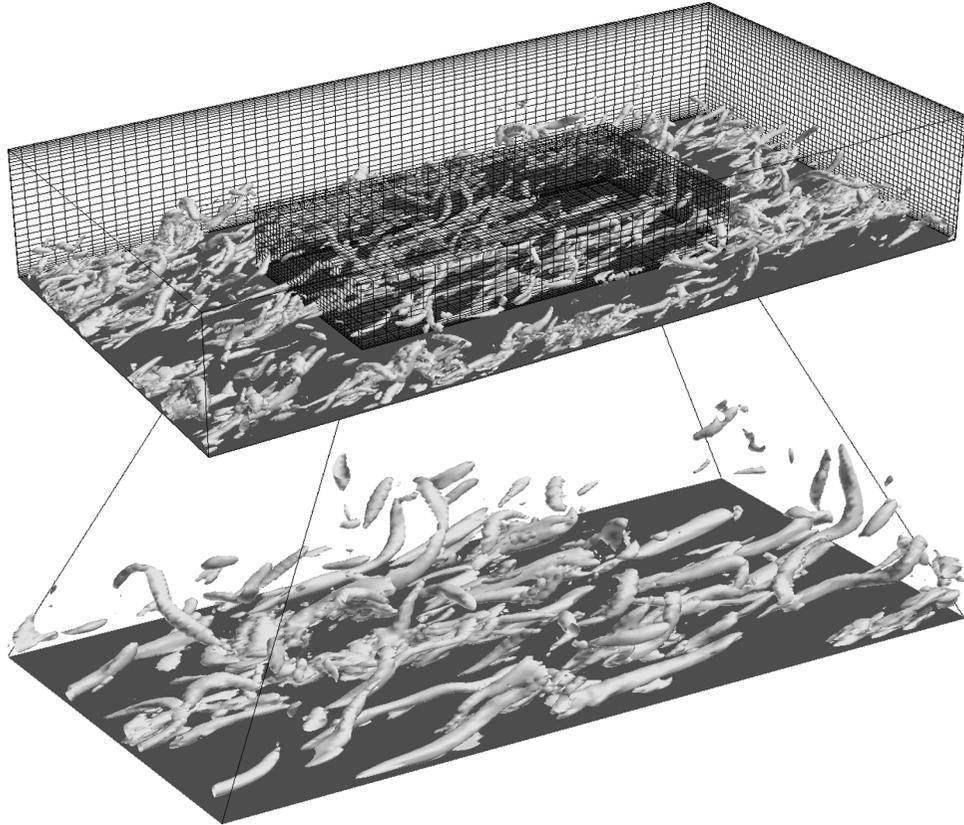

### 13.7 Extrapolation: Linear Control of Nonlinear Systems

Once a decentralized linear compensator of the present form is developed, a verification of its utility for the transition problem may be obtained by applying it to the laminar flow depicted in Figure 13.1 with either finite-amplitude (but sufficiently small) initial flow perturbations and/or finite-amplitude (but sufficiently small) applied external disturbances. The resulting finite-amplitude flow perturbations are governed by the fully nonlinear Navier–Stokes equation and have been simulated in well resolved direct numerical simulations (DNS) with the code benchmarked in Bewley et al. (2001). Representative simulations are shown in Figure 13.10, indicating that linear compensators can indeed relaminarize perturbed flows that would otherwise proceed rapidly towards transition to turbulence. With the framework presented here, extensive numerical studies promise to significantly extend our fundamental understanding of the process of transition and how this process may be inhibited by control feedback.

It is also of interest to consider the application of decentralized linear compensation to the fully nonlinear problem of a turbulent flow, such as that shown in Figure 13.11. The first reason to try such an approach is simply because we can: linear control theory leads to implementable control algorithms and grants a lot of flexibility in the compensator design. Nonlinear turbulence control strategies, though currently under active development (see Sections 13.9 to 13.13), are much more difficult to design and implement and require substantial further research before they will provide implementable control strategies as flexible and powerful as those which we currently have at our disposal in the linear setting.

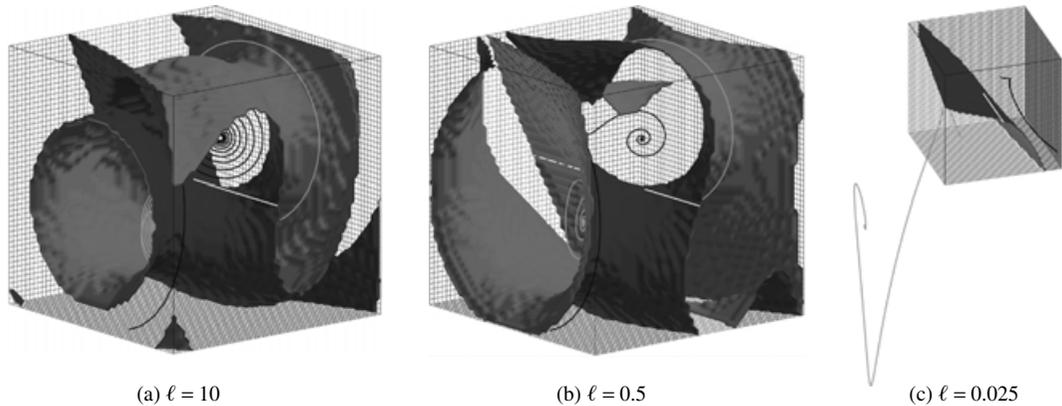

**FIGURE 13.10** Evolution of oblique waves (left) and an initially random flow perturbation (right) added to a laminar flow at  $Re = 2000$ , with and without decentralized linear control feedback. The magnitude of the initial flow perturbations in these simulations greatly exceed the thresholds reported by Reddy et al. (1998) that lead to transition to turbulence in an uncontrolled flow (by a factor of 225 for the oblique waves and by a factor of 15 for the random initial perturbation). Solid lines indicate the energy evolution in the controlled case, dashed lines indicate the energy evolution in the uncontrolled case. Both of the uncontrolled systems lead quickly to transition to turbulence, whereas both of the controlled systems relaminarize. For the controlled cases, initial perturbations with greater energy fail to relaminarize, whereas initial perturbations with less energy relaminarize earlier. (From Högberg, M., and Bewley, T.R., *Automatica* (submitted). With permission from Elsevier Science.)

**FIGURE 13.11** (Color figure follows p. 12-26.) Visualization of the coherent structures of uncontrolled near-wall turbulence at  $Re_\tau = 180$ . Despite the geometric simplicity of this flow (see Figure 13.1), it is phenomenologically rich and is characterized by a large range of length scales and time scales over which energy transport and scalar mixing occur. The relevant spectra characterizing these complex nonlinear phenomena are continuous over this large range of scales, thus such flows have largely eluded accurate description via dynamic models of low state dimension. The nonlinearity, the distributed nature, and the inherent complexity of its dynamics make turbulent flow systems particularly challenging for successful application of control theory. (Simulation by Bewley, T.R., Moin, P., and Temam, R. (2001) *J. Fluid Mech.* Reprinted with permission of Cambridge University Press.)

There is some evidence in the fluids literature that applying linear control feedback to turbulence might be at least partially effective. Though the significance of this result has been debated in the fluid mechanics community, Farrell and Ioannou (1993) have clearly shown that linearized Navier–Stokes systems in plane channel flows, when excited with the appropriate stochastic forcing, exhibit behavior reminiscent of the streamwise vortices and streamwise streaks that characterize actual near-wall turbulence. Whatever information the linearized Navier–Stokes equation actually contains about the mechanisms sustaining these turbulence structures, the present linear control framework (perhaps restricted to a finite horizon) should be able to exploit. Though the life cycle of the near-wall coherent structures of turbulence appears to involve important nonlinear phenomena [see, e.g., Hamilton et al., 1995], that in itself does not disqualify the utility of linear control strategies to effectively disrupt critical linear terms of this nonlinear process. Indeed, recent numerical experiments by Kim and Lim (2000) support this idea by conclusively demonstrating the importance of the coupling term  $C$  in the linearized system matrix  $A$  (see Eq. (13.10)) for maintaining near-wall turbulence in nonlinear simulations.

**FIGURE 13.12** (Color figure follows p. 12-26.) Example of the spectacular failure of linear control theory to stabilize a simple nonlinear chaotic convection system governed by the Lorenz equation. Plotted are the regions of attraction to the desired stationary point (blue) and to an undesired stationary point (red) in the linearly controlled nonlinear system, and typical trajectories in each region (black and green, respectively). The cubical domain illustrated is  $\Omega = (-25, 25)^3$  in all subfigures; for clarity, different viewpoints are used in each subfigure. (Reprinted from Bewley, T.R. (1999) *Phys. Fluids* **11**, 1169–1186. Copyright 1999, American Institute of Physics. With permission.)

In order to understand the possible pitfalls of applying linear feedback to nonlinear systems, a low-order nonlinear convection problem governed by the Lorenz equation was studied by Bewley (1999). As with the problem of turbulent channel flow, but in a low-order system easily amenable to analysis, control feedback was determined with linear control theory by linearizing the governing equation about a desired fixed point. Once a linear controller was determined by such an approach, it was then applied directly to the fully nonlinear system. The result is depicted in [Figure 13.12](#).

For control feedback determined by linear control theory with a large weighting  $\ell$  on the control effort, direct application of linear feedback to the full nonlinear system stabilizes both the desired state and an undesired state, indicated by the two trajectories marked in [Figure 13.12a](#). An unstable manifold exists between these two states, indicated by the contorted surface shown. Any initial state on one side of this manifold will converge to the desired state, and any initial state on the other side of this manifold will converge to the undesired state.

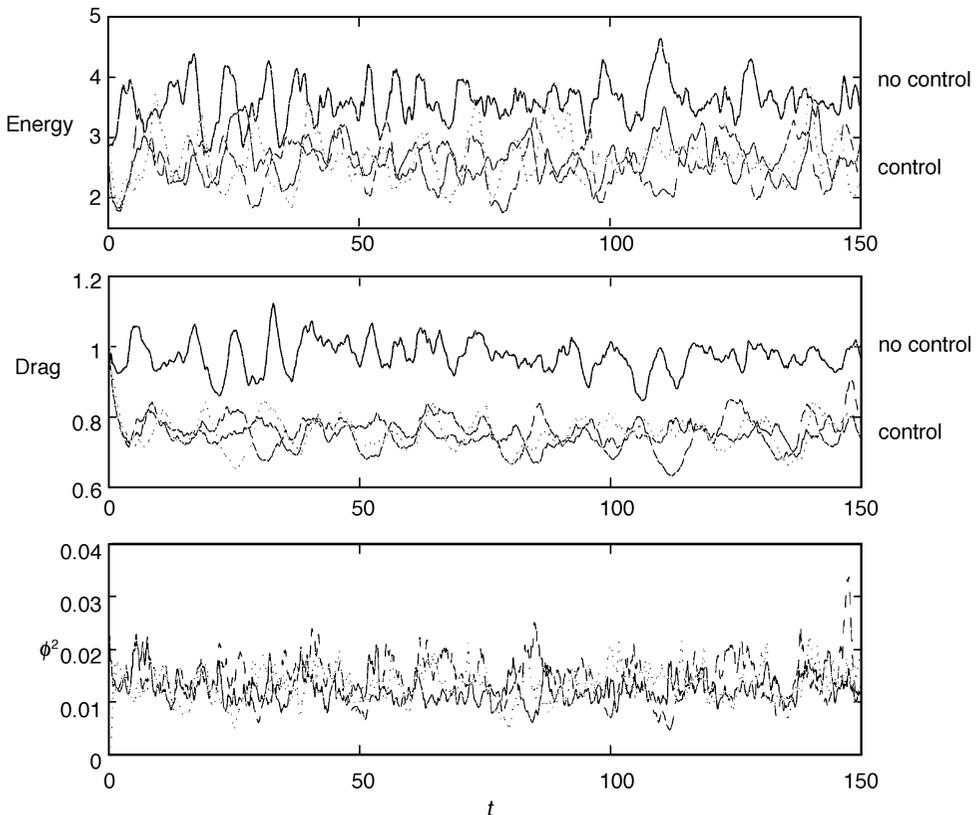

As seen in [Figures 13.12b](#) and [c](#), as the weighting on the control effort  $\ell$  is turned down and the desired stationary state is stabilized more aggressively, the domain of convergence to the undesired stabilized state remains large. This undesired state is “aggravated” by the enhanced control feedback, moving farther from the origin. The undesired state eventually escapes to infinity for sufficiently small  $\ell$ , indicating instability of the nonlinear system from a wide range of initial conditions even though the desired stationary point is endowed with a high degree of linear stability. Implication: strong linear stabilization of a desired system state (such as laminar flow) will not necessarily eliminate undesired nonlinear system behavior (such as turbulence) in a chaotic system.

Some form of nonlinearity in the feedback rule was required to eliminate this undesired behavior. One effective technique is to apply a switch such that the linear control feedback is turned on only when the state  $\mathbf{x}(t)$  is within some sufficiently small neighborhood of the desired stabilized state  $\bar{\mathbf{x}}$  in the linearly controlled system. The chaotic dynamics of the uncontrolled Lorenz system will bring the system into this neighborhood in finite time, after which control may be applied to “catch” the system at the desired equilibrium state.

Thus, even in this simple model problem, linear feedback can have a destabilizing influence if applied outside the neighborhood for which it was designed. For the full Navier–Stokes problem, though a certain set of linear feedback gains might stabilize the laminar state, on the “other side of the manifold” might

lie a turbulent state aggravated by the same linear controls. Application of linear control to nonlinear chaotic systems must therefore be done with vigilance, lest nonlinearities destabilize the closed-loop system, as shown here. The easy fix found for this low-order model problem (that is, simply turn off the control until the chaotic dynamics bring the state into a neighborhood of the desired state) might not be available for the (high-dimensional) problem of turbulence, as fully turbulent flows appear to remain at all times far from the laminar state.

In our preliminary attempts at applying the decentralized compensators developed above to turbulence, we have succeeded in reducing the drag of a fully developed turbulent flow by 25% with state-feedback controllers, as shown in Figure 13.13. Interestingly, for the choice of control parameters selected here, there is no evidence of an aggravated turbulent state. A 25% drag reduction, though significant, is comparable to the drag reductions obtained with a variety of other *ad hoc* control approaches in this flow. We are actively pursuing modification of this linear control feedback to improve upon this result. Interdisciplinary considerations, such as those involved in the design of linear compensation for the problem of transition, are essential in this effort. Specifically, the (unmodeled) nonlinear terms in the Navier–Stokes equation provide insight as to the structure of the disturbances,  $G_1$ , to be accounted for in the linear control formulation in order to best compensate for their unmodeled effects. Additionally,

**FIGURE 13.13** Evolution of fully developed turbulence at  $Re_\tau = 100$  with and without decentralized linear control feedback. Note that this flow has approximately the same mass flux as the laminar flow at  $Re = 2000$ . (Top) Energy of flow perturbation. (Middle) Drag (note approximately 25% reduction in the controlled cases). (Bottom) Control effort used. The uncontrolled energy and drag are the (upper) solid lines in the top and middle figures. A gain scheduling approach is used to tune the control feedback gains to the instantaneous mean flow profile. (From Höggberg, M., and Bewley, T.R., *Automatica* (submitted). With permission from Elsevier Science.)

the coherent structures of fully developed near-wall turbulence, believed to be a major player in the self-sustaining nonlinear process of turbulence generation near the wall, provide a phenomenological target that may be exploited in the selection of the weighting on the flow perturbations  $Q$  in the cost function.

## 13.8 Generalization: Extending to Spatially Developing Flows

Extension of the decentralized linear control framework developed here to a large class of slightly nonparallel flows is heuristic but straightforward. To accomplish this, the parabolic mean flow profile  $U(y)$  indicated in Figure 13.1 is replaced with an appropriate “quasi-one-dimensional” profile, such as the Blasius boundary layer profile. As long as the mean flow profile evolves slowly enough in space (as compared to the wavelengths of the significant instabilities in the problem), it may be assumed to be constant in space for the purpose of developing the linear control feedback. Such an assumption of slow spatial divergence forms the foundation of the study of local and global modes used in the characterization of absolute and convective instabilities [Huerre and Monkewitz, 1990], and has proven to be a quite powerful concept. For the appropriate flows, we believe this concept is also appropriate in the context of the development of control feedback.

Implementation of the decentralized control concept in this setting is a heuristic extension of the approach presented in Figure 13.7: gradual variations in the mean flow are accounted for by local extension of the mean flow profile in the compensator derivation for each tile, gradually scaling the compensation rules from one tile to the next as the flow develops downstream. For example, we may consider developing this strategy for the laminar boundary layer (LBL) solutions of the Falkner–Skan–Cooke family, found by solving the ordinary differential equation (ODE)

$$f''' + ff'' + \beta(1 - f'^2) = 0$$

with  $f(0) = f'(0) = 0$  and  $f'(\infty) \rightarrow 1$  and defining

$$U = U_0 f'(\eta) \quad \text{and} \quad V = \sqrt{\frac{\nu U_0}{2x}} [\eta f'(\eta) - f(\eta)].$$

Cases of interest include the Blasius profile, modeling a zero-pressure-gradient, flat-plate LBL with

$$U_0 = U_\infty, \quad \beta = 0, \quad \eta = y \sqrt{\frac{U_0}{2\nu x}},$$

the Falkner–Skan profile, modeling a nonzero-pressure-gradient LBL or wedge flow by taking

$$U_0 = Kx^m, \quad \beta = \frac{2m}{1+m}, \quad \eta = y \sqrt{\frac{(m+1)U_0}{2\nu x}},$$

and the Falkner–Skan–Cooke profile, which models the addition of sweep to the leading edge by solving the supplemental ODE

$$g'' + fg' = 0$$

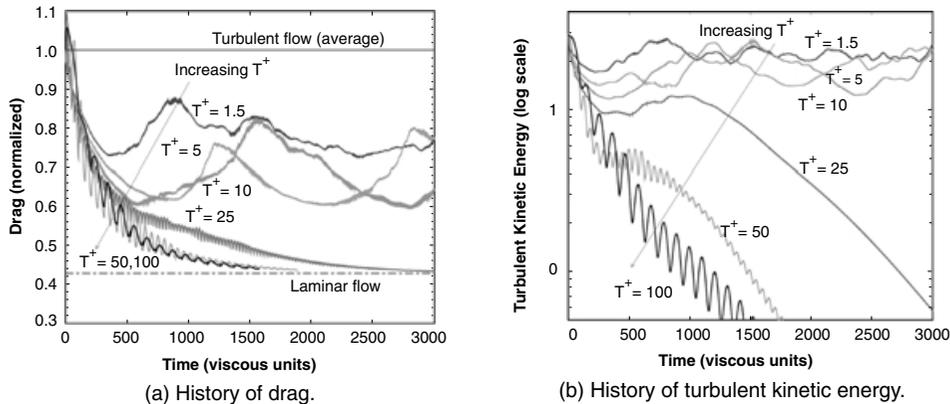

with  $g(0) = 0$  and  $g(\infty) \rightarrow 1$  and defining  $W = W_\infty g(\eta)$ . Note that the self-similarity of the LBL profiles might lead to simplified parameterizations of the convolution kernels for the control and estimation problems. Extension of this approach to a variety of other spatially developing flows (self-similar or otherwise) should also be straightforward.

## 13.9 Nonlinear Optimization: Local Solutions for Full Navier–Stokes

Given an idealized setting of full state information, no disturbances, and extensive computational resources, significant finite-horizon optimization problems may be formulated and (locally) solved for complex nonlinear systems using iterative, adjoint-based, gradient optimization strategies. Such optimization problems can now be solved for high-dimensional discretizations of turbulent flow systems, incorporating the full nonlinear Navier–Stokes equation, locally minimizing cost functionals representing a variety of control problems of physical interest within a given space of feasible control variables. The mathematical framework for such optimizations will be reviewed briefly in Section 13.9.1 and is described in greater detail by Bewley, Moin, and Temam (2001), hereafter referred to as BMT01.

The optimizations obtained via this approach are, strictly speaking, only “local” over the domain of feasible controls (that is, unless restrictive assumptions are made in the formulation of the control problem). Thus, the performance obtained via this approach usually cannot be guaranteed to be “globally optimal.” However, the performance obtained with such nonlinear optimizations often far exceeds that possible with other control design approaches (see, for example, Figure 13.14). In addition, this approach is quite flexible, as it can be used to iteratively improve high-dimensional control distributions directly, as will be illustrated below, or, alternatively, to optimize open-loop forcing schedules, shape functions, or the coefficients of practical, implementable, and possibly nonlinear feedback control rules. Thus, interest in adjoint-based optimization strategies for turbulent flow systems goes far beyond that of establishing performance benchmarks via predictive optimizations of the control distribution itself. Establishing such benchmarks is only a first step toward a much wider range of applications for adjoint-based tools in turbulent flow systems.

The general idea of this approach, often referred to as *model predictive control*, is well motivated by comparing and contrasting it to massively parallel brute-force algorithms recently developed to play the game of chess. The goal when playing chess is to capture the other player’s king through an alternating

**FIGURE 13.14** (Color figure follows p. 12-26.) Performance of optimized blowing/suction controls for formulations based on minimizing  $\mathcal{J}_0(\phi)$ , case *c* (see Section 13.9.1.2), as a function of the optimization horizon  $T^+$ . The direct numerical simulations of turbulent channel flow reported here were conducted at  $Re_\tau = 100$ . For small optimization horizons ( $T^+ = O(1)$ , sometimes called the “suboptimal approximation”), approximately 20% drag reduction is obtained, a result that can be obtained with a variety of other approaches. For sufficiently large optimization horizons ( $T^+ \geq 25$ ), the flow is returned to the region of stability of the laminar flow, and the flow relaminarizes with no further control effort required. No other control algorithm tested in this flow to date has achieved this result with this type of flow actuation. (From Bewley, T.R., Moin, P., and Temam, R., *J. Fluid Mech.*, to appear. With permission of Cambridge University Press.)

series of discrete moves with the opponent; at any particular turn, a player has to select one move out of at most 20 or 30 legal alternatives.

To accomplish its optimization, a computer program designed to play the comparatively “simple” game of chess, such as *Deep Blue* [Newborn, 1997], must, in the worst case, plan ahead by iteratively examining a tree of possible evolutions of the game several moves into the future [Atkinson, 1993], a strategy based on “function evaluations” alone. At each step, the program selects the move that leads to its best expected outcome, given that the opponent is doing the same in a truly noncooperative competition. The version of *Deep Blue* that defeated Garry Kasparov in 1997 was able to calculate up to 200 billion moves in the three minutes it was allowed to conduct each turn. Even with this extreme number of function evaluations at its disposal on this relatively simple problem, the algorithm was only about an even match with Kasparov’s human intuition.

An improved algorithm compared to those based on function evaluations alone, suitable for optimizing the present problem in a reasonable amount of time, is available because (1) we know the equation governing the evolution of the present system, and (2) we can state the problem of interest as a functional to be minimized. Taking these two facts together, we may devise an iterative procedure based on gradient information, derived from an *adjoint field*, to optimize the controls for the desired purpose on the prediction horizon of interest in an efficient manner. Only by exploiting such gradient information can the high-dimensional optimization problem at hand (up to  $O(10^7)$  control variables per optimization horizon in some of our simulations) be made tractable.

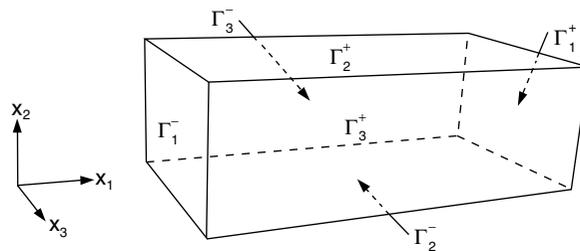

### 13.9.1 Adjoint-Based Optimization Approach

#### 13.9.1.1 Governing Equation

The problem we consider here is the control of a fully developed turbulent channel flow with full flowfield information and copious computational resources available to the control algorithm. The flow is governed by the incompressible Navier–Stokes equation inside a three-dimensional rectangular domain (Figure 13.15) with unsteady wall-normal velocity boundary conditions  $\phi$  applied on the walls as the control. Three vector fields are first defined: the flow state  $\mathbf{q}$ , the flow perturbation state  $\mathbf{q}'$ , and the adjoint state  $\mathbf{q}^*$ :

$$\mathbf{q}(\mathbf{x}, t) = \begin{pmatrix} p(\mathbf{x}, t) \\ \mathbf{u}(\mathbf{x}, t) \end{pmatrix}, \quad \mathbf{q}'(\mathbf{x}, t) = \begin{pmatrix} p'(\mathbf{x}, t) \\ \mathbf{u}'(\mathbf{x}, t) \end{pmatrix}, \quad \mathbf{q}^*(\mathbf{x}, t) = \begin{pmatrix} p^*(\mathbf{x}, t) \\ \mathbf{u}^*(\mathbf{x}, t) \end{pmatrix}.$$

Each of these vector fields is composed of a pressure component and a velocity component, all of which are continuous functions of space  $\mathbf{x}$  and time  $t$ . The velocity components themselves are also vectors, with

**FIGURE 13.15** Channel flow geometry. The interior of the domain is denoted  $\Omega$  and the boundaries of the domain in the  $x_i$  direction are denoted  $\Gamma_i^\pm$ . Unsteady wall-normal velocity boundary conditions are applied on the walls  $\Gamma_2^\pm$  as the control, with periodic boundary conditions applied in the streamwise direction  $x_1$  and spanwise direction  $x_3$ . An external pressure gradient is applied to induce a mean flow in the  $x_1$  direction.

components in the streamwise direction  $x_1$ , the wall-normal direction  $x_2$ , and the spanwise direction  $x_3$ . Partial differential equations governing all three of these fields will be derived in due course, and the motivation for introducing  $\mathbf{q}'$  and  $\mathbf{q}^*$  will be given as the need for these fields arises in the control derivation. Only after the optimization approach has been derived completely in differential form is it discretized in space and time; an alternative strategy, discretizing the state equation in space before determining the adjoint operator, is discussed in Section 13.9.2.

The governing equation is written as

$$\begin{aligned}\mathcal{N}(\mathbf{q}) &= \mathbf{F} && \text{in } \Omega, \\ \mathbf{u} &= -\phi \mathbf{n} && \text{on } \Gamma_2^\pm, \\ \mathbf{u} &= \mathbf{u}_0 && \text{at } t = 0,\end{aligned}\tag{13.11}$$

where  $\mathcal{N}(\mathbf{q})$  is the (nonlinear) Navier–Stokes operator

$$\mathcal{N}(\mathbf{q}) = \begin{pmatrix} \frac{\partial u_j}{\partial x_j} \\ \frac{\partial u_i}{\partial t} + \frac{\partial u_j u_i}{\partial x_j} - \nu \frac{\partial^2 u_i}{\partial x_j^2} + \frac{\partial p}{\partial x_i} \end{pmatrix},$$

$\mathbf{F}$  is a forcing vector accounting for an externally applied mean pressure gradient driving the flow in the streamwise direction, and  $\mathbf{n}$  is the unit outward normal to the boundary  $\partial\Omega$ . The boundary conditions on the state  $\mathbf{q}$  are periodic in the streamwise and spanwise directions. A wall-normal control velocity  $\phi$  is distributed over the walls as indicated, and is constrained to inject zero net mass such that  $\forall t, \int_{\Gamma_2^+} \phi \, d\mathbf{x} = \int_{\Gamma_2^-} \phi \, d\mathbf{x} = 0$ . Initial conditions on the velocity,  $\mathbf{u}_0$ , of fully developed turbulent channel flow are prescribed.

### 13.9.1.2 Cost Functional

As in the linear setting, an essential step in the framing of the nonlinear optimization problem is the representation of the control objective as a cost functional to be minimized. Several cases of physical interest may be represented by a cost functional of the generic form

$$\mathcal{J}_0(\phi) = \frac{1}{2} \int_0^T \int_\Omega |C_1 \mathbf{u}|^2 \, d\mathbf{x} \, dt + \frac{1}{2} \int_\Omega |C_2 \mathbf{u}(\mathbf{x}, T)|^2 \, d\mathbf{x} - \int_0^T \int_{\Gamma_2^\pm} C_3 \nu \frac{\partial \mathbf{u}}{\partial \mathbf{n}} \cdot \mathbf{r} \, d\mathbf{x} \, dt + \frac{\ell^2}{2} \int_0^T \int_{\Gamma_2^\pm} |\phi|^2 \, d\mathbf{x} \, dt.$$

Four cases of particular interest are:

- a.  $C_1 = d_1 I$  and  $C_2 = C_3 = 0 \Rightarrow$  regulation of turbulent kinetic energy;
- b.  $C_1 = d_2 \nabla \times$  and  $C_2 = C_3 = 0 \Rightarrow$  regulation of the square of the vorticity;
- c.  $C_2 = d_3 I$  and  $C_1 = C_3 = 0 \Rightarrow$  terminal control of turbulent kinetic energy;
- d.  $C_3 = d_4 I$  and  $C_1 = C_2 = 0 \Rightarrow$  minimization of the time-averaged skin friction in the direction  $\mathbf{r}$  integrated over the boundary of the domain, where  $\mathbf{r}$  is a unit vector in the streamwise direction.

All four of these cases, and many others, may be considered in the current framework, and the extension to other cost functionals is straightforward. The dimensional constants  $d_i$  (which are the appropriate functions of the kinematic viscosity, the channel width and the bulk velocity), as well as  $\ell$ , are included to make the cost functional dimensionally consistent and to account for the relative weight of each individual term.

Clearly, in both the chess problem and the turbulence problem, the further into the future one can optimize the problem the better (Figure 13.14); however, both problems get exponentially more difficult to optimize as the prediction horizon is increased. Because only intermediate-term optimization is tractable, it is not always the best approach to represent the final objective in the cost functional. In the

chess problem, though the final aim is to capture the other player's king, it is most effective to adopt a mid-game strategy of establishing good board position and achieving material advantage. Similarly, if the turbulence control objective is reducing drag, it was found in BMT01 that it is most effective along the way to minimize a finite-horizon cost functional related to the turbulent kinetic energy of the flow, as the turbulent transport of momentum is responsible for inducing a substantial portion of the drag in a turbulent flow. In a sense, turbulence is the “cause” and high drag is the “effect,” and it is most effective to target the “cause” in the cost functional when optimizations on only intermediate prediction horizons are possible.

In addition, a smart optimization algorithm allows for excursions in the short term if it leads to a long-term advantage. For example, in chess, a good player is willing to sacrifice a lesser piece if, by so doing, a commanding board position is attained and/or a restoring exchange is forced a few moves later. Similarly, by allowing a turbulence control scheme to increase (temporarily) the turbulent kinetic energy of a flow, a transient may ensue which, eventually, effectively diminishes the strength of the near-wall coherent structures. It was found in BMT01 that terminal control strategies, aimed at minimizing the turbulence only at the end of each optimization period, have a decided advantage over regulation strategies, which penalize excursions of, for example, the turbulent kinetic energy over the entire prediction horizon.

### 13.9.1.3 Gradient of Cost Functional

As suggested by Abergel and Temam (1990), a rigorous procedure may be developed to determine the sensitivity of a cost functional  $\mathcal{J}$  to small modifications of the control  $\phi$  for nonlinear problems of this sort. To do this, consider the perturbation to the cost functional resulting from a small perturbation to the control  $\phi$  in the direction  $\phi'$ . (Note that this control perturbation direction  $\phi'$  is arbitrary and scaled to have unit norm.) Define  $\mathcal{J}'$  as the Fréchet differential [Vainberg, 1964] of a cost functional  $\mathcal{J}$  such that

$$\mathcal{J}' \triangleq \lim_{\varepsilon \rightarrow 0} \frac{\mathcal{J}(\phi + \varepsilon\phi') - \mathcal{J}(\phi)}{\varepsilon} \triangleq \int_0^T \int_{\Gamma_2^\pm} \frac{\mathcal{D}\mathcal{J}(\phi)}{\mathcal{D}(\phi)} \phi' dt d\mathbf{x}.$$

The quantity  $\mathcal{J}'$  is the cost functional perturbation due to a control perturbation  $\varepsilon\phi'$  scaled by the inverse of the control perturbation magnitude  $\varepsilon$  in the limit that  $\varepsilon \rightarrow 0$ . The above relation, considered for arbitrary  $\phi'$ , also defines the gradient of the cost functional  $\mathcal{J}$  with respect to the control  $\phi$ , which is written  $\mathcal{D}\mathcal{J}(\phi)/\mathcal{D}\phi$ .

In the current approach, the cost functional perturbation  $\mathcal{J}'$  defined above will be expressed as a simple linear function of the direction of the control perturbation  $\phi'$  through the solution of an adjoint problem. By the above formula, such a representation then reveals the gradient direction  $\mathcal{D}\mathcal{J}(\phi)/\mathcal{D}\phi$  directly. With this gradient information, the control  $\phi$  is updated on  $(0, T]$  in the direction that, at least locally (i.e., for infinitesimal control updates), most effectively reduces the cost functional. The finite distance the control is updated in this direction is then found by a line search routine, which makes this iteration procedure stable even when controlling nonlinear phenomena. The flow resulting from this modified control is then computed according to the (nonlinear) Navier–Stokes equation (13.11), the sensitivity of this new flow to further control modification is computed, and the process repeated. Upon convergence of this iteration, the flow is advanced over the interval  $(0, T_1]$ , where  $T_1 \leq T$ , and an iteration for the optimal control over a new time interval  $(T_1, T_1 + T]$  begins anew.

The cost functional perturbation  $\mathcal{J}'$  resulting from a control perturbation in the direction  $\phi'$  is given by

$$\begin{aligned} \mathcal{J}'_0(\phi) &= \frac{1}{2} \int_0^T \int_{\Omega} C_1^* C_1 \mathbf{u} \cdot \mathbf{u}' d\mathbf{x} dt + \frac{1}{2} \int_{\Omega} (C_2^* C_2 \mathbf{u} \cdot \mathbf{u}')_{t=T} d\mathbf{x} - \int_0^T \int_{\Gamma_2^\pm} \nu C_3^* \mathbf{r} \cdot \frac{\partial \mathbf{u}'}{\partial n} d\mathbf{x} dt \\ &+ \ell^2 \int_0^T \int_{\Gamma_2^\pm} \phi \phi' d\mathbf{x} dt \triangleq \int_0^T \int_{\Gamma_2^\pm} \frac{\mathcal{D}\mathcal{J}_0(\phi)}{\mathcal{D}(\phi)} \phi' d\mathbf{x} dt, \end{aligned}$$

where  $\mathbf{u}'$  is the Fréchet differential of  $\mathbf{u}$ , as defined in the following subsection. Adjoint calculus is used simply to re-express the integrals involving  $\mathbf{u}'$  as a linear function of  $\phi'$ . Once this is accomplished,  $\phi'$  is factored out of the integrands and, as the equation holds for arbitrary  $\phi'$ , an expression for the gradient  $\mathcal{D}\mathcal{J}_0(\phi)/\mathcal{D}\phi$  is identified.

### 13.9.1.4 Linearized Perturbation Field

Now consider the linearized perturbation  $\mathbf{q}'$  to the flow  $\mathbf{q}$  resulting from a perturbation  $\phi'$  to the control  $\phi$ . Again, the quantity  $\mathbf{q}'$  may be defined by the limiting process of a Fréchet differential such that

$$\mathbf{q}' \triangleq \lim_{\varepsilon \rightarrow 0} \frac{\mathbf{q}'(\phi + \varepsilon\phi') - \mathbf{q}(\phi)}{\varepsilon}.$$

For the purpose of gaining physical intuition, it is useful to note that the quantity  $\mathbf{q}'$ , described above as a differential quantity, may instead be defined as the small perturbation to the state  $\mathbf{q}$  arising from a small control perturbation  $\phi'$  to the control  $\phi$ . In such derivations, the notations  $\delta\phi$  and  $\delta\mathbf{q}$ , denoting small perturbations to  $\phi$  and  $\mathbf{q}$ , are used instead of the differential quantities  $\phi'$  and  $\mathbf{q}'$ . The two derivations are roughly equivalent, though the present derivation does not assume that primed quantities are small.

The equation governing the dependence of the linearized flow perturbation  $\mathbf{q}'$  on the control perturbation  $\phi'$  may be found by taking the Fréchet differential of the state equation (13.11). The result is

$$\begin{aligned} \mathcal{N}'(\mathbf{q})\mathbf{q}' &= 0 && \text{in } \Omega, \\ \mathbf{u}' &= -\phi'\mathbf{n} && \text{on } \Gamma_2^\pm, \\ \mathbf{u}' &= 0 && \text{at } t = 0, \end{aligned} \tag{13.12}$$

where the linearized Navier–Stokes operation  $\mathcal{N}'(\mathbf{q})\mathbf{q}'$  is given by

$$\mathcal{N}'(\mathbf{q})\mathbf{q}' = \begin{pmatrix} \frac{\partial u'_j}{\partial x_j} \\ \frac{\partial u'_i}{\partial t} + \frac{\partial}{\partial x_j}(u_j u'_i + u'_j u_i) - \nu \frac{\partial^2 u'_i}{\partial x_j^2} + \frac{\partial p'}{\partial x_i} \end{pmatrix}.$$

The operation  $\mathcal{N}'(\mathbf{q})\mathbf{q}'$  is a linear operation on the perturbation field  $\mathbf{q}'$ , though the operator  $\mathcal{N}'(\mathbf{q})\mathbf{q}'$  is itself a function of the solution  $\mathbf{q}$  of the Navier–Stokes problem. Equation (13.12) thus reflects the linear dependence of the perturbation field  $\mathbf{q}'$  in the interior of the domain on the control perturbation  $\phi'$  at the boundary. However, the implicit linear relationship  $\mathbf{q}' = \mathbf{q}'(\phi')$  given by this equation is not yet tractable for expressing  $\mathcal{J}'_0$  in a simple form from which  $\mathcal{D}\mathcal{J}_0(\phi)/\mathcal{D}\phi$  may be deduced. For the purpose of determining a more useful relationship with which we may determine  $\mathcal{D}\mathcal{J}_0(\phi)/\mathcal{D}\phi$ , we now appeal to an adjoint identity.

### 13.9.1.5 Statement of Adjoint Identity

This subsection derives the adjoint of the linear partial differential operator  $\mathcal{N}'(\mathbf{q})\mathbf{q}'$ . For readers not familiar with this approach, a review of the derivation of an adjoint operator for a very simple case in the present notation is given in Appendix A of BMT01. The adjoint derivation presented below extends in a straightforward manner to more complex equations, such as the compressible Euler equation, as shown in Appendix B of BMT01 (again, using the same notation). Such generality highlights the versatility of the present approach.

Define an inner product over the domain in space-time under consideration such that

$$\langle \mathbf{q}^*, \mathbf{q}' \rangle = \int_0^T \int_{\Omega} \mathbf{q}^* \cdot \mathbf{q}' \, dx \, dt$$

and consider the identity

$$\langle \mathbf{q}^*, \mathcal{N}'(\mathbf{q})\mathbf{q}' \rangle = \langle \mathcal{N}'(\mathbf{q})^*\mathbf{q}^*, \mathbf{q}' \rangle + b. \quad (13.13)$$

Integration by parts may be used to move all differential operations from  $\mathbf{q}'$  on the left-hand side of Eq. (13.13) to  $\mathbf{q}^*$  on the right-hand side, resulting in the derivation of the adjoint operator

$$\mathcal{N}'(\mathbf{q})^*\mathbf{q}^* = \left( \begin{array}{c} \frac{\partial u_j^*}{\partial x_j} \\ -\frac{\partial u_i^*}{\partial t} - u_j \left( \frac{\partial u_i^*}{\partial x_j} + \frac{\partial u_j^*}{\partial x_i} \right) - \nu \frac{\partial^2 u_i^*}{\partial x_j^2} - \frac{\partial p^*}{\partial x_i} \end{array} \right),$$

where, again, the operation  $\mathcal{N}'(\mathbf{q})^*\mathbf{q}^*$  is a linear operation on the adjoint field  $\mathbf{q}^*$ , and the operator  $\mathcal{N}'(\mathbf{q})^*$  is itself a function of the solution  $\mathbf{q}$  of the Navier–Stokes problem. From the integrations by parts, we also get several boundary terms:

$$b = \int_{\Omega} (u_j^* u'_j)_{t=0}^{t=T} d\mathbf{x} + \int_0^T \int_{\Omega} n_j \left[ u_i^* (u_j u'_i + u'_j u_i) + p^* u'_j - \nu \left( u_i^* \frac{\partial u'_i}{\partial x_j} - u'_i \frac{\partial u_i^*}{\partial x_j} \right) + u_j^* p' \right] d\mathbf{x} dt.$$

The identity (13.13) is the key to expressing  $\mathcal{J}'$  in the desired form. An adjoint field  $\mathbf{q}^*$  is first defined using the operator  $\mathcal{N}'(\mathbf{q})^*$  together with appropriate forcing on an interior equation with appropriate boundary conditions and initial conditions. There is here some flexibility which we exploit to obtain a simple expression of  $\mathcal{J}'$ . Indeed, combining this definition of  $\mathbf{q}^*$  with the definitions of  $\mathbf{q}$  in Eq. (13.11) and  $\mathbf{q}'$  in Eq. (13.12), the identity (13.13) reveals the desired expression, as will now be shown.

### 13.9.1.6 Definition of Adjoint Field

Consider an adjoint state defined (as yet, arbitrarily) by

$$\begin{aligned} \mathcal{N}'(\mathbf{q})^*\mathbf{q}^* &= \begin{pmatrix} 0 \\ C_1^* C_1 \mathbf{u} \end{pmatrix} \quad \text{in } \Omega, \\ \mathbf{u}^* &= C_3^* \mathbf{r} \quad \text{on } \Gamma_2^\pm, \\ \mathbf{u}^* &= C_2^* C_2 \mathbf{u} \quad \text{at } t = T, \end{aligned} \quad (13.14)$$

where the adjoint operation  $\mathcal{N}'(\mathbf{q})^*$  is derived in the previous subsection. Note by Eq. (13.14) that, depending on where the cost functional weighs the flow perturbations (see Section 13.9.1.2), the adjoint problem may be driven by the initial conditions, by the boundary conditions, or by the RHS of the adjoint PDE itself. Note also that the adjoint “initial” conditions are defined at  $t = T$  and are thus best referred to as “terminal” conditions. With this definition, the adjoint field must be marched *backward* in time over the optimization horizon; due to the sign of the time derivative and viscous terms in the adjoint operator  $\mathcal{N}'(\mathbf{q})^*$ , this is the natural direction for this time march. However, as both the adjoint operator  $\mathcal{N}'(\mathbf{q})^*$  and the RHS forcing on Eq. (13.14a) are functions of  $\mathbf{q}$ , computation of the adjoint field  $\mathbf{q}^*$  requires storage of the flow field  $\mathbf{q}$  on  $t \in [0, T]$ , which itself must be computed with a *forward* march. This storage issue presents one of the numerical complications that preclude solution of the present optimization problem for large optimization intervals  $T$ . However, this storage issue is not insurmountable for intermediate values of  $T^+ < O(100)$ . The adjoint problem Eq. (13.14), though linear, has complexity similar to that of the Navier–Stokes problem, Eq. (13.11), and may be solved with similar numerical methods.

### 13.9.1.7 Identification of Gradient

The identity (13.13) is now simplified using the equations defining the state field, Eq. (13.11), the perturbation field, Eq. (13.12), and the adjoint field, Eq. (13.14). Due to the judicious choice of the forcing terms driving the adjoint problem, the identity (13.13) reduces (after some manipulation) to

$$\int_0^T \int_{\Omega} C_1^* C_1 \mathbf{u} \cdot \mathbf{u}' \, d\mathbf{x} \, dt + \int_{\Omega} (C_2^* C_2 \mathbf{u} \cdot \mathbf{u}')_{t=T} \, d\mathbf{x} - \int_0^T \int_{\Gamma_2^{\pm}} \nu C_3^* \mathbf{r} \cdot \frac{\partial \mathbf{u}'}{\partial n} \, d\mathbf{x} \, dt = \int_0^T \int_{\Gamma_2^{\pm}} p^* \phi' \, d\mathbf{x} \, dt.$$

Using this equation, the cost functional perturbation  $\mathcal{J}'_0$  may be rewritten as

$$\mathcal{J}'_0(\phi; \phi') = \int_0^T \int_{\Gamma_2^{\pm}} (p^* + \ell^2 \phi) \phi' \, d\mathbf{x} \, dt \triangleq \int_0^T \int_{\Gamma_2^{\pm}} \frac{\mathcal{D}\mathcal{J}_0(\phi)}{\mathcal{D}(\phi)} \phi' \, d\mathbf{x} \, dt.$$

As  $\phi'$  is arbitrary, we may identify (weakly) the desired gradient as

$$\frac{\mathcal{D}\mathcal{J}_0(\phi)}{\mathcal{D}(\phi)} = p^* + \ell^2 \phi.$$

The desired gradient  $\mathcal{D}\mathcal{J}_0(\phi)/\mathcal{D}\phi$  is thus found to be a simple function of the solution of the adjoint problem proposed in Eq. (13.14); specifically, in the present case of boundary forcing by wall-normal blowing and suction, it is found to be a simple function of the adjoint pressure on the walls.

In fact, this simple result hints at the more fundamental physical interpretation of what the adjoint field actually represents:

The adjoint field  $\mathbf{q}^*$ , when properly defined, is a measure of the sensitivity of the terms of the cost functional that appraise the state  $\mathbf{q}$  to additional forcing of the state equation.

Note that there are exactly as many components of the adjoint field  $\mathbf{q}^*$  as there are components of the state PDE on the interior of the domain, and that the adjoint field may take nontrivial values at the initial time  $t=0$  and on the boundaries  $\Gamma_2^{\pm}$ . Depending upon where the control is applied to the state equation (13.11), (i.e., on the RHS of the mass or momentum equations on the interior of the domain, on the boundary conditions, or on the initial conditions), the adjoint field will appear in the resulting expression for the gradient accordingly.

To summarize, the forcing on the adjoint problem is a function of where the flow perturbations are weighed in the cost functional. The dependence of the gradient  $\mathcal{D}\mathcal{J}(\phi)/\mathcal{D}\phi$  on the resulting adjoint field, on the other hand, is a function of where the control enters the state equation.

### 13.9.1.8 Gradient Update to Control

A control optimization strategy using a steepest descent algorithm may now be proposed such that

$$\phi^k = \phi^{k-1} - \alpha^k \frac{\mathcal{D}\mathcal{J}_0(\phi^{k-1})}{\mathcal{D}\phi}$$

over the entire time interval  $t \in (0, T]$ , where  $k$  indicates the iteration number and  $\alpha^k$  is a parameter of descent that governs how large an update is made, which is adjusted at each iteration step to be the value that minimizes  $\mathcal{J}$ . This algorithm updates  $\phi$  at each iteration in the direction of maximum decrease of  $\mathcal{J}$ . As  $k \rightarrow \infty$ , the algorithm should converge to some local minimum of  $\mathcal{J}$  over the domain of the control  $\phi$  on the time interval  $t \in (0, T]$ . Note that convergence to a global minimum will not in general be attained by such a scheme and that, as time proceeds,  $\mathcal{J}$  will not necessarily decrease.

The steepest descent algorithm described above illustrates the essence of the approach, but is usually not very efficient. Even in linear low-dimensional problems, for cases in which the cost functional has a long, narrow “valley,” the lack of a momentum term from one iteration to the next tends to cause the steepest descent algorithm to bounce from one side of the valley to the other without turning to proceed along the valley floor. Standard nonlinear conjugate gradient algorithms [e.g., Press et al., 1986] improve this behavior considerably with relatively little added computational cost or algorithmic complexity, as discussed further in BMT01.

As mentioned previously, the dimension of the control in the present problem (once discretized) is quite large, which precludes the use of second-order techniques based on the computation or approximation of the Hessian matrix  $\partial^2 \mathcal{J} / \partial \phi_i \partial \phi_j$  or its inverse during the control optimization. The number of elements in such a matrix scales with the square of the number of control variables and is unmanageable in the present case. However, reduced-storage variants of variable metric methods [Vanderplaats, 1984], such as the Davidon–Fletcher–Powell (DFP) method, the Broydon–Fletcher–Goldfarb–Shanno (BFGS) method, and the sequential quadratic programming (SQP) method, approximate the inverse Hessian information by outer products of stored gradient vectors and thus achieve nearly second-order convergence without storage of the Hessian matrix itself. Such techniques should be explored further for very large-scale optimization problems such as the present in future work.

### 13.9.2 Continuous Adjoint vs. Discrete Adjoint

Direct numerical simulations (DNS) of the current three-dimensional nonlinear system necessitate carefully chosen numerical techniques involving a stretched, staggered grid, an energy-conserving spatial discretization, and a mixture of implicit and multistep explicit schemes for accurate time advancement, with incompressibility enforced by an involved fractional step algorithm. The optimization approach described above, which will be referred to as “optimize then discretize” (OTD), avoids all of these cumbersome numerical details by deriving the gradient of the cost functional in the continuous setting, discretizing in time and space only as the final step before implementation in numerical code. The remarkable similarity of the flow and adjoint systems allows both to be coded with similar numerical techniques. For systems which are well resolved in the numerical discretization, this approach is entirely justifiable, and is found to yield adjoint systems which are easy to derive and implement in numerical code.

Unfortunately, many PDE systems, such as high-Reynolds-number turbulent flows, are difficult or impossible to simulate with sufficient resolution to capture accurately all of the important dynamic phenomena of the continuous system. Such systems are often simulated on coarse grids, usually with some “subgrid-scale model” to account for the unresolved dynamics. This setting is referred to as large eddy simulation (LES), and a variety of techniques are currently under development to model the significant subgrid-scale effects.

There are important unresolved issues concerning how to approach large eddy simulations in the optimization framework. If we continue with the OTD approach, in which the optimization equations are determined before the numerical discretization is applied, it is not yet clear at what point the LES model should be introduced. Prof. Scott Collis’ group (Rice University) has modified the numerical code of BMT01 in order to study this issue; Chang and Collis (1999) report on their preliminary findings.

An alternative approach to the OTD setting, in which one spatially discretizes the governing equation before determining the optimization equations, may also be considered.<sup>4</sup> After spatially discretizing the governing equation, this approach, which will be referred to as “discretize then optimize” (DTO), follows an analogous sequence of steps as the OTD approach presented previously, with these steps now applied in the discrete setting. Derivation of the adjoint operator is significantly more cumbersome in this discrete setting. In general, the processes of optimization and discretization do not commute, and

---

<sup>4</sup>Note that we may also consider temporally discretizing the governing equation before determining the optimization equations. Generally, the spatial discretization of a turbulent system is the most restrictive issue, however, so we focus on that problem here.

thus the OTD and DTO approaches are not necessarily equivalent even upon refinement of the space/time grid [Vogel and Wade, 1995]. However, by carefully framing the discrete identity defining the DTO adjoint operator as a discrete approximation of the identity given in Eq. (13.13), these two approaches can be posed in an equivalent fashion for Navier–Stokes systems.

It remains the topic of some debate whether or not the DTO approach is better than the OTD approach for marginally resolved PDE systems. The argument for DTO is that it clearly is the most direct way to optimize the discrete problem actually being solved by the computer. The argument against DTO is that one really wants to optimize the continuous problem, so gradient information that identifies and exploits deficiencies in the numerical discretization that can lead to performance improvements in the discrete problem might be misleading when interpreting the numerical results in terms of the physical system.

## 13.10 Robustification: Appealing to Murphy’s Law

Though optimal control approaches possess an attractive mathematical elegance and are now proven to provide excellent results in terms of drag and turbulent kinetic energy reduction in fully developed turbulent flows, they are often impractical. One of the most significant drawbacks of this nonlinear optimization approach is that it tends to “over-optimize” the system, leaving a high degree of design-point sensitivity. This phenomenon has been encountered frequently in, for example, the adjoint-based optimization of the shape of aircraft wings. Overly optimized wing shapes might work quite well at exactly the flow conditions for which they were designed, but their performance is often abysmal at off-design conditions. In order to abate such system sensitivity, the noncooperative framework of robust control provides a natural means to “detune” the optimized results. This concept can be applied easily to a broad range of related applications.

The noncooperative approach to robust control, one might say, amounts to Murphy’s law taken seriously:

If a worst-case disturbance can disrupt a controlled closed-loop system, it will.

When designing a robust controller, therefore, one might plan on a finite component of the worst-case disturbance aggravating the system, and design a controller suited to handle even this extreme situation. A controller designed to work even in the presence of a finite component of the worst-case disturbance will also be robust to a wide class of other possible disturbances which, by definition, are not as detrimental to the control objective as the worst-case disturbance. This concept is exactly that which leads to the  $\mathcal{H}_\infty$  control formulation discussed previously in the linear setting, and can easily be extended to the optimization of nonlinear systems.

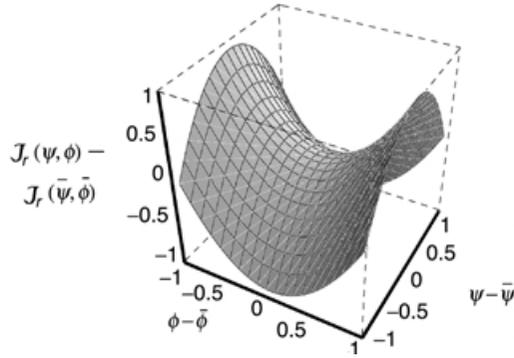

Based on the ideas of  $\mathcal{H}_\infty$  control theory presented in Section 13.3, the extension of the nonlinear optimization approach presented in Section 13.9 to the noncooperative setting is straightforward. A disturbance is first introduced to the governing equation (13.11); as an example, we may consider disturbances that perturb the state PDE itself such that

$$\mathcal{N}(\mathbf{q}) = \mathbf{F} + \mathbf{B}_1(\psi) \quad \text{in } \Omega.$$

(Accounting for disturbances to the boundary conditions and initial conditions of the governing equation is also straightforward.) The cost functional is then extended to penalize these disturbances in the noncooperative framework, as was also done in the linear setting

$$\mathcal{J}_r(\psi, \phi) = \mathcal{J}_0 - \frac{\gamma^2}{2} \int_0^T \int_\Omega |\psi|^2 \, d\mathbf{x} \, dt.$$

This cost functional is simultaneously minimized with respect to the controls  $\phi$  and maximized with respect to the disturbances  $\psi$  (Figure 13.16). The parameter  $\gamma$  is used to scale the magnitude of the

**FIGURE 13.16** Schematic of a saddle point representing the neighborhood of a solution to a robust control problem with one scalar disturbance variable  $\psi$  and one scalar control variable  $\phi$ . When the robust control problem is solved, the cost function  $\mathcal{J}_r$  is simultaneously maximized with respect to  $\psi$  and minimized with respect to  $\phi$ , and a saddle point such as  $(\bar{\psi}, \bar{\phi})$  is reached. An essentially infinite-dimensional extension of this concept may be formulated to achieve robustness to disturbances and insensitivity to design point in fluid-mechanical systems. In such approaches, the cost  $\mathcal{J}_r$  is related to a distributed disturbance  $\psi$  and a distributed control  $\phi$  through the solution of the Navier–Stokes equation.

disturbances accounted for in this noncooperative competition, with the limit of large  $\gamma$  recovering the optimal approach discussed in Section 13.9 (i.e.,  $\psi \rightarrow 0$ ). A gradient-based algorithm may then be devised to march to the saddle point, such as the simple algorithm given by:

$$\phi^k = \phi^{k-1} - \alpha^k \frac{\mathcal{D}\mathcal{J}_r(\psi^{k-1}; \phi^{k-1})}{\mathcal{D}\phi},$$

$$\psi^k = \psi^{k-1} + \beta^k \frac{\mathcal{D}\mathcal{J}_r(\psi^{k-1}; \phi^{k-1})}{\mathcal{D}\psi}.$$

The robust control problem is considered to be solved when a saddle point  $(\bar{\psi}, \bar{\phi})$  is reached; note that such a solution, if it exists, is not necessarily unique.

The gradients  $\mathcal{D}\mathcal{J}_r(\psi; \phi)/\mathcal{D}\phi$  and  $\mathcal{D}\mathcal{J}_r(\psi; \phi)/\mathcal{D}\psi$  may be found in a manner analogous to that leading to  $\mathcal{D}\mathcal{J}_0(\phi)/\mathcal{D}\phi$  discussed in Section 13.9. In fact, both gradients may be extracted from the single adjoint field defined by Eq. (13.14). Thus, the additional computational complexity introduced by the noncooperative component of the robust control problem is simply a matter of updating and storing the appropriate disturbance variables.

### 13.10.1 Well-Posedness

Based on the extensive mathematical literature on the Navier–Stokes equation, Abergel and Temam (1990) established the well-posedness of the mathematical framework for the optimization problem presented in Section 13.9. This characterization was generalized and extended to the noncooperative framework of Section 13.10 in Bewley, Temam, and Ziane (2000).

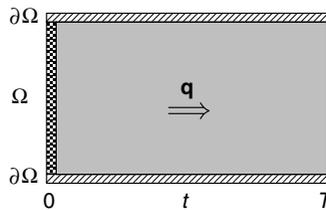

Due to the fact that the inequalities currently available for estimating the magnitude of the various terms of the Navier–Stokes equation are limited, the mathematical characterizations in both of these articles are quite conservative. In our numerical simulations, we regularly apply numerical optimization techniques to control problems that are well outside the range over which we can mathematically establish well-posedness. However, such mathematical characterizations are still quite important, as they give us confidence that, for example, if  $\ell$  and  $\gamma$  are at least taken to be large enough, a saddle point of the noncooperative optimization problem will exist. Once such mathematical characterizations are derived, numerically determining the values of  $\ell$  and  $\gamma$  for which solutions of the control problem may still be obtained is reduced to a simple matter of implementation.

### 13.10.2 Convergence of Numerical Algorithm

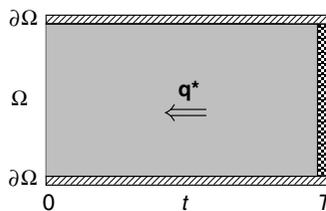

Saddle points are typically more difficult to find than minimum points, and particular care needs to be taken to craft efficient but stable numerical algorithms for finding them. In the approach described above, sufficiently small values of  $\alpha^k$  and  $\beta^k$  must be selected to ensure convergence. Fortunately, the same mathematical inequalities used to characterize well-posedness of the control problem can also be used to characterize convergence of proposed numerical algorithms. Such characterizations lend valuable insight when designing practical numerical algorithms. Preliminary work in the development of such saddle point algorithms is reported by Tachim Medjo (2000).

### 13.11 Unification: Synthesizing a General Framework

The various cost functionals considered previously led to three possible sources of forcing for the adjoint problem: the right-hand side of the PDE, the boundary conditions, and the initial conditions. Similarly, three different locations of forcing may be identified for the flow problem. As illustrated in Figures 13.17 and 13.18 and discussed further in Bewley, Temam, and Ziane (2000), the various regions of forcing of the flow and adjoint problems together form a general framework that can be applied to a wide variety of problems in fluid mechanics including both flow control (e.g., drag reduction, mixing enhancement, and noise control) and flow forecasting (e.g., weather prediction and storm forecasting). Related techniques, but applied to the time-averaged Navier–Stokes equation, have also been used extensively to optimize the shapes of airfoils [see, e.g., Reuther et al., 1996].

**FIGURE 13.17** Schematic of the space–time domain over which the flow field  $\mathbf{q}$  is defined. The possible regions of forcing in the system defining  $\mathbf{q}$  are: (1) the right-hand side of the PDE, indicated with shading, representing flow control by interior volume forcing (e.g., externally applied electromagnetic forcing by wall-mounted magnets and electrodes); (2) the boundary conditions, indicated with diagonal stripes, representing flow control by boundary forcing (e.g., wall transpiration); (3) the initial conditions, indicated with checkerboard, representing optimization of the initial state in a data assimilation framework (e.g., the weather forecasting problem).

**FIGURE 13.18** Schematic of the space–time domain over which the adjoint field  $\mathbf{q}^*$  is defined. The possible regions of forcing in the system defining  $\mathbf{q}^*$ , corresponding exactly to the possible domains in which the cost functional can depend on  $\mathbf{q}$ , are: (1) the right-hand side of the PDE, indicated with shading, representing regulation of an interior quantity (e.g., turbulent kinetic energy); (2) the boundary conditions, indicated with diagonal stripes, representing regulation of a boundary quantity (e.g., wall skin friction); (3) the terminal conditions, indicated with checkerboard, representing terminal control of an interior quantity (e.g., turbulent kinetic energy).

By identifying a range of problems that all fit into the same general framework, we can better understand how to extend, for example, the idea of noncooperative optimizations to a full suite of related problems in fluid mechanics. Though advanced research projects must often be highly focused and specialized in order to obtain solid results, the importance of making connections of such research to a large scope of related problems must be recognized in order to realize fully the potential impact of the techniques developed.

## 13.12 Decomposition: Simulation-Based System Modeling

---

For the purpose of developing model-based feedback control strategies for turbulent flows, reduced-order nonlinear models of turbulence that are effective in the closed-loop setting are highly desired. Recent work in this direction, using proper orthogonal decompositions (POD) to obtain these reduced-order representations, is reviewed by Lumley and Blossey (1998).

The POD technique uses analysis of a simulation database to develop an efficient reduced-order basis for the system dynamics represented within the database [Holmes et al., 1996]. One of the primary challenges of this approach is that the dynamics of the system in closed loop (after the control is turned on) is often quite different than the dynamics of the open-loop (uncontrolled) system. Thus, development of simulation-based reduced-order models for turbulent flows should probably be coordinated with the design of the control algorithm itself in order to determine system models that are maximally effective in the closed-loop setting. Such coordination of simulation-based modeling and control design is largely an unsolved problem. A particularly sticky issue is the fact that, as the controls are turned on, the dynamics of the turbulent flow system are nonstationary (they evolve in time). The system eventually relaminarizes if the control is sufficiently effective. In such nonstationary problems, it is not clear which dynamics the POD should represent (of the flow shortly after the control is turned on, of the nearly relaminarized flow, or something in between), or if in fact several PODs should be created and used in a scheduled approach in an attempt to capture several different stages of the nonstationary relaminarization process.

Note that reduced-order models that are effective in the closed-loop setting need not capture the majority of the energetics of the unsteady flow. Rather, the essential feature of a system model for the purpose of control design is that the model capture the important effects of the control on the system dynamics. Future control-oriented modeling efforts might benefit by deviating from the standard POD mindset of simply attempting to capture the energetics of the system dynamics, instead focusing on capturing the significant effects of the control on the system in a reduced-order fashion.

## 13.13 Global Stabilization: Conservatively Enhancing Stability

---

Global stabilization approaches based on Lyapunov analysis of the system energetics have recently been explored for two-dimensional channel-flow systems (in the continuous setting) by Balogh et al. (2001). In the setting considered there, localized tangential wall motions are coordinated with local measurements of skin friction via simple proportional feedback strategies. Analysis of the flow at  $Re \leq 0.125$  motivates such feedback rules, indicating appropriate values of proportional feedback coefficients that enhance the  $L^2$  stability of the flow. Though such an approach is very conservative, rigorously guaranteeing enhanced stability of the channel-flow system only at extremely low Reynolds numbers, extrapolation of the feedback strategies so determined to much higher Reynolds numbers also indicates effective enhancements of system stability, even for three-dimensional systems up to  $Re = 2000$  (A. Balogh, pers. comm.).

An alternative approach for achieving global stabilization of a nonlinear PDE is the application of nonlinear backstepping to the discretized system equation. Boškovic and Krstic (2001) report on recent efforts in this direction (applied to a thermal convection loop). Backstepping is typically an aggressive approach to stabilization. One of the primary difficulties with this approach is that proofs of convergence to a continuous, bounded function upon refinement of the grid are difficult to attain due to increasing controller complexity as the grid is refined. Significant advancements will be necessary before this approach will be practical for turbulent flow systems.

## 13.14 Adaptation: Accounting for a Changing Environment

---

Adaptive control algorithms, such as least mean squares (LMS), neural networks (NN), genetic algorithms (GA), simulated annealing, extremum seeking, and the like, play an important role in the control of fluid-mechanical systems when the number of undetermined parameters in the control problem is fairly small ( $O(10)$ ) and individual “function evaluations” (i.e., quantitative characterizations of the effectiveness of the control) can be performed relatively quickly. Many control problems in fluid mechanics are of this type, and are readily approachable by a wide variety of well-established adaptive control strategies. A significant advantage of such approaches over those discussed previously is that they do not require extensive analysis or coding of localized convolution kernels, adjoint fields, etc., but may instead be applied directly “out of the box” to optimize the parameters of interest in a given fluid-mechanical problem. This also poses a bit of a disadvantage, however, because the analysis required during the development of model-based control strategies can sometimes yield significant physical insight that black-box optimizations fail to provide.

In order to apply the adaptive approach, one needs an inexpensive simulation code or an experimental apparatus in which the control parameters of interest can be altered by an automated algorithm. Any of a number of established methodological strategies can then be used to search the parameter space for favorable closed-loop system behavior. Given enough function evaluations and a small enough number of control parameters, such strategies usually converge to effective control solutions. Koumoutsakos et al. (1998) demonstrate this approach (computationally) to determine effective control parameters for exciting instabilities in a round jet. Rathnasingham and Breuer (1998) demonstrate this approach (experimentally) for the feedforward reduction of turbulence intensities in a boundary layer.

Unfortunately, due to an effect known as “the curse of dimensionality,” as the number of control parameters to be optimized is increased, the ability of adaptive strategies to converge to effective control solutions based on function evaluations alone is diminished. For example, in a system with 1000 control parameters, it takes 1000 function evaluations to determine the gradient information available in a single adjoint computation. Thus, for problems in which the number of control variables to be optimized is large, the convergence of adaptive strategies based on function evaluations alone is generally quite poor. In such high-dimensional problems, for cases in which the control problem of interest is plagued by multiple minima, a blend of an efficient adjoint-based gradient optimization approach with GA-type management of parameter “mutations” or the simulated annealing approach of varying levels of “noise” added to the optimization process might prove to be beneficial.

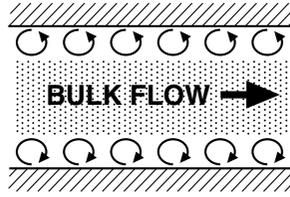

Adaptive strategies are also quite valuable for recognizing and responding to changing conditions in the flow system. In the low-dimensional setting, they can be used online to update controller gains directly as the system evolves in time (for instance, as the mean speed or direction of the flow changes or as the sensitivity of a sensor degrades). In the high-dimensional setting, adaptive strategies can be used to identify certain critical aspects of the flow (such as the flow speed), and, based on this identification, an appropriate control strategy may be selected from a look-up table of previously computed controller gains.

The selection of what level of adaptation is appropriate for a particular flow control problem of interest is, again, a consideration that must be guided by physical insight of the particular problem at hand.

## 13.15 Performance Limitation: Identifying Ideal Control Targets

---

Another important, but as yet largely unrealized, role for mathematical analysis in the field of flow control is in the identification of fundamental limitations on the performance that can be achieved in certain flow control problems. For example, motivated by the active debate surrounding the proposed physical mechanism for channel-flow drag reduction illustrated in [Figure 13.19](#), we formally state the following, as yet unproven, conjecture:

**FIGURE 13.19** An enticing picture: fundamental restructuring of the near-wall unsteadiness to insulate the wall from the viscous effects of the bulk flow. It has been argued [Nosenchuck, 1994; Koumoutsakos, 1999] that it might be possible to maintain a series of so-called “fluid rollers” to effectively reduce the drag of a near-wall flow. Such rollers are depicted in the figure above by indicating total velocity vectors in a reference frame convecting with the vortices themselves; in this frame, the generic picture of fluid rollers is similar to a series of stationary Kelvin–Stuart cat’s eye vortices. A possible mechanism for drag reduction might be akin to a series of solid cylinders serving as an effective conveyor belt, with the bulk flow moving to the right above the vortices and the wall moving to the left below the vortices. It is still the topic of some debate whether or not a continuous flow can be maintained in such a configuration by an unsteady control in such a way as to sustain the mean skin friction below laminar levels. Such a control might be implemented either by interior electromagnetic forcing (applied with wall-mounted magnets and electrodes) or by boundary controls such as zero-net mass-flux blowing/suction.

**Conjecture:** The lowest sustainable drag of an incompressible constant mass-flux channel flow, in either two or three dimensions, when controlled via a distribution of zero-net mass-flux blowing/suction over the channel walls, is exactly that of the laminar flow.

Note that by “sustainable drag” we mean the long-time average of the instantaneous drag, given by:

$$D_\infty = \lim_{(T \rightarrow \infty)} \frac{-1}{T} \int_0^T \int_{\Gamma_2^\pm} v \frac{\partial u_1}{\partial n} d\mathbf{x} dt$$

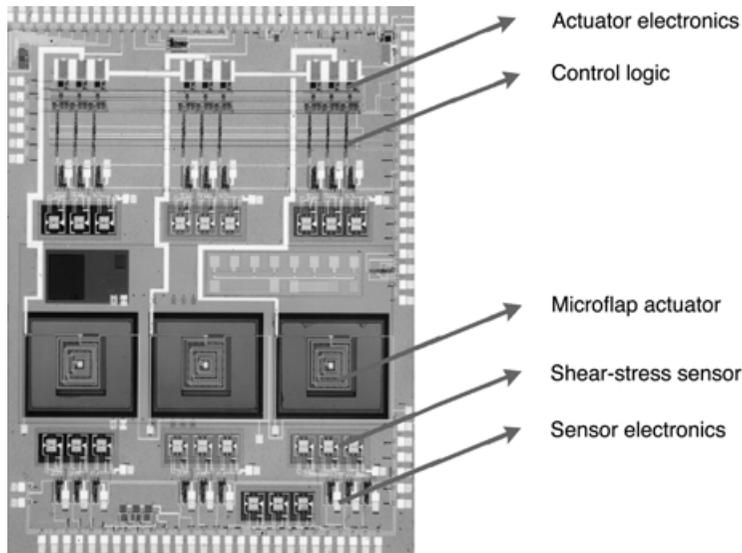

Proof (by mathematical analysis) or disproof (by counterexample) of this conjecture would be quite significant and lead to greatly improved physical understanding of the channel flow problem. If proven to be correct, it would provide rigorous motivation for targeting flow relaminarization when the problem one actually seeks to solve is minimization of drag. If shown to be incorrect, our target trajectories for future flow control strategies might be substantially altered.

Similar fundamental performance limitations may also be sought for exterior flow problems, such as the minimum drag of a circular cylinder subject to a class of zero-net control actions, such as rotation or transverse oscillation (B. Protas, pers. comm.).

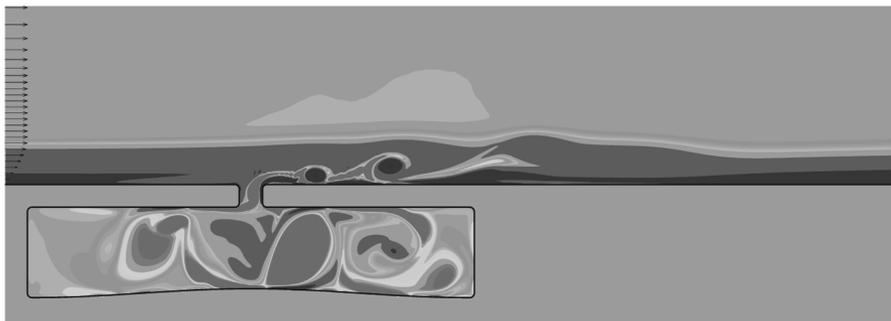

## 13.16 Implementation: Evaluating Engineering Trade-Offs

We are still some years away from applying the distributed control techniques discussed herein to micro-electromechanical systems (MEMS) arrays of sensors and actuators, such as that depicted in [Figure 13.20](#). One of the primary hurdles left to be tackled in order to bring us closer to actual implementation is that of accounting for practical designs of sensors and actuators in the control formulations, rather than the idealized distributions of blowing/suction and skin-friction measurements that we have assumed here. Detailed simulations, such as that shown in [Figure 13.21](#), of proposed actuator designs will be essential for developing reduced-order models of the effects of the actuators on the system of interest in order to make control design for realistic arrays of sensors and actuators tractable.

By performing analysis and control design in a high-dimensional, unconstrained setting, as discussed in this chapter, it is believed that we can obtain substantial insight into the physical characteristics of highly effective control strategies. Such insight naturally guides the engineering trade-offs that follow in order to make the design of the turbulence control system practical. Particular traits of the present control solutions in which we are especially interested include the times scales and the streamwise and spanwise

**FIGURE 13.20** (Color figure follows p. 12-26.) A MEMS tile integrating sensors, actuators and control logic for distributed flow control applications. (Developed by Profs. Chih-Ming Ho, UCLA, and Yu-Chong Tai, Caltech.)

**FIGURE 13.21** (Color figure follows p. 12-26.) Simulation of a proposed driven-cavity actuator design (Prof. Rajat Mittal, University of Florida). The fluid-filled cavity is driven by vertical motions of the membrane along its lower wall. Numerical simulation and reduced-order modeling of the the influence of such flow-control actuators on the system of interest will be essential for the development of feedback control algorithms to coordinate arrays of realistic sensor/actuator configurations.

length scales that are dominant in the optimized control computations (which shed insight on suitable actuator bandwidth, dimensions, and spacing) and the extent and structure of the convolution kernels (which indicate the distance and direction over which sensor measurements and state estimates should propagate when designing the communication architecture of the tiled array).

It is recognized that the control algorithm finally to be implemented must be kept fairly simple for its realization in the on-board electronics to be feasible. We believe that an appropriate strategy for determining implementable feedback algorithms that are both effective and simple is to learn how to solve the high-dimensional, fully resolved control problem first, as discussed herein. This results in high-dimensional compensator designs that are highly effective in the closed-loop setting. Compensator reduction strategies combined with engineering judgment may then be used to distill the essential features of such well-resolved control solutions to implementable feedback designs with minimal degradation of the closed-loop system behavior.

## 13.17 Discussion: A Common Language for Dialog

---

It is imperative that an accessible language be developed that provides a common ground upon which people from the fields of fluid mechanics, mathematics and controls can meet, communicate and develop new theories and techniques for flow control. Pierre-Simon de Laplace (quoted by Rose, 1998) once said

Such is the advantage of a well-constructed language that its simplified notation often becomes the source of profound theories.

Similarly, it was recognized by Gottfried Wilhelm Leibniz (quoted by Simmons, 1992) that

In symbols one observes an advantage in discovery which is greatest when they express the exact nature of a thing briefly...then indeed the labor of thought is wonderfully diminished.

Profound new theories are still possible in this young field. To a large extent, however, we have not yet homed in on a common language in which such profound theories can be framed. Such a language needs to be actively pursued; time spent on identifying, implementing and explaining a clear “compromise” language that is approachable by those from the related “traditional” disciplines is time well spent.

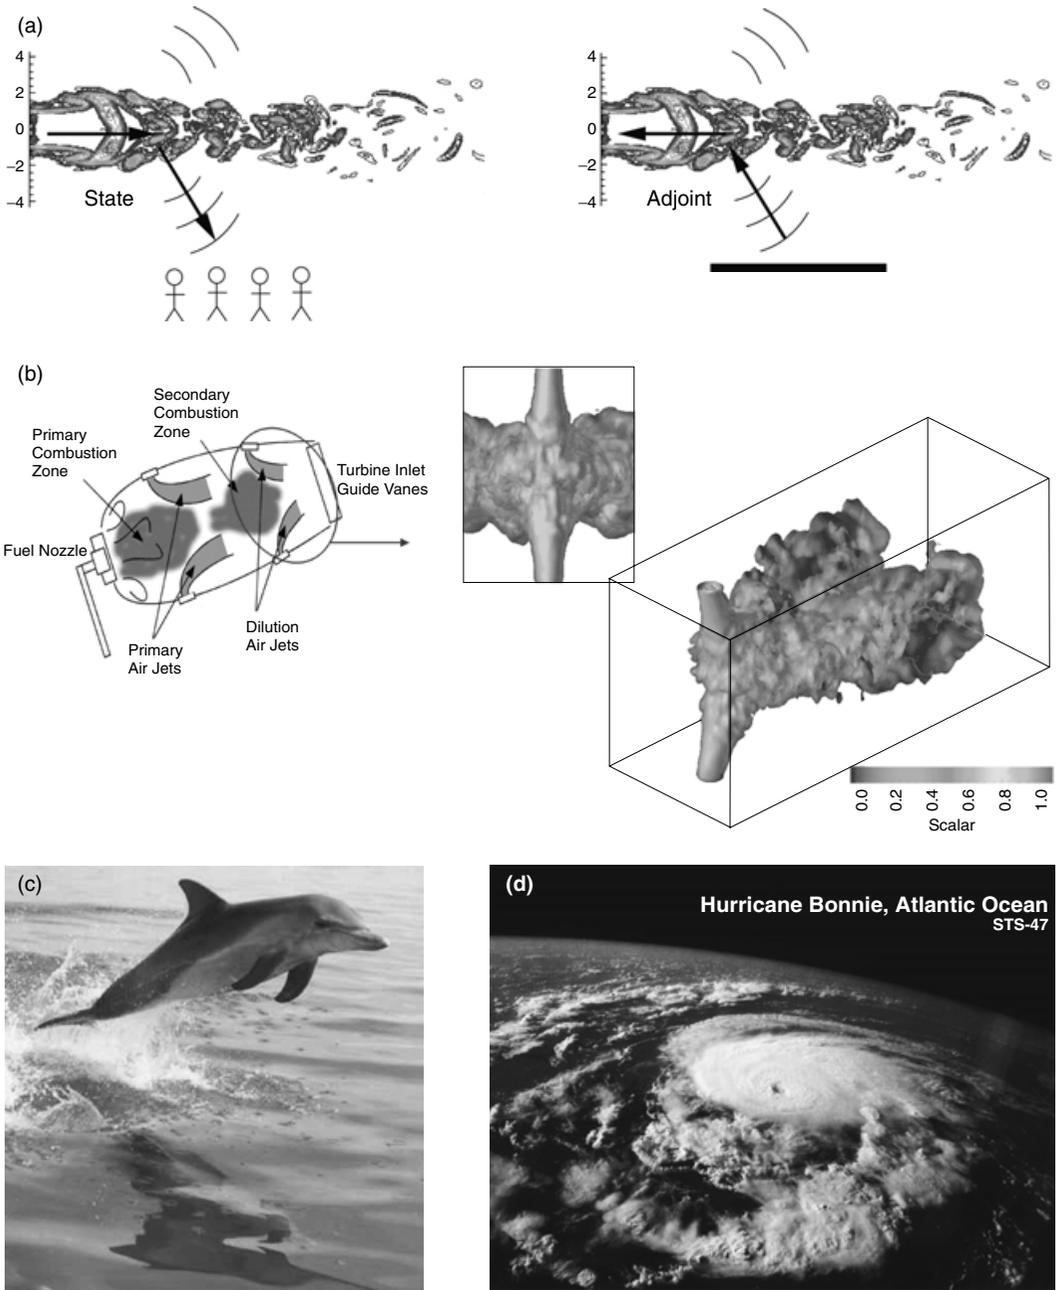

In particular, care should be taken to respect the meaning of certain “loaded” words which imply specific techniques, qualities, or phenomena in some disciplines but only general notions in others. When both writing and reading papers on flow control, one must be especially alert, as these words are sometimes used outside of their more narrow, specialized definitions, creating undue confusion. With time, a common language will develop. In the meantime, avoiding the use of such words outside of their specialized definitions, precisely defining such words when they are used, and identifying and using the existing names for specialized techniques already well established in some disciplines when introducing such techniques into other disciplines, will go a long way towards keeping us focused and in sync as an extended research community.

There are, of course, some significant obstacles to the implementation of a common language. For example, fluid mechanics have historically used  $\mathbf{u}$  to denote flow velocities and  $\mathbf{x}$  to denote spatial coordinates, whereas the controls community overwhelmingly adopts  $\mathbf{x}$  as the state vector and  $\mathbf{u}$  as the control. The simplified two-dimensional system that fluid mechanics often study examines the flow in a vertical plane, whereas the simplified two-dimensional system that meteorologists often study examines the flow in a horizontal plane; thus, when studying three-dimensional problems such as turbulence, those with a background in fluid mechanics usually introduce their third coordinate,  $z$ , in a horizontal direction, whereas those with a background in meteorology normally have “their zed in the clouds.” Writing papers in a manner conscious to such different backgrounds and notations, elucidating, motivating, and distilling the suitable control strategies, the relevant flow physics, the useful mathematical inequalities, and the appropriate numerical methods to a general audience of specialists from other fields is certainly extra work. However, such efforts are necessary to make flow control research accessible to the broad audience of scientists, mathematicians, and engineers whose talents will be instrumental in advancing this field in the years to come.

## 13.18 The Future: A Renaissance

---

The field of flow control is now poised for explosive growth and exciting new discoveries. The relative maturity of the constituent traditional scientific disciplines contributing to this field provides us with key elements that future efforts in this field may leverage. The work described herein represents only our first, preliminary steps towards laying an integrated, interdisciplinary footing upon which future efforts in this field may be based. Many technologically significant and fundamentally important problems lie before us, awaiting analysis and new understanding in this setting. With each of these new applications come significant new questions about how best to integrate the constituent disciplines. The answers to these difficult questions will only come about through a broad knowledge of what these disciplines have to offer and how they can best be used in concert. A few problems that might be studied in the near future in the present interdisciplinary framework are highlighted in [Figure 13.22](#).

**FIGURE 13.22** (Color figure follows p. 12-26.) Future interdisciplinary problems in flow control amenable to adjoint-based analysis:

- (a) minimization of sound radiating from a turbulent jet (simulation by Prof. Jon Freund, UCLA),
- (b) maximization of mixing in interacting cross-flow jets (simulation by Dr. Peter Blossey, UCSD) [Schematic of jet engine combustor is shown at left. Simulation of interacting cross-flow dilution jets, designed to keep the turbine inlet vanes cool, are visualized at right.],
- (c) optimization of surface compliance properties to minimize turbulent skin friction, and
- (d) accurate forecasting of inclement weather systems.

Unfortunately, there are particular difficulties in pursuing truly interdisciplinary investigations of fundamental problems in flow control in our current society, as it is impossible to conduct such investigations from the perspective of any particular traditional discipline alone. Though the language of interdisciplinary research is in vogue, many university departments, funding agencies, technical journals and, therefore, college professors fall back on the pervasive tendency of the twentieth-century scientist to categorize and isolate difficult scientific questions, often to the exclusion of addressing the fundamentally interdisciplinary issues. The proliferation and advancement of science in the twentieth century was, in fact, largely due to such an approach; by isolating specific and difficult problems with single-minded focus into narrowly defined scientific disciplines, great advances could once be achieved. To a large extent, however, the opportunities once possible with such a narrow focus have stagnated in many fields, though we are left with the scientific infrastructure in which that approach once flourished. To advance, we must courageously lead our research groups outside of the various neatly defined scientific domains into which this infrastructure injects us, and pursue the significant new opportunities appearing at their intersection. University departments and technical journals can and will follow suit as increasingly successful interdisciplinary efforts, such as those in the field of flow control, gain momentum. The endorsement that professional societies, technical journals and funding agencies might bring to such interdisciplinary efforts holds the potential to significantly accelerate this reformation of the scientific infrastructure.

In order to promote interdisciplinary work in the scientific community at large, describing oneself as working at the intersection of disciplines  $X$  and  $Y$  (or, where they are still disjoint, the bridge between such disciplines) needs to become more commonplace. People often resort to the philosophy “I do  $X$ ... oh, and I also sometimes dabble a bit with  $Y$ ,” but the philosophy “I do  $X * Y$ ,” where  $*$  denotes something of the nature of an integral convolution, has not been in favor since the Renaissance. Perhaps the primary reason for this is that  $X$  and  $Y$  (and  $Z, W, \dots$ ) have gotten progressively more and more difficult. By specialization (though often to the point of isolation), we are able to “master” our more and more narrowly defined disciplines. In the experience of the author, not only is it often the case that  $X$  and  $Y$  are not immiscible, but the solution sought may often not be formulated with the ingredients of  $X$  or  $Y$  alone. In order to advance, the essential ingredients of  $X$  and  $Y$  must be crystallized and communicated across the artificial disciplinary boundaries. New research must then be conducted at the intersection of  $X$  and  $Y$ . To be successful in the years to come, we must prepare ourselves and our students with the training, perspective and resolve to seize the new opportunities appearing at such intersections with a Renaissance approach.

## Acknowledgments

---

This chapter is adapted from the article by the same author, “Flow control: new challenges for a new Renaissance,” *Progress in Aerospace Sciences*, **37**, 21–58, 2001, with permission from Elsevier Science.

The author is thankful to Prof. Robert Skelton, for his vision to promote integrated controls research at the intersection of disciplines, to Profs. Roger Temam and Mohammed Ziane, for their patient attention to the new mathematical challenges laying the foundation for this development, and to Profs. Dan Henningson, Patrick Huerre, John Kim and Parviz Moin, for their physical insight and continued support of this sometimes unconventional effort within the fluid mechanics community. The author has also benefited from numerous technical discussions with Profs. Jeff Baggett, Bassam Bamieh, Bob Bitmead, Scott Collis, Brian Farrell, Jon Freund, Petros Ioannou, and Miroslav Krstic, and remains indebted to the several graduate students and post-docs who are making it all happen, including Dr. Peter Blossey, Markus Högberg, Eric Lauga and Scott Miller. We also thank the AFOSR, NSF, and DARPA for the foresight to sponsor several of these investigations. This article is dedicated to the memory of Prof. Mohammed Dahleh, whose charisma and intellect endure as a continual inspiration to all who knew him.

### 14.1 Introduction

---

Many important applications of microelectromechanical systems (MEMS) devices involve the control of complex systems, be they fluid, solid or thermal. For example, MEMS have been used for microsensors and microactuators [Subramanian et al., 1997; Nagaoka et al., 1997]. They have also been used in conjunction with optimal closed-loop control to increase the critical buckling load of a pinned-end column and for structural stability [Berlin et al., 1998]. Another example is that of the active control of noise inside an enclosure from exterior noise sources that is accomplished by the use of MEMS sensors placed on the enclosure wall. Varadan et al. (1995) used them for the active vibration and noise control of thin plates. Vandelli et al. (1998) developed a MEMS microvalve array for fluid flow control. Nelson et al. (1998) applied control theory to the microassembly of MEMS devices.

Solving the problem of control of other complex systems, such as fluid flows and structures, using these techniques appears to be promising. Ho and Tai (1996, 1998) have reviewed the applications of MEMS to flow control, Gad-el-Hak (1999) discussed the fluid mechanics of microdevices, and Lofdahl and Gad-el-Hak (1999) provided an overview of the applications of MEMS technology to turbulence and flow control. Sen and Yang (2000) have reviewed applications of artificial neural networks and genetic algorithms to thermal systems.

A previous chapter has outlined the basics of control theory and some of its applications. Apart from the traditional approach, there is another perspective that can be taken towards control, that of artificial intelligence (AI). This is a body of diverse techniques that have been recently developed in the computer science community to solve problems that could not be solved, or were difficult to solve, by other means. Though AI is difficult to define, it is often referred to as doing through means of a computer what a

human being would do to solve a given problem. The objective here, however, is not to discuss AI but to point out that some of the techniques developed in the context of AI can be transported to applications that involve MEMS. If the latter is the hardware of the future, the former may be its software. AI encompasses a broad spectrum of computational techniques and methods which are often thought of as being based on heuristics rather than algorithms. Thus, they are often not guaranteed to work, but have a high probability of success. As a general characteristic they imitate nature in some sense, though the difference between manmade computers and nature itself is so vast that the analogy is far from perfect.

There are some specific techniques within AI, collectively known as soft computing (SC), that have matured to the point of being computationally useful for complex engineering problems. SC includes artificial neural networks, genetic algorithms and fuzzy logic and related techniques in probabilistic reasoning. SC techniques are especially useful for complex systems, which, for purposes of this discussion, will be defined to mean those that can be broken into a number of subsystems that are individually simple and may be analytically or numerically computed but together cannot be analyzed in real time for control purposes. The physical phenomena behind these complex systems may or may not be known, or the system may or may not be possible to model mathematically. Often the model equations, as in the case of turbulent fluid flow, are too many or too difficult to permit analytical solutions or rapid numerical computations.

The objective of this chapter is to describe the basic SC techniques that can be applied to control problems relevant to MEMS. The sections below will describe the artificial neural network, genetic algorithm and fuzzy logic methodologies in outline. The description will be at an introductory level so as to let the reader decide whether the technique has some utility to his or her own application, and then will point to references for further details. It is important to emphasize that these are tools, and as such work much better in some circumstances than in others so that caution must always be used in their use. Reference will also be made to some of the applications that have been reported in the literature to give an idea of the kind of problems that can be approached.

Several excellent books and texts can be consulted on the general subject of SC. Aminzadeh and Jamshidi (1994), Yager and Zadeh (1994), Bouchon-Meunier et al. (1995) and Jang et al. (1997) cover broad aspects of SC; Schalkoff (1997) and Haykin (1999) deal with artificial neural networks; Fogel (1999) provides an outline of evolutionary programming; Goldberg (1989) presents an exposition on genetic algorithms; and Mordeson and Nair (1988) introduce the topic of fuzzy logic. Books covering more specific areas include those by Jain and Fukuda (1998) on the application of SC to robotic systems and Buckley and Feuring (1999) and Pal and Mitra (1999) on neuro-fuzzy systems.

## **14.2 Artificial Neural Networks**

---

One of the most common SC-based techniques is that of artificial neural networks (ANN). Excellent introductory texts are available on the subject, among them those by Schalkoff (1997) and Haykin (1999), in which an account of its history and mathematical background can be found. The technique has been applied to such diverse fields as philosophy, psychology, business and economics, in addition to science and engineering. What all these applications have in common is complexity, for which the ANN is particularly suitable.

### **14.2.1 Background**

Inspiration for the ANN comes from the study of biological neurons in humans and other animals. These neurons learn from experience and are also able to handle and store information that is not precise [Eeckman, 1992]. Each neuron in a biological network of interconnecting neurons receives input signals from other neurons and, if the accumulation of inputs exceeds a certain threshold, puts out a signal that is sent to other neurons to which it is connected. The decision to fire or not represents the ability of the ANN to learn and store information. In spite of the analogy between the biological and computational

neurons, there are significant differences that must be kept in mind. Though the biological processes in a neuron are slower, the connections are massively parallel as compared to its computational analogue, which must be limited by the speed of the currently available hardware.

Artificial neural networks are designed to mimic the biological behavior of natural neurons. Each artificial neuron (or node) in this network has connections (or synapses) with other neurons and has an input/output characteristic function. An ANN is composed of a number of artificial neurons, and each interneural connection has associated with it a certain weight and each neuron itself with a certain bias. Central to the use of an ANN is its training, which is also called the *learning process*. Training is the use of existing data to find a suitable set of weights and biases.

Many different ANN structures and configurations have been proposed along with various methodologies of training [Warwick et al., 1992]. The one we shall discuss in some detail is the multilayer ANN operating in the feedforward mode, and we will use the backpropagation algorithm for training. This combination has been found to be useful for many engineering and control purposes [Zeng, 1998]. The ANN, once trained, works as an input–output system with multiple inputs and outputs, and learning is accomplished by adjusting the weights and biases so that the training data are reproduced.

### 14.2.2 Feedforward ANN

Figure 14.1 shows a feedforward ANN consisting of a series of layers, each with a number of neurons. The first and last layers are for input and output, respectively, while the ones in between are the hidden layers. The ANN is said to be fully connected when any neuron in a given layer is connected to all the neurons in the adjacent layers.

Though notation in this subject is not standard, we will use the following. The  $j$ th neuron in the  $i$ th layer will be written  $(i, j)$ . The input of the neuron  $(i, j)$ , is  $x_{ij}$ , its output is  $y_{ij}$ , its bias is  $\theta_{ij}$ , and  $w_{i-1,k}^{i,j}$  is the synaptic weight between neurons  $(i - 1, k)$  and  $(i, j)$ . A number of parameters determine the configuration:  $I$  is the total number of layers, and  $J_i$  is the number of neurons in the  $i$ th layer. There are thus  $J_1$  input values to the ANN and  $J_1$  output.

Each neuron processes the information between its input and output. The input of a neuron is the sum of all the outputs from the previous neurons modified by the respective internodal synaptic weights and a bias at the neuron. Thus, the relation between the output of the neurons  $(i - 1, k)$  for  $k = 1, \dots, J_{i-1}$

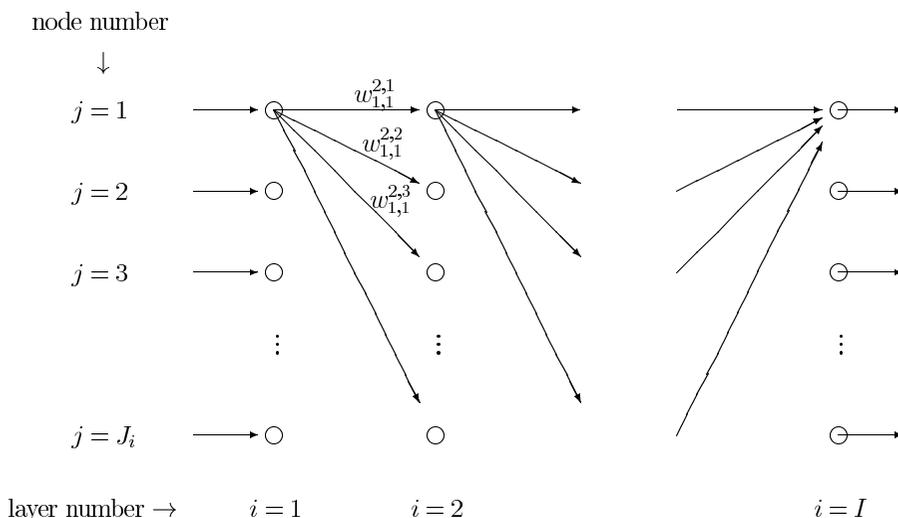

FIGURE 14.1 Schematic of feedforward neural network.

in one layer and the input of a neuron  $(i, j)$  in the following layer is

$$x_{i,j} = \theta_{i,j} + \sum_{k=1}^{J_{i-1}} w_{i-1,k}^{i,j} y_{i-1,k} \quad (14.1)$$

The input and output of the neuron  $(i, j)$  are related by:

$$y_{i,j} = \phi_{i,j}(x_{i,j}) \quad \text{for } i > 1 \quad (14.2)$$

and

$$y_{i,j} = x_{i,j} \quad \text{for } i = 1 \quad (14.3)$$

The function  $\phi_{i,j}(x)$ , called the *activation function*, plays a central role in the processing of information by the ANN. When the input signal is small, the neuron suppresses the signal altogether, resulting in a small output, and when the input exceeds a certain threshold the neuron fires and sends a signal to all the neurons in the next layer. Several appropriate activation functions have been used, the most popular being the logistic sigmoid function:

$$\phi_{i,j}(x) = \frac{1}{1 + \exp(-x/c)} \quad (14.4)$$

where  $c$  is a parameter that determines the steepness of the function. This function has several useful characteristics: It is an approximation to the step function that simulates the operation of firing and not firing but with continuous derivatives, and its output always lies between 0 and 1.

### 14.2.3 Training

Once the configuration of an ANN is fixed, the weights between the neurons and the bias at each neuron define its input–output characteristics. The weights determine the relative importance of each one of the signals received by a neuron from those of the previous layer, and the bias is the propensity for the combined input to trigger a response from the neuron. The process of training is the adjustment of the weights and biases to reproduce a known set of input–output values that have to be provided.

Though there are many methods in use, the backpropagation technique is a widely used deterministic training algorithm for this type of ANN [Rumelhart et al., 1986]. The method is based on the minimization of an error function by the method of steepest descent. Descriptions of this algorithm may be found in many recent texts on ANN (for instance, Rzepoluck [1998]), and only a brief outline will be given here. First, initial values are assigned to the weights and biases. Then, for a given input to the ANN, the output is determined. The synaptic weights and biases are iteratively modified until the output values differ little from the target outputs.

In the backpropagation method, an error  $\delta_{l,j}$  is quantified for the last layer by:

$$\delta_{l,j} = (y_{l,j}^T - y_{l,j}) y_{l,j} (1 - y_{l,j}) \quad (14.5)$$

where  $y_{l,j}^T$  is the target output for the  $j$ th neuron of the last layer. This equation comes from a finite-difference approximation of the derivative of the sigmoid function. After all the  $\delta_{l,j}$  have been calculated, the computation moves back to the layer  $l - 1$ . There are no target outputs for this layer, so the value,

$$\delta_{l-1,k} = y_{l-1,k} (1 - y_{l-1,k}) \sum_{j=1}^{J_l} \delta_{l,j} w_{l-1,k}^{l,j} \quad (14.6)$$

is used instead. A similar procedure is used for all the inner layers until layer 2 is reached. After all these errors have been determined, changes in the weights and biases are calculated from:

$$\begin{aligned}\Delta w_{i-1,k}^{I,j} &= \lambda \delta_{i,j} y_{i-1,k} \\ \Delta \theta_{i,j} &= \lambda \delta_{i,j}\end{aligned}\tag{14.7}$$

for  $i < I$ , where  $\lambda$  is the learning rate. From this the new weights and biases are determined.

In one cycle of training, a new set of synaptic weights and biases is determined for all training data after which the error defined by:

$$E = \frac{1}{2} \sum_{j=1}^{J_I} (y_{I,j}^T - y_{I,j})^2\tag{14.8}$$

is calculated. The error of the ANN at the end of each cycle can be based on either a maximum or averaged value for the output errors. The process is repeated over many cycles with the weights and biases being continuously updated throughout the training runs and cycles. The training is terminated when the error is low enough to be satisfactory in some pre-determined sense.

## 14.2.4 Implementation Issues

Several choices must be made to construct a suitable ANN for a given problem, and they are fairly important in achieving good results. There is no general theoretical basis for these choices, and experience combined with trial and error are still the best guides.

### 14.2.4.1 Configuration

The first choice that must be made in using an ANN is its configuration (i.e., the number of layers and the number of neurons in each layer). Though the accuracy of prediction sometimes becomes better (at other times, all it does is pick up additional noise) as the number of layers and neurons becomes larger, the number of cycles to achieve this also increases. It is possible to do some optimization by beginning with one hidden layer as a starting point and then adding more neurons and layers while checking the prediction error [Flood and Kartam, 1994]. Practical considerations dictate a compromise between accuracy and computational speed. It is usual to not go beyond two or three hidden layers, though many users prefer only one.

There are other suggestions for choosing the parameters of the ANN. Karmin (1990) used a relatively large ANN reduced in size by removing neurons that do not significantly affect the results. In the so-called radial-Gaussian system, hidden neurons are added to the ANN in a systematic way during the training process [Gagarin et al., 1994]. It is also possible to use evolutionary programming to optimize the ANN configuration [Angeline et al., 1994]. Some authors, e.g., Thibault and Grandjean (1991), present studies of the effect of varying these parameters.

### 14.2.4.2 Normalization

The data that the ANN handles are usually dimensional and thus have to be normalized. Furthermore, the slope of the sigmoid function  $\phi_{i,j}(x)$  used as the activation function becomes smaller as  $x \rightarrow \pm \infty$ . To use the central part of the function it is desirable to normalize all physical variables. In other words, the range between the minimum and maximum values in the training data is linearly mapped into a restricted range such as [0.15, 0.85] or [0.1, 0.9]. The exact choice is somewhat arbitrary and the operation of the ANN is not very sensitive to these values.

### 14.2.4.3 Learning Rate

The learning rate,  $\lambda$ , is another parameter that must be arbitrarily assumed. If it is large, the changes in the weights and biases in each step will be large; the ANN will learn quickly, but the training process could be oscillatory or unstable. Small learning rates, on the other hand, lead to a longer training period

to achieve the same accuracy. Its value is usually taken to be around 0.4 and determined by trial and error; there are also other possibilities [Kamarthi et al., 1992].

#### 14.2.4.4 Initial Values

Initial values of weights and biases have to be assigned at the beginning of the training process. Its importance lies in the fact that both the final values reached after training and the number of cycles needed to reach a reasonable convergence depend on the initial values. A simple method is to assign the values in a random fashion, though Wessels and Barnard (1992), Drago and Ridella (1992) and Lehtokangas et al. (1995) have suggested other methods for determining the initial assignment. Sometimes, the ANN is trained or upgraded on new data for which the old values can be used as the initial weights and biases.

#### 14.2.4.5 Training Cutoff

Training is repeated until a certain criterion is reached. A simple one is a fixed number of cycles. It is also common to specify the minimum in the error-number of cycles curve as the end of training. This has a possible pitfall in that there may be local minimum, beyond which the error may decrease some more.

### 14.2.5 Neurocontrol

The ANN described up to now is a static input–out system; that is, given an input vector it is able to predict an output. For purposes of real-time control the procedure must be extended to variables that are changing in time. This means that time  $t$  must also be a variable for both training and predictions. There are two ways in which this can be done: Either the time  $t$  or a time-step  $\Delta t$  between predictions can be considered to be additional inputs to the ANN. The latter procedure, which is convenient for microprocessor applications, has the advantage in that the initial values not really relevant to a control system after a long time quickly become irrelevant. The time step  $\Delta t$  in this procedure may be constant or may vary according to the needs of the prediction as time goes on.

The ANN can be trained as before. The trained ANN can predict values of variables at an instant  $t + \Delta t$  if the values at  $t$  are given. The dynamic simulation can be introduced into a prediction-based controller to control the behavior of a system.

### 14.2.6 Heat Exchanger Application

The general procedures and methodology of ANNs have been discussed up to now. In this section, we will apply the method to the specific problem of heat exchangers. A heat exchanger is merely an example of a system that, under the definition used here, is complex. Though the physical phenomena going on are well known, in the face of problems such as turbulence, secondary flows, developing flows, complicated geometry, property variations, conduction along walls, etc. it becomes impossible to compute the desired operating variables for prediction or, what is more difficult, in real time for control purposes. It will be shown that an ANN can be used for this purpose. Much of the work reported here is in Díaz (2000).

The heat exchanger used in tests is schematically shown in [Figure 14.2](#). The experiments were carried out in a variable-speed, open wind-tunnel facility [Zhao, 1995]. Hot water flows inside the tubes of the heat exchanger, and room air is drawn over the outside of the tubes. The flow rates of air and water are measured, along with the temperatures of the two fluids going in and out.

#### 14.2.6.1 Steady State

For a given heat exchanger, the heat transfer rate  $\dot{Q}$  under steady-state conditions depends on the flow rates of air and water,  $\dot{m}_a$  and  $\dot{m}_w$ , respectively, and their inlet temperatures,  $T_a^{\text{in}}$  and  $T_w^{\text{in}}$ , respectively. From the heat transfer rate, secondary quantities such as the fluid outlet temperatures,  $T_a^{\text{out}}$  and  $T_w^{\text{out}}$ , respectively, can be determined. For the present experiments, a total of 259 runs were made, of which only data for 197 runs were used for training, while the rest were used for testing the predictions.

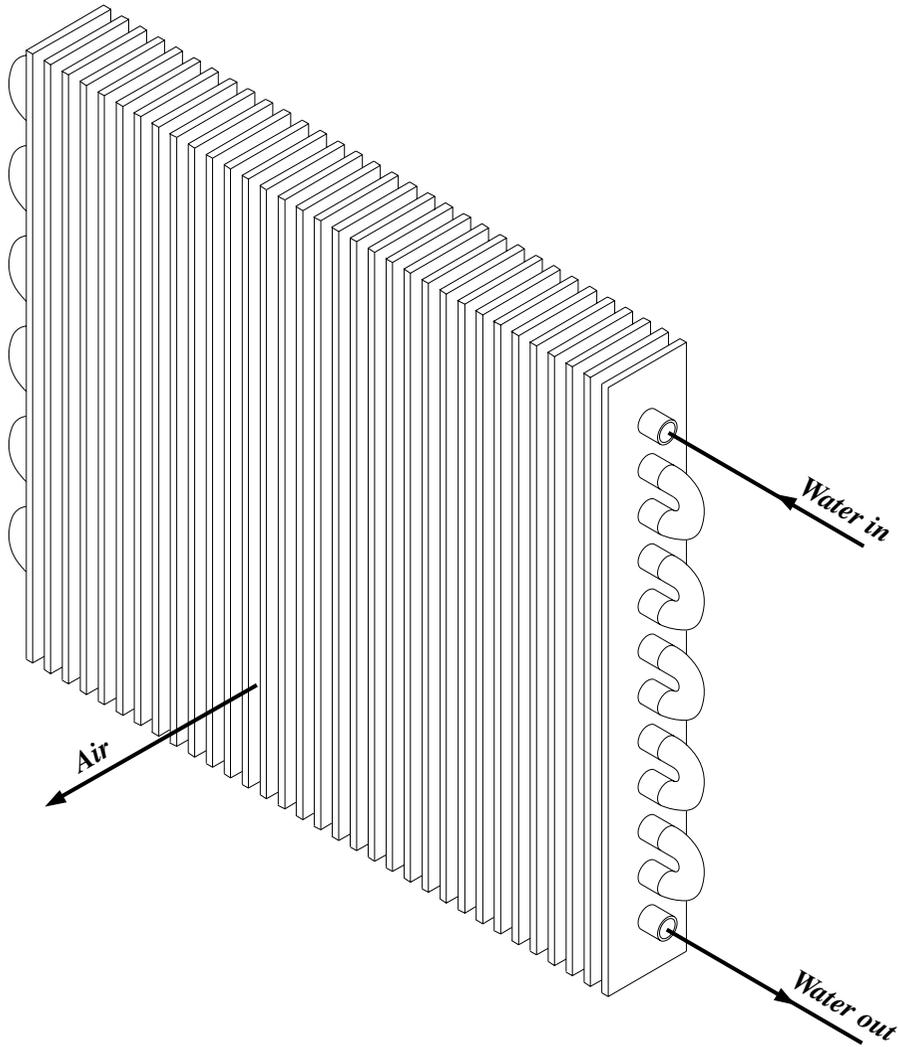

FIGURE 14.2 Schematic of compact heat exchanger.

For each test run the six quantities,  $\dot{Q}$ ,  $\dot{m}_a$ ,  $\dot{m}_w$ ,  $T_a^{\text{in}}$ ,  $T_w^{\text{in}}$ ,  $T_a^{\text{out}}$  and  $T_w^{\text{out}}$  were measured or determined from measurements. The work here is described in detail in Díaz et al. (1999).

From the data an ANN was trained. This network had four inputs,  $\dot{m}_a$ ,  $\dot{m}_w$ ,  $T_a^{\text{in}}$  and  $T_w^{\text{in}}$ , and a single output,  $\dot{Q}$ . Many different configurations and numbers of training cycles were tried. Good results were found for a 4–5–5–1 (i.e., four layers with 4, 5, 5 and 1 neurons in each layer, respectively) configuration trained for 200,000 cycles. The trained ANN was tested on the dataset set aside for the purpose. Figure 14.3 shows the results of the ANN prediction,  $\dot{Q}_{\text{ANN}}^p$ , plotted against the actual measurement,  $\dot{Q}^e$ . The 45° line that is shown would be an exact prediction, while the dotted lines represent errors of  $\pm 10\%$ . The prediction of a power-law correlation for the same data,  $\dot{Q}_{\text{cor}}^p$  [Zhao, 1995], is also shown. The ANN is seen to do a better job than the correlation.

#### 14.2.6.2 Thermal Neurocontrol

Once again the same heat exchanger was used to develop and use the neurocontrol methodology. Dynamic data were obtained by varying the water inlet temperatures by changing the heater settings while keeping the other variables constant. Training data were obtained from experiments in which the water inlet

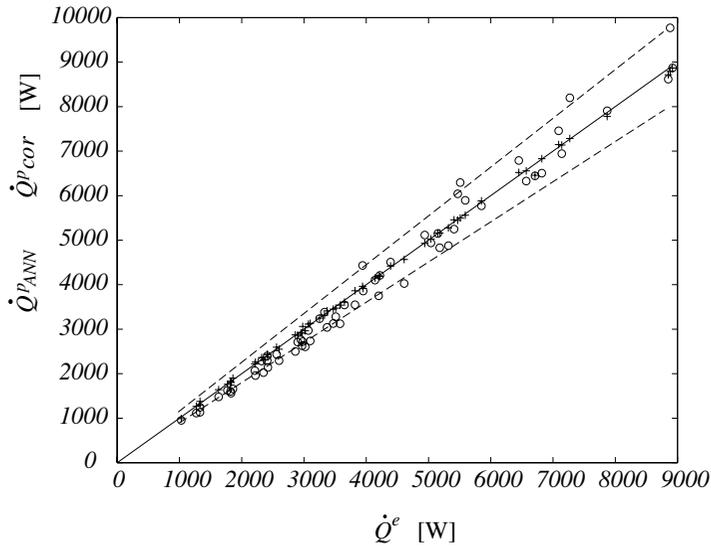

FIGURE 14.3 Predictions of 4–5–5–1 neural network (+) and correlation (○).

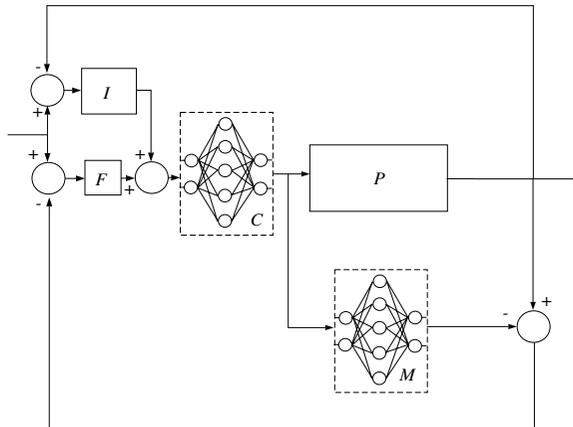

FIGURE 14.4 Closed-loop neurocontrol ( $P$  = plant,  $M$  = ANN model of plant,  $C$  = neurocontroller,  $F$  = filter,  $I$  = integral controller).

temperature was varied in small increments of  $5.56^{\circ}\text{C}$  from  $32.2^{\circ}\text{C}$  up to  $65.6^{\circ}\text{C}$ . Further details are in Díaz et al. (2001a). A nonlinear system may be controlled in many different ways. The method chosen for neurocontrol testing is shown in Figure 14.4. Control of the heat exchanger is by an inverse-ANN controller,  $C$ , while the plant,  $P$ , is modeled by a forward ANN,  $M$ . The controller is trained as a dynamic ANN. The desired control objective was to keep the outlet air temperature  $T_a^{\text{out}}$  constant.

In the first test, the system was subjected to a step change in the set temperature. The system was stabilized around  $T_a^{\text{out}} = 32^{\circ}\text{C}$ , after which the set temperature was suddenly changed to  $36^{\circ}\text{C}$ . Figure 14.5 shows how the neurocontroller behaved as compared to conventional PID (proportional–integral–derivative) and PI (proportional–integral) controllers. All the controllers work properly, but the neurocontroller has fewer oscillations. In a second test, we looked at the disturbance rejection ability of the controller. At steady operation, the water flow is completely shut down for a short interval: between  $t = 40$  s and  $t = 70$  s. Figure 14.6 shows how the system variables respond to PID and neurocontrol during and after the disturbance pulse. In the neurocontroller, oscillations are quickly damped out.

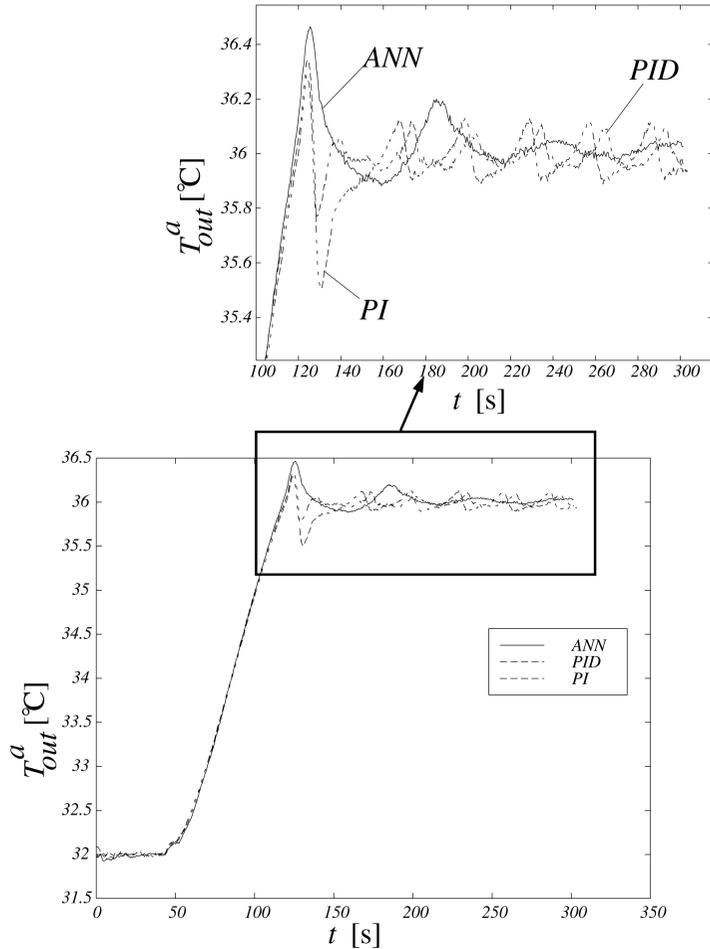

FIGURE 14.5 Response to change in set point.

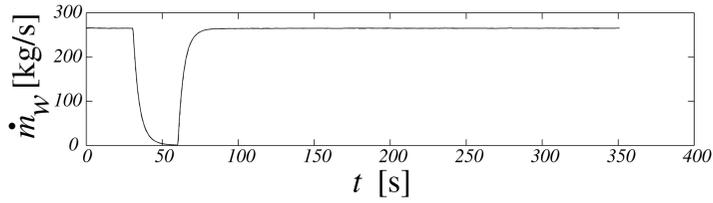

The procedure outlined above in which the ANN simulates the plant to be controlled is fairly straightforward. Other special aspects should be examined further.

#### 14.2.6.2.1 Stabilization of Feedback Loop

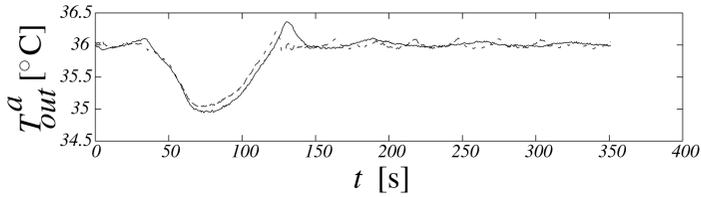

(See Díaz et al. [2001b].) The static ANN, once incorporated into the feedback loop, may lead to a dynamical system that is unstable. In order to avoid such a possibility, the ANN has to be trained not only to make accurate predictions but also to give dynamical stability to the loop. Because the weights are not unique, it is possible to come up with an algorithm that does both. The stabilization algorithm was designed and tested on the heat exchanger facility. Figure 14.7 shows the behavior of two controllers  $C_1$  and  $C_2$ , where the former is a stable controller and the latter is unstable. In each case, the air flow rate is being controlled and the air outlet temperature is shown as a function of time. The stable controller works well, while in the unstable case the air flow rate is increased as far it as will go without achieving the desired result.

#### 14.2.6.2.2 Adaptive Neurocontrol

(See Díaz et al. [2001c].) The major advantage of neurocontrollers is that they can be made adaptive. For such a system, the ANN can be made to go through a process of retraining if its predictions are not accurate due to change in system characteristics. The adaptive controller is tested in two different ways. The first is a disturbance on the water side, shown in Figure 14.8;  $v_a$  in the figure is the air velocity.

(a)

(b)

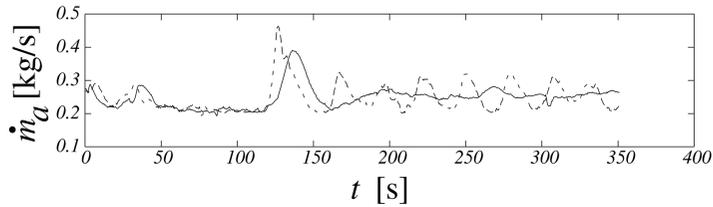

FIGURE 14.6 Disturbance rejection (continuous line is neural network, broken line is PID).

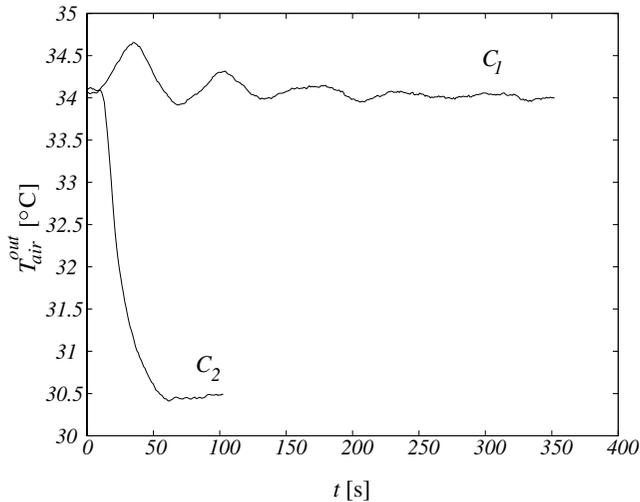

FIGURE 14.7 Performance of stable and unstable neurocontrollers.

Initially, the neurocontroller keeps the system close to  $T_a^{\text{out}} = 34^\circ\text{C}$ . From  $t = 100\text{ s}$  to  $t = 130\text{ s}$ , the water is shut off. The neurocontroller tries to control until  $t = 110\text{ s}$ , at which point it hands off to a backup PID controller while it adapts to the new circumstances. Then, once it is able to make reasonable predictions, it resumes control at  $t = 170\text{ s}$ . The second test is a sudden reduction of inlet area of the wind tunnel test facility, shown in Figure 14.9. The controller keeps  $T_a^{\text{out}}$  at  $34^\circ\text{C}$ , and then half of the inlet is

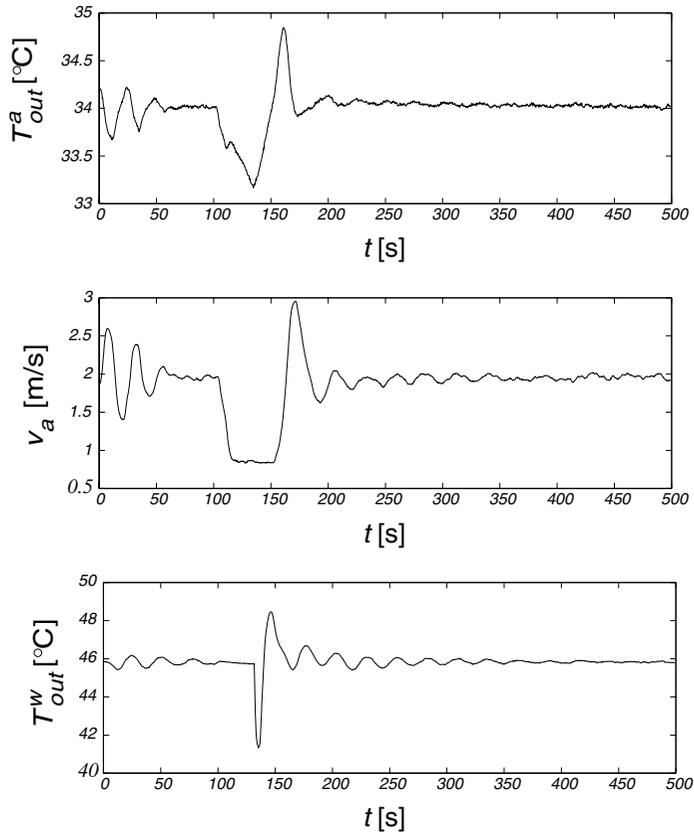

FIGURE 14.8 Response of adaptive neurocontroller to pulsed stoppage in water flow.

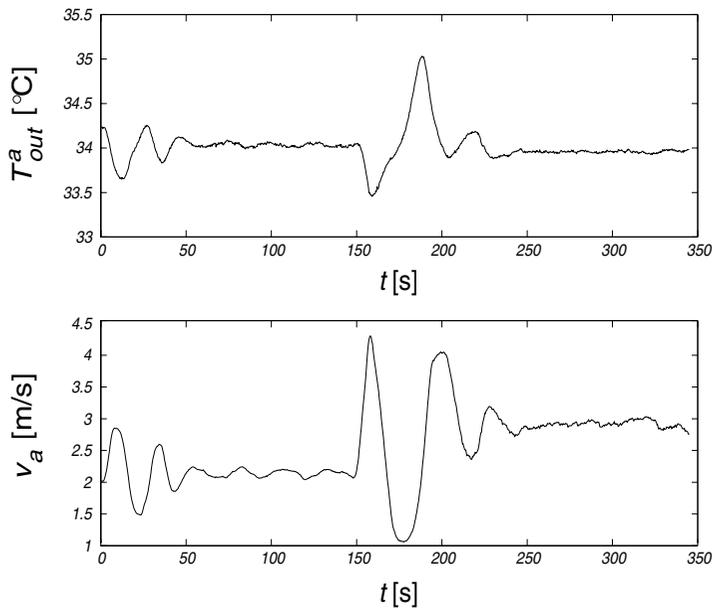

FIGURE 14.9 Response of adaptive neurocontroller to sudden change in wind-tunnel inlet area.

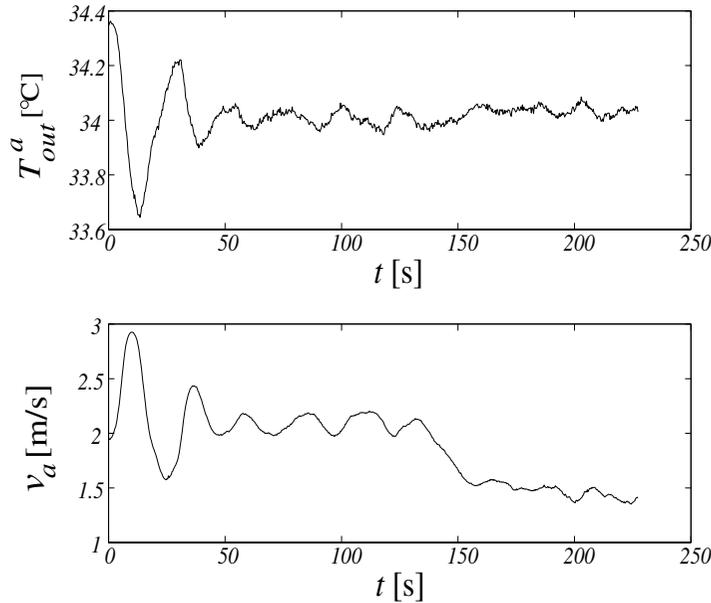

FIGURE 14.10 Application of energy minimization procedure.

suddenly blocked at  $t = 150$  s. The neurocontroller adapts until it learns the behavior of the new system, until finally at  $t = 240$  s it resumes control of the system.

#### 14.2.6.2.3 Optimal Control

For systems where there is more than one variable to be controlled, it is often required that it be controlled under an optimizing constraint. For thermal systems, for example, it may be possible to require that the system use the least energy at the new setpoint. Figure 14.10 shows the neurocontroller being used in this mode with the water and air flow rates being the control variables. In this case, the ANN has been fed information related to the energy consumption of the energy-consuming components of the facility: the hydraulic pump, the fan and the electric heater. We first let the controller stabilize  $T_a^{\text{out}}$  at  $34^\circ\text{C}$ . Around  $t = 130$  s, the energy minimization routine is turned on and the controller adjusts both the water and air flow rates to minimize energy usage while keeping  $T_a^{\text{out}}$  roughly at its set value.

### 14.2.7 Other Applications

Many other applications of neurocontrol have been reported in the literature, including inflow-related problems. Gad-el-Hak (1994) has given an overview of the problem of flow control in turbulent boundary layers. Control has been attempted by Jacobson and Reynolds (1993); Lee et al. (1997) used ANNs for turbulence control for drag reduction purposes; Suzuki and Kasagi (1997) were able to use it for the optimal control of vortex shedding behind a square cylinder, minimizing, at the same time, the angular motion of the cylinder; and Chan and Rad (2000) used it for the purpose of real-time flow control.

### 14.2.8 Concluding Remarks

The implementation of ANN procedures in a complex problem is really very straightforward. It relieves the necessity of having a first-principles model that may not be available for devices, such as those based on MEMS which are relatively new. Predictions can be made and systems can be controlled on the basis of available information without the need for models. In addition, the ANN is also extremely adaptable to changing circumstances.

## 14.3 Genetic Algorithms

Evolutionary algorithms are those that change or evolve as they do their work. The genetic algorithm (GA) is a specific type of search technique based on the Darwinian evolutionary principles of natural selection to attain its objective of optimization. Optimization by itself is fundamental to many applications in engineering. For example, it is important in the design of systems; although analysis permits the prediction of the behavior of a given system, optimization is the technique that searches among all possible designs of the system to find the one that is the best for the application. Optimization is also intimately related to the control problem where parameters have to be chosen: The configuration of neural networks has to be selected, and the constants of PID control have to be set. The importance of this problem has given rise to a wide variety of techniques that help search for the optimum. In this context, local and global optima must be distinguished. If one visualizes a multivariable function with many peaks, any one of these is a local maximum, while only one is the highest.

Genetic algorithms are described in monographs by Goldberg (1989), Michalewicz (1992), Mitchell (1997) and Man et al. (1999). GAs are generally used for the purpose of global optimization. They are not gradient-based and are an alternative to other global optimization techniques such as simulated annealing. Because local gradient information is not used, a GA usually finds the global optimum as opposed to a local one, a characteristic that is often useful. Furthermore, the fact that gradients are not used may be significant in problems in which the variables to be optimized are functions of discrete quantities and their derivatives are not possible.

Robustness, a central characteristic for survival of natural species, is also a feature of genetic algorithms. Goldberg (1989) compared the genetic algorithm from this perspective with other search techniques. Methods based on the calculus, such as equating to zero the derivatives of a function to obtain the extrema, are indirect. In a direct method, the iteration moves in a direction determined by the local gradient of the function. Both these methods are local and depend on the local existence of derivatives. Another class of methods is based on evaluation of a function at every point on a fine but finite grid. For most practical applications this approach is too time consuming. In yet another class of techniques, randomness is used in some way. Simulated annealing and genetic algorithm are examples of this. They search from a population of points rather than from a single point, they use only the function rather than its derivative, and they use probabilistic rather than deterministic rules. The search using many points makes the method global rather than local.

### 14.3.1 Procedure

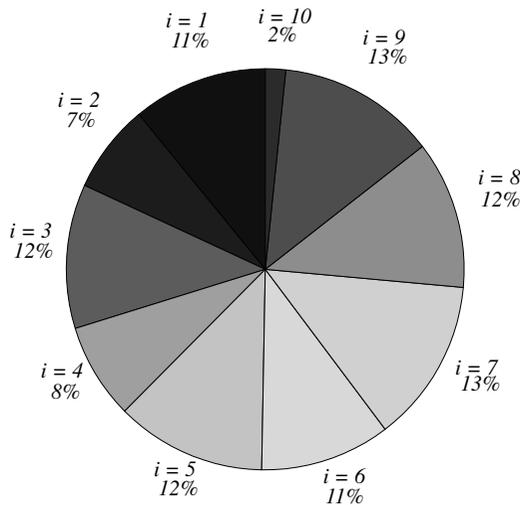

There are many variants of the genetic algorithm procedure. A simple approach is described here, but it is not the only one. We can illustrate the GA procedure by finding the maximum of a function  $f(x)$  within a given domain  $x \in U \subset \mathfrak{R}^n$ . In a gradient-based method, the slope of the tangent plane at a given value of  $x$  indicates which way to “go up” within an iterative procedure. The GA does not work this way. For simplicity, in the following we will assume that  $U = [a, b] \subset \mathfrak{R}$ , though the method can be easily generalized to higher dimensions. Furthermore, we will map the interval  $[a, b]$  to  $[0, 2^c - 1]$ . This way, the independent variable  $x$  can be represented by a binary string of length  $c$  running from 000...000 all the way up to 111...111. The example function chosen for maximization is  $f(x) = x(1 - x)$ .

*Step 1:* We begin by randomly selecting  $r$  candidate numbers within the desired domain (i.e.,  $x_1, \dots, x_r$ ). This is the first generation. An example is shown in Table 14.1, where we have taken  $r = 10$  and  $c = 6$ . The second column shows the numbers in decimal form, the third column the same numbers in binary form, and the fourth the normalized binary version of the same. The function  $f(x_i)$  for each number which, in the context of this algorithm, is called the fitness is indicated in the fifth column. The reason for this name is that, the higher the fitness is, the closer  $x_i$  is to its value where  $f(x_i)$  is a maximum. In other words, we seek the value of  $x$  for which  $f(x)$  is the fittest. The maximum fitness of the members of the this generation is 0.2469 for  $x_i = 0.4444$ . The last column is the normalized fitness  $s(x_i)$ , the values of the previous column divided by the sum of the fitnesses; thus,  $s(x_i) = f(x_i)/\sum f(x_i)$ .

**TABLE 14.1** Binary, Decimal and Normalized Forms of the First Generation of Candidate Numbers and Their Absolute and Normalized Fitnesses

$i$	$x_i(d)$	$x_i(b)$	$x_i(d, n)$	$f(x_i)(d)$	$s(x_i)(d)$
1	18	010010	0.2857	0.2041	0.1096
2	53	110101	0.8413	0.1335	0.0717

4	11	001011	0.1746	0.1441	0.0774
5	22	010110	0.3492	0.2273	0.1221
6	46	101110	0.7302	0.1970	0.1058
7	28	011100	0.4444	0.2469	0.1326
8	42	101010	0.6667	0.2222	0.1194
9	25	011001	0.3968	0.2394	0.1286
10	61	111101	0.9683	0.0307	0.0165

Note:  $b$  = binary;  $d$  = decimal;  $n$  = normalized.

**FIGURE 14.11** (Color figure follows p. 12-26.) “Old” fitness.

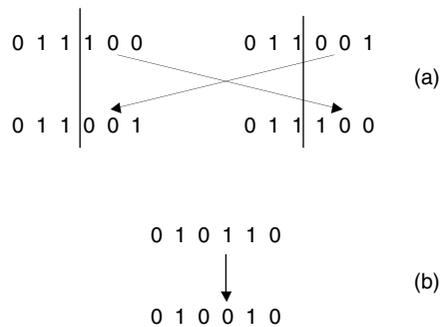

*Step 2:* From the first generation of numbers, pairs of parents are chosen which then give rise to offspring that form the next generation. To visualize the process we draw a pie chart, shown in Figure 14.11, with slices that have angles proportional to the normalized fitness  $s(x_i)$ . To form parents, pairs of numbers are randomly selected from the chart as if it were a roulette wheel. Of course, the numbers with larger normalized fitnesses have the higher probability of being selected. The result of such a selection process is shown in the second column of Table 14.2 as generation  $G = 1/4$ . These are then shuffled to produce column  $G = 1/2$ . The first two entries in this column are a set of parents, the next two another set, and so on.

*Step 3:* Each pair of parents produces a pair of offspring by crossover, which can be done in different ways. Here, we have randomly chosen a point along the two binary strings that form the parents and have interchanged the part of the string beyond this point. This is a single-point crossover. An example is shown in Figure 14.12, where the crossover point is in the middle of the string and the numbers 011100 and 011001 produce the offspring 011001 and 011100. The crossover point in the other pairs may be different. The final result of crossover between the parents is column  $G = 3/4$ .

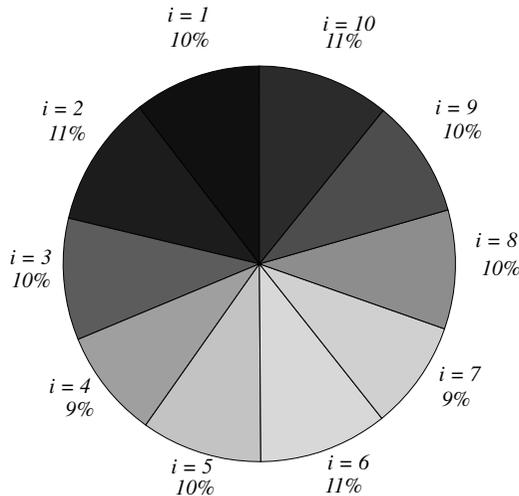

*Step 4:* The column  $G = 1$  is obtained from  $G = 3/4$  by mutation. This is obtained by selecting a randomly chosen bit and changing it from 0 to 1, or vice versa. One bit in the fourth number can be seen to have been changed, as shown in Figure 14.12. The procedure above gives a new generation with

**TABLE 14.2** From One Generation to the Next

$G = 0$	$G = 1/4$	$G = 1/2$	$G = 3/4$	$G = 1$
010010	011100	011100	011001	011001

101010	010110	101010	101010	101010
011001	011001	101011	101010	101010
111101	010110	011100	011101	011101

**FIGURE 14.12** (a) Crossover and (b) mutation in a genetic algorithm.

**FIGURE 14.13** (Color figure follows p. 12-26.) “New” fitness.

members that are generally fitter (i.e., give a value of the function that is closer to the maximum). The new pie-chart of the normalized fitness, [Figure 14.13](#), shows much more uniformity in fitnesses since the “unfit” have disappeared. The maximum fitness of this generation turns out to be  $f(x_i) = 0.2484$  at  $x_i = 0.4603$  compared to the value of  $f(x_i) = 0.2469$  at  $x_i = 0.4444$  for the previous generation. The process of finding a new generation is repeated several times until some criterion is satisfied. Either a desired number of cycles

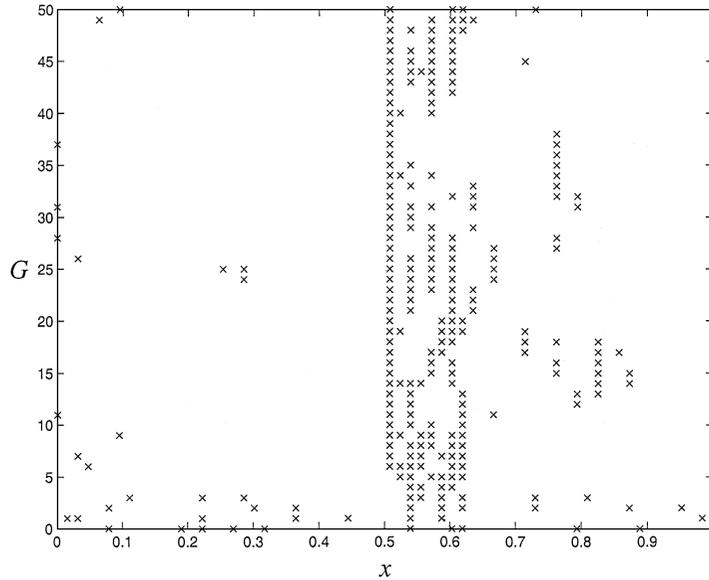

FIGURE 14.14 Change in population as a function of generation number.

have been completed, the maximum fitness of the generation does not change much, or the value of  $x$  at which this maximum fitness is obtained does not change significantly.

Some programming details need to be taken care of in actual implementation. Parameters such as the number of members of a generation and the length of a binary string must be decided upon. In addition, a finite probability for crossover and mutation must be prescribed. The crossover does the bulk of the work in selecting the new generation. Although the probability of mutation is generally kept small, it is vital as mutation enables a possible solution to break out of the neighborhood of a local optimum and go somewhere else that may turn out to have a better local optimum. It is also common to keep the best of each generation in the next to make sure that the fitness of the generation is nondecreasing. The algorithm itself is probabilistic so that it cannot be guaranteed to find the global optimum. In fact, every time it is run, the exact results obtained will be different.

Figure 14.14 shows the result of running a GA code (written by A. Pacheco-Vega) to continue the process indicated in Tables 14.1 and 14.2. The probability of crossover is taken to be unity, and that of mutation is 0.03. The abscissa shows the distribution of the population  $x_1, \dots, x_r$  at a generation number  $G$  indicated in the ordinate. The initial population at  $G = 0$  is indicated by 10 different crosses (the exact values are different from those in Tables 14.1 and 14.2 because of the generation of different random numbers). In the following generations, some of the crosses overlap as numbers may repeat themselves within a population. The code has been terminated after 50 generations. A certain crowding of the population around the correct value  $x = 0.5$  is observed as well as the presence of values relatively far from it. This is a consequence of the global nature of the search and is a characteristic of the GA. In addition, even at  $G = 50$  the value of  $x_i$  that gives the highest value of the function is close to the correct value but is not exact.

### 14.3.2 Heat Exchanger Application

Application of this SC technique will again be illustrated by its use in the heat exchanger described before. The optimization problem here is to find the best correlation that fits experimental data. A set of  $N = 214$  experimental runs provided the database. In each case, the heat rate  $\dot{Q}$  is found as a function of the two flow rates  $m_w$  and  $m_a$  as well as the two inlet fluid temperatures  $T_a^{\text{in}}$  and  $T_w^{\text{in}}$ . Details are in Pacheco-Vega et al. (1998).

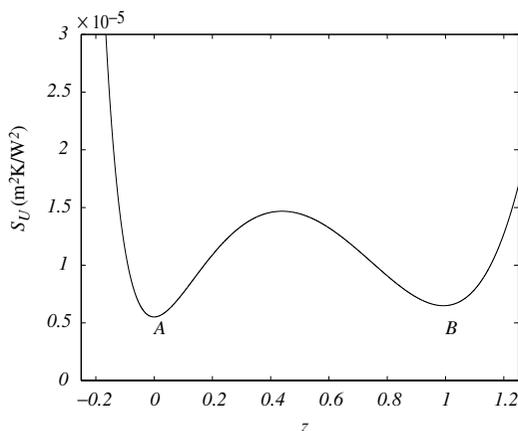

FIGURE 14.15 Global vs. local minima in optimization problem.

There are two resistances to the flow of heat by convection: on the inside with water and on the outside with air. The conventional way of handling data is to determine correlations for the inner and outer heat transfer coefficients. For example, in power-law relations of the form  $Nu = aRe^n$  between the Nusselt and Reynolds numbers,  $Nu$  and  $Re$ , respectively, on both sides of the tube wall are often assumed. There are then four constants to determine:  $a_1$ ,  $a_2$ ,  $n_1$  and  $n_2$ . One possible procedure is to minimize the root mean square (rms) error  $S_U(a_1, a_2, n_1, n_2)$  in total thermal resistance to heat transfer between prediction and data in the least-square sense. The total resistance is the sum of the air-side and water-side resistances.

It is found that this procedure leads to a large number of local minima due to the nonlinearity of the function to be minimized. Figure 14.15 shows a pair of such minima. In the figure, a section of the error surface  $S_U(a_1, a_2, n_1, n_2)$  that passes through two local minima A and B is shown. The coordinate  $z$  is a linear combination of  $a_1$ ,  $a_2$ ,  $n_1$  and  $n_2$  such that it is zero at A and unity at B, and the ordinate is the rms error. Though the values  $S_U$  of for the two correlations obtained at A and at B are very similar and the heat rate predictions for the resulting correlations are also almost equally accurate,  $a_1$ ,  $a_2$ ,  $n_1$ ,  $n_2$  and the predictions of the thermal resistances on either side are very different. This shows the importance, at least in this case, of using global minimization techniques for nonlinear regression analysis. If the GA is used to find the global minimum, the point A is in fact seen to be the global minimum. The correlation (not shown) found as a result of the global search is the best that fits the assumed power laws and is closest to the experimental data.

### 14.3.3 Other Applications

Many other applications of GAs to optimization and control problems include optimization of a control scheme by Seywald et al. (1995), Michalewicz et al. (1992), Perhinschi (1998) and Tang et al. (1996b). Reis et al. (1997) and Kao (1999) have used the GA to find the optimal location of control valves in a piping network. Gaudenzi et al. (1998) optimized the control of a beam using the technique. Several workers have applied the method to the motion of robots [Nakashima et al., 1998; Nordin et al., 1998]. Katsikas et al. (1995) and Tang et al. (1996a) used the genetic algorithm for active noise control. Nagaya and Ryu (1996) controlled the shape of a flexible beam using a shape memory alloy and Keane (1995) optimized the geometry of structures for vibration control. Dimeo and Lee (1995) controlled a boiler and turbine using the genetic algorithm. Sharatchandra et al. (1998) used the GA for shape optimization of a micropump. Kaboudan (1999) have used genetic algorithms for time-series prediction. Luk et al. (1999) developed a GA-based fuzzy logic control of a solar power plant using distributed collector fields. Additional applications of GAs combined with other SC techniques have been used for optimization of the control process [e.g., Matsuura et al., 1995; Trebi-Ollennu and White, 1997; Rahmoun and Benmohamed, 1998; Ranganath et al., 1999; Lin and Lee, 1999].

### 14.3.4 Final Remarks

There are two main advantages in using a genetic or evolutionary approach to optimization. One is that the methods seek the global optimum. The other advantage is that they can be used in discrete systems, in which derivatives do not exist or are meaningless. Examples of this are piping networks and positioning of electronic components. As with all tools, the reader who is interested in this procedure must evaluate the advantages and disadvantages in terms of specific applications.

## 14.4 Fuzzy Logic and Fuzzy Control

### 14.4.1 Introduction

Fuzzy sets and fuzzy logic date back to the early 1960s with the work of Lotfi Zadeh [Zadeh, 1965; 1968a; 1968b; 1971] concerning complex systems and have been present in controls applications since the late 1970s [Mamdani, 1974; Mamdani and Assilian, 1975; Mamdani and Baaklini, 1975]. The main utility of fuzzy logic and its application to feedback control is comprised of two components. First, fuzzy logic is not model based so it can be applied to systems for which developing analytical models, either from first principles or from some identification techniques, is impractical or expensive. Second, it provides a convenient mechanism for application to feedback control of human (or expert) intuition regarding how a system should be controlled. This section outlines basic fuzzy set definitions, fuzzy logic concepts and their primary application to control systems. First, an illustrative controls application of fuzzy logic is presented in complete detail. The example is followed by a more complete exposition of the mathematics of fuzzy logic intended to provide the reader with a complete set of tools with which to approach a fuzzy control problem.

### 14.4.2 Example Implementation of Fuzzy Control

This section first introduces a typical structure of fuzzy controllers by presenting an example of a common fuzzy control application—namely, to stabilize the inverted pendulum system illustrated in Figure 14.16, where the control input is a force of magnitude  $u$ . In this problem, only the pendulum angle is stabilized. This is accomplished via linguistic variables and fuzzy if–then rules such as:

1. If the pendulum angle is zero and the angular velocity is zero, then the control force should be zero.
2. If the pendulum angle is positive and small and the angular velocity is zero, then the control force should be positive and small.

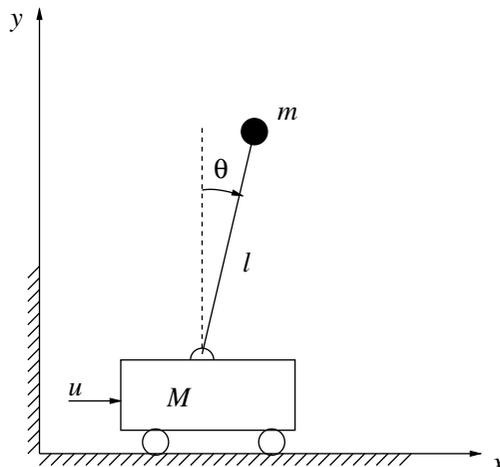

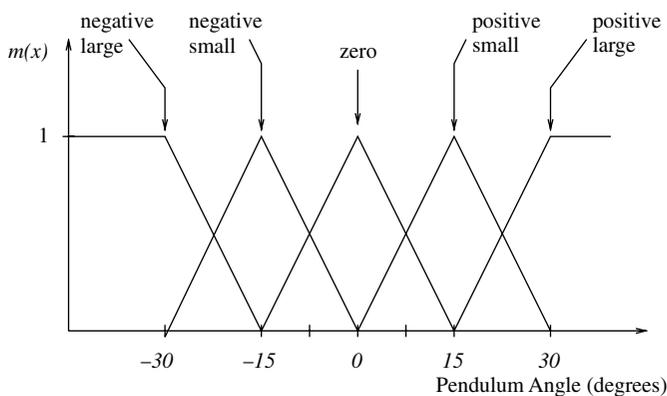

FIGURE 14.16 Pendulum system.

**TABLE 14.3** Fuzzy Logic Rules to Determine Control Force

Error	Angular Velocity				
	Negative Large (1)	Negative Small (2)	Zero (3)	Positive Small (4)	Positive Large (5)
(1) Negative large	Negative large	Negative large	Negative large	Negative small	Zero
(2) Negative small	Negative large	Negative large	Negative small	Zero	Positive small
(3) Zero	Negative large	Negative small	Zero	Positive small	Positive large
(4) Positive small	Negative small	Zero	Positive small	Positive large	Positive large
(5) Positive large	Zero	Positive small	Positive large	Positive large	Positive large

**FIGURE 14.17** Pendulum angle fuzzy set.

3. If the pendulum angle is positive and large and the angular velocity is zero, then the control force should be positive and large.
4. If the pendulum angle is positive and small and the pendulum angular velocity is negative and small, then the control force should be zero.

The linguistic variables are the angle error and the angular velocity. These rules are better expressed in tabular form in Table 14.3. The first enumerated rule is expressed in the third column and third row of the table. The second rule is in the third column and fourth row. The third rule is in the third column and fifth row. The fourth rule is in the second column and fourth row. An important point is that these rules were determined by intuition. For example, whether the second column and second row should be “negative small” or “negative large” is determined by experience, guesswork or tuning.

The next basic element of the fuzzy controller is the fuzzy set, which basically encapsulates the notion of to what degree the angle is “zero,” “negative small,” etc. The fuzzy sets that define the fuzzy state of the angle of the pendulum system are illustrated in Figure 14.17. In the figure, if the pendulum angle is, for example,  $-7.5^\circ$ , then the degree of membership in the “negative small” fuzzy set is 0.5 and the degree of membership in the “zero” fuzzy set is also 0.5. The degree of membership in the other fuzzy sets is 0. Similar fuzzy sets can be defined for the angular velocity and the control force, as illustrated in Figures 14.18 and 14.19, respectively.

The overall control structure is illustrated in Figure 14.20. First, the state  $(\theta, \dot{\theta})$  is measured by some sensor. Next, the state is “fuzzified” by computing the degree of membership of the state in each of the fuzzy sets,  $A_i$ , used in the if-then rules. Then, the if-then rules in the rule base are evaluated in parallel, and the output of each rule is the fuzzy set (control force), which has the shape of the fuzzy set associated with the output of the if-then rule but is “capped” or “cut off” at the degree of membership of the state

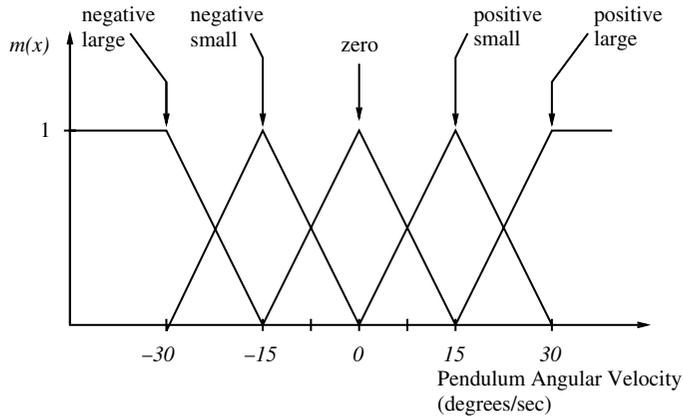

FIGURE 14.18 Pendulum velocity fuzzy set.

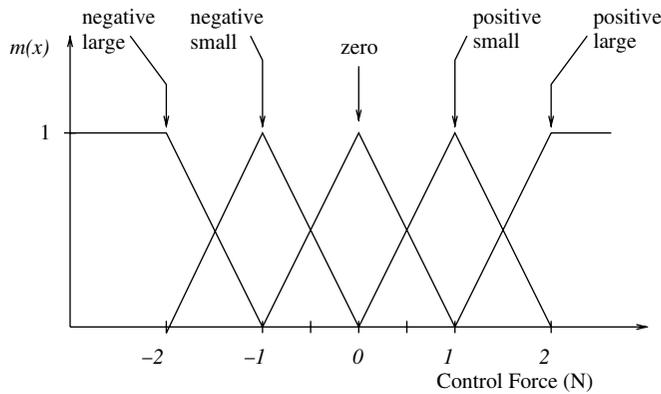

FIGURE 14.19 Pendulum force fuzzy set.

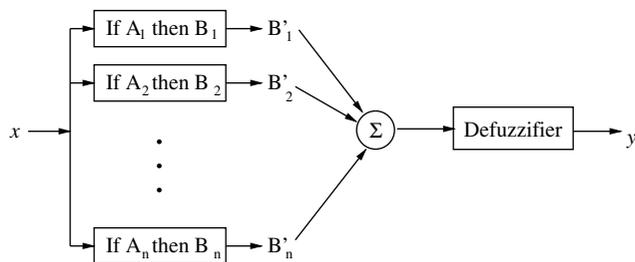

FIGURE 14.20 Fuzzy control structure.

in the associated fuzzy set. If there is a logical operation, such as “and” in the antecedent (the “if” part) of the rule, then the minimum of the degree of membership in each of the fuzzy sets is used.

As a concrete example of this “fuzzy inference,” consider the case where the pendulum angle is  $-20^\circ$  and the angular velocity is  $+22.5^\circ/\text{s}$ . Then, the fuzzy state of the angle of the system is determined according to Figure 14.21, where the state of the system is represented by a 0.25 degree of membership

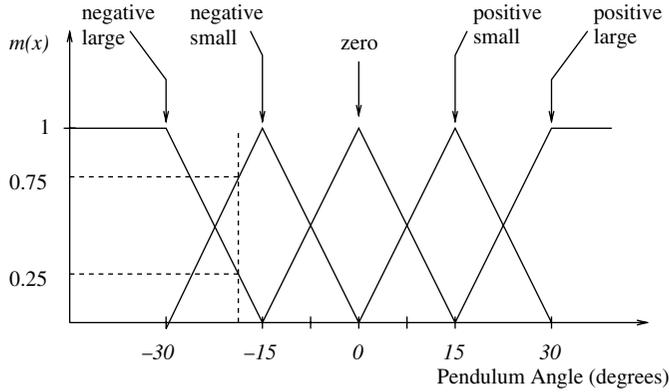

FIGURE 14.21 Fuzzification of pendulum angle.

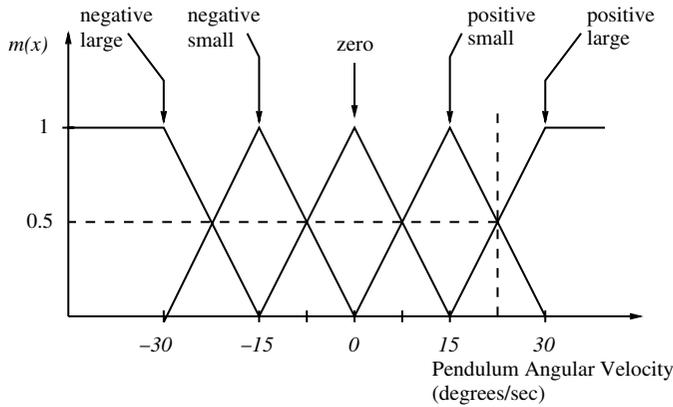

FIGURE 14.22 Fuzzification of pendulum angular velocity.

in the “negative large” fuzzy set, and a 0.75 degree of membership in the “negative small” fuzzy set. Correspondingly, the velocity is characterized by a 0.5 degree of membership in both the “positive large” fuzzy set and the “positive small” fuzzy set, as is illustrated in Figure 14.22.

Now, the output of each rule will be the corresponding force fuzzy set, but modified so that its maximum value is capped to be the minimum degree of membership of the two elements of the antecedent part of each rule. In particular, only four of the rules listed in the table will evaluate to nonzero values—namely, the top two rows in the last two columns of Table 14.3. Considering the “negative large” position and “positive small” velocity first, the “negative small” force output will be capped at 0.25, which is the degree of membership in the “negative large” position fuzzy set which is less than the 0.5 membership of the angular velocity in the “positive small” fuzzy set. In the “negative large” position and “positive large” velocity, the output will again be capped at 0.25, as similarly, it is less than the 0.5 membership of the angular velocity in the “positive large” fuzzy set. In the cases of “negative small” position and “positive small” velocity, as well as “negative small” position and “positive large” velocity, the output of the “zero” and “positive small” output force fuzzy sets will both be capped at 0.5. Once the outputs from each if-then rule are computed, they are aggregated into one large fuzzy set. In this aggregation, if two of the fuzzy outputs overlap, then (opposite to the “and” combination for the fuzzy rules) the maximum of the two sets is taken. Returning to the example, the aggregation of the four rules for the angle of  $-20^\circ$  and angular velocity of  $+22.5^\circ/\text{s}$  is illustrated in Figure 14.23. “Defuzzification” is necessary

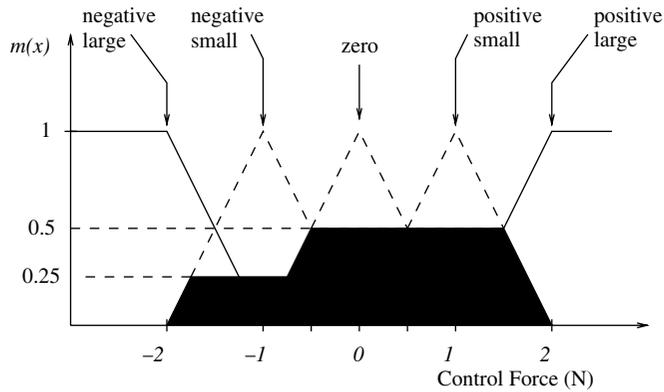

FIGURE 14.23 Aggregation of fuzzy output sets.

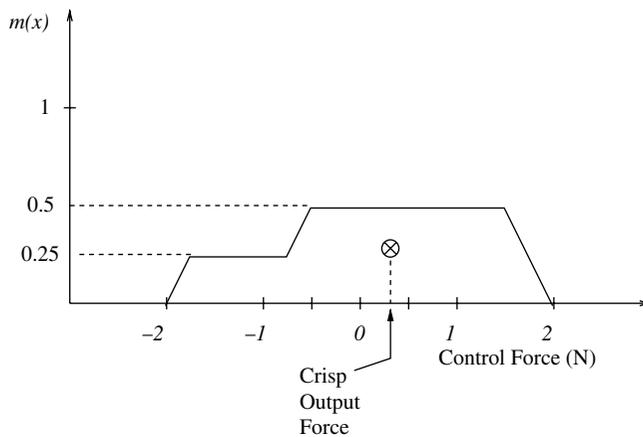

FIGURE 14.24 Defuzzification of output by computing centroid.

to have a crisp output force, and a common technique to do that is to compute the value of the crisp output as the centroid of the aggregated fuzzy output set, as is illustrated [Figure 14.24](#).

Simulating such a system is straightforward using Matlab. If the pendulum mass is 0.1 kg, the cart mass 2.0 kg, and the length of the pendulum 0.5 m, and the values of the membership functions are as illustrated in [Figure 14.25](#), the response of the cart and pendulum system is illustrated in [Figures 14.26](#) and [14.27](#). [Figure 14.26](#) illustrates the response of the pendulum angle and [Figure 14.27](#) illustrates the velocity of the pendulum. The control effort is illustrated in [Figure 14.28](#). Because the cart position was not controlled, its steady-state response is actually a constant, nonzero velocity. The “response surface” (i.e., the plot of the function defining the control force computed by the fuzzy controller as a function of the two input variables) is illustrated in [Figure 14.29](#).

The remainder of this section will outline the mathematical foundations of fuzzy logic which will allow the reader to adapt this example as necessary for a particular application. In particular, note that in the pendulum example, the “and” conjunction, the aggregation of the outputs and the means to defuzzify the output were all implemented in certain, specific ways. However, these are not necessarily the only or best implementations. The mathematical outline will consider in more general terms fuzzy statements such as, “If A and B, then C” or “If A or B, then C,” which will lead to a list of possible alternative implementations of such a fuzzy inference system. Which type of implementation is “best” may be application dependent, although the procedure outlined above is the predominant approach to fuzzy control.

## 14.4.3 Fuzzy Sets and Fuzzy Logic

### 14.4.3.1 Introduction

This section introduces fuzzy sets and fuzzy logic and the mathematical foundations thereof. First, this section considers the concept of a membership function which extends the notion of whether or not an element belongs to a set to casting membership in a set to be a matter of degree; that is, instead of either belonging or not belonging to a crisp set, an element can partially belong to a “fuzzy” set. Several examples of fuzzy sets are provided, and the properties of traditional crisp sets are compared with the analogous

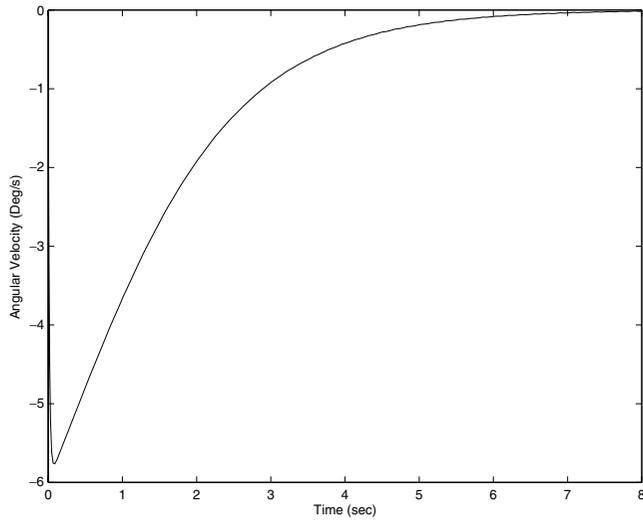

FIGURE 14.27 Pendulum velocity.

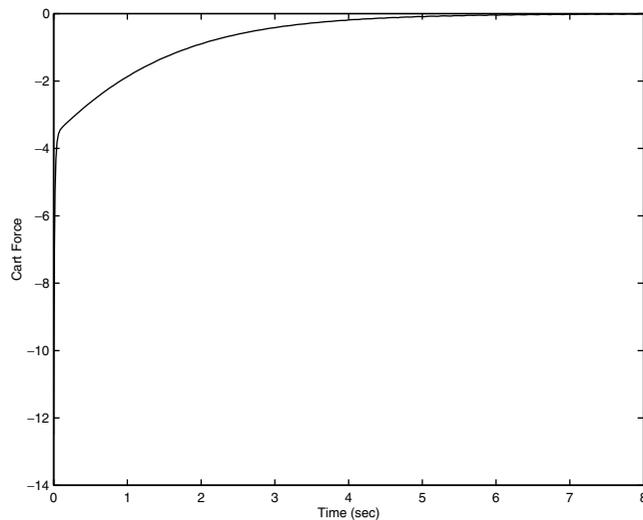

FIGURE 14.28 Control effort required to stabilize inverted pendulum.

properties of fuzzy sets. There is a “crisp” aspect to the normal definition of fuzzy sets in that the membership function returns a crisp value. Fuzzy sets defined as such can be generalized to have fuzzy-valued membership functions. After defining fuzzy sets and outlining their properties, operations on fuzzy sets such as the compliment, intersection, etc. are defined and contrasted with the analogous operations on crisp sets. Finally, fuzzy arithmetic and fuzzy logic are introduced as well as the notion of an additive fuzzy system, which is the basic framework utilized in most fuzzy control (in fact, the pendulum example above utilized this type of inference system).

### 14.4.3.2 Fuzzy vs. Crisp Sets

The traditional notion of a set will be called a *crisp set*. Examples of crisp sets include:

1. The set of integers  $\{\dots, -2, -1, 0, 1, 2, \dots\}$
2. The set of all people taller than five feet, eight inches

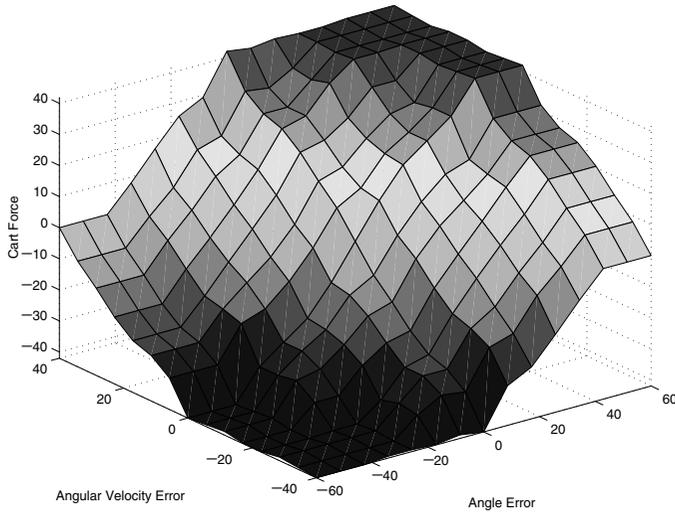

FIGURE 14.29 (Color figure follows p. 12-26.) Response surface for pendulum fuzzy controller.

3. Closed or open intervals of real numbers between  $a$  and  $b$ :  $[a, b]$ ,  $(a, b)$ , respectively
4. A set defined by explicitly listing its elements, such as the set containing the letters  $a$ ,  $b$  and  $c$ :  $\{a, b, c\}$ .

Unless otherwise indicated, crisp sets will not be considered ordered. The fundamental characteristic of crisp sets that will later distinguish them from fuzzy sets is that an element either is a member of the set or it is not a member of the set. Mathematically, then, one can define a membership function,  $m$ , which maps from a universal set,  $U$ , which is the set of all possible elements, to the set  $\{0, 1\}$ , where for set  $A$  and element  $x \in U$ ,

$$m : U \rightarrow \{0, 1\} \quad (14.9)$$

That is, the membership function returns a 1 if  $x$  is a member of  $A$ , and returns 0 if  $x$  is not a member of  $A$ .

Crisp sets have a list of standard properties related to concepts in classical logic. In particular, if the following operations are defined:

1. Complement:  $\bar{A} = U - A = \{x \in U | x \notin A\}$
2. Union:  $A \cup B = \{x \in U | x \in A \text{ or } x \in B\}$
3. Intersection:  $A \cap B = \{x \in U | x \in A \text{ and } x \in B\}$

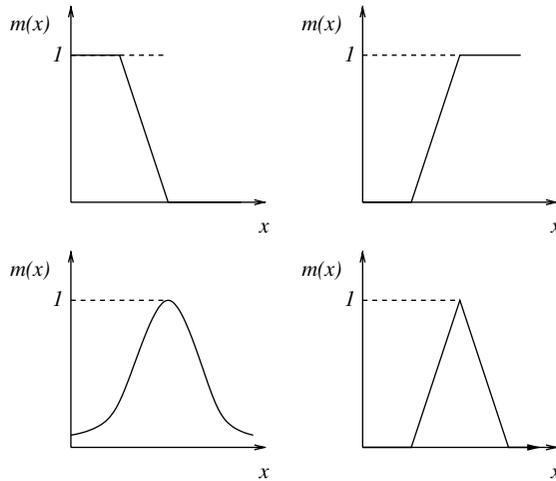

then verifying the following partial list of fundamental properties of crisp sets is straightforward:

1. Involution:  $\bar{\bar{A}} = A$
2. Contradiction:  $A \cap \bar{A} = \phi$
3. Excluded middle:  $A \cup \bar{A} = U$

Having defined the membership function as a mapping from the universal set to the set containing zero and one, it is natural to consider a generalization of the mapping. Instead of considering the membership function as a binary mapping, the membership function for a fuzzy set is a mapping to the interval  $[0, 1]$ , i.e.:

$$m : U \rightarrow [0, 1] \quad (14.10)$$

Now the mapping returns a value anywhere in the range between and including zero and one which encapsulates the notion that membership can be a matter of degree. This notion of degree enables

**FIGURE 14.30** Examples of membership functions. (Adapted from Klir, G.J., and Yuan, B. (1995) *Fuzzy Sets and Fuzzy Logic: Theory and Application*, Prentice-Hall, Englewood Cliffs, NJ.)

fuzzy sets to express transitions between membership in sets where the transition is gradual (as opposed to crisp).

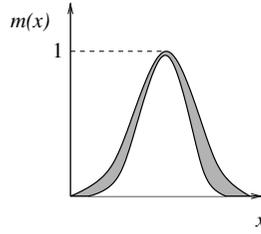

A prototypical example is temperature and whether the temperature on any given day is hot or cold. There is the set of “hot” days and the set of “cold” days. If these sets were crisp, they would require sharp boundaries. For example, if the temperature is above 80°F, it is hot; otherwise, it is not hot. Similarly, if the temperature is below 45°F, it is cold; otherwise, it is not cold. Such a rigid mathematical treatment of the notions of hot and cold is not appealing, as human inclination is to treat the transition to and from the set of hot and cold temperatures as gradual. A more appealing notion is that a given temperature may have a degree of membership in the set of hot days having a value of zero or one or some value between zero and one. These “in-between” values represent the transition from a day being not hot to the day being hot.

So far, membership functions have been described only as a mapping from the universal set to the interval from zero to one. Several examples of typical membership functions are illustrated in Figure 14.30. The membership function illustrated in the upper left figure is an example of a membership function that may model “cold” where the variable  $x$  represents temperature. For low temperatures, the value of the membership function is one, illustrating that the temperature is “cold.” In contrast, high temperatures do not belong to the set of cold days, hence the value of the membership function is zero. Between the two extremes is a transition period where the temperature only partially belongs to the set of cold days. The figure in the upper right-hand corner is the analogous membership function for the set of hot days. Other fuzzy sets may require that only values within a certain range have a significant degree of membership in the fuzzy set. Possible examples of such membership functions are illustrated in the bottom two figures, which could, for example, represent warm days.

An interesting feature of all the examples of fuzzy sets presented above is that the membership functions are crisp values; that is,  $m(x)$  is a crisp number. Depending on the application, requiring  $m$  to return a crisp value may be overly precise. Fuzzy sets can be generalized by defining membership functions to return a range of values instead of a crisp value. In particular,

$$m : U \rightarrow I([0, 1]) \tag{14.11}$$

where  $I$  represents the family of all closed intervals of real numbers in  $[0, 1]$  as is illustrated by the shaded portion in Figure 14.31. Note that further generalization is possible in that interval valued

**FIGURE 14.31** Fuzzy set defined by a fuzzy membership function.

membership functions can be generalized to have their intervals be fuzzy. Further generalizations are subsequently possible in a recursive fashion. The reader is referred to Klir and Yuan (1995) for complete details.

### 14.4.3.3 Operations on Fuzzy Sets

Analogous to operations on crisp sets, a variety of operations can be defined on fuzzy sets. Adopting the standard notational shortcut where:

$$A(x) = m(x) \tag{14.12}$$

where  $m(x)$  is the membership function that defines the fuzzy set  $A$ , we define the “standard” fuzzy complement, intersection and union as follows:

1. Complement:  $\bar{A}(x) = 1 - A(x)$
2. Intersection:  $(A \cap B)(x) = \min[A(x), B(x)]$
3. Union:  $(A \cup B)(x) = \max[A(x), B(x)]$
4. Subsethood:  $A \subseteq B \Leftrightarrow A(x) \leq B(x)$

where each operation holds for all  $x$ . It is important to note that these are not the only ways to define these operations, although they are the typical ways. In fact, the intersection can also be defined in three other common ways:

$$\begin{aligned} (A \cap B)(x) &= A(x) \cdot B(x), \\ (A \cap B)(x) &= \max[0, A(x) + B(x) - 1] \\ (A \cap B)(x) &= \begin{cases} a & \text{if } b = 1 \\ b & \text{if } a = 1 \\ 0 & \text{otherwise} \end{cases} \end{aligned} \tag{14.13}$$

Similarly, the union can alternatively be defined by:

$$\begin{aligned} (A \cup B)(x) &= A(x) + B(x) - A(x) \cdot B(x), \\ (A \cup B)(x) &= \min[1, A(x) + B(x)], \\ (A \cup B)(x) &= \begin{cases} a & \text{if } b = 0 \\ b & \text{if } a = 0 \\ 0 & \text{otherwise} \end{cases} \end{aligned} \tag{14.14}$$

For a more complete, axiomatic development, and a list of further possible definitions of intersections and unions of fuzzy sets, see Klir and Yuan (1995). In the more mathematical literature, intersections may be called t-norms, and unions may be called t-conorms. It is straightforward to show that most properties associated with crisp sets still hold for fuzzy sets, except for the properties of contradiction and excluded middle. The equality conditions of contradiction and excluded middle for crisp sets are replaced by subset conditions for fuzzy sets:

1. Contradiction:  $A \cap \bar{A} \supset \phi$
2. Excluded Middle:  $A \cup \bar{A} \subset U$

#### 14.4.4 Fuzzy Logic

Fuzzy sets and their operations and properties provide the mathematical foundation for fuzzy logic, which in turn is the basis for fuzzy control and other applications of fuzzy logic. Because feedback control is based upon measuring state variables, an important type of fuzzy set for fuzzy control is defined by a membership function whose domain is the set of real numbers:

$$m : \Re \rightarrow [0, 1] \quad (14.15)$$

which provides the degree to which a given variable is “close” to a specified value. Arithmetic operations on fuzzy numbers can then be defined as follows:

1. Addition:  $(A + B)(z) = \sup_z \min[A(x), B(y)],$   
 $z = x + y$
2. Subtraction:  $(A + B)(z) = \sup_z \min[A(x), B(y)],$   
 $z = x - y$
3. Multiplication:  $(A + B)(z) = \sup_z \min[A(x), B(y)],$   
 $z = x \cdot y$
4. Division:  $(A + B)(z) = \sup_z \min[A(x), B(y)],$   
 $z = x/y$

This arithmetic basis provides the foundation for the application of the use of linguistic variables in fuzzy control algorithms. A linguistic variable is a fuzzy number that represents some sort of linguistic concept such as “very cold,” “cold,” “chilly,” “comfortable,” “warm,” “hot” or “very hot.” An example of a linguistic variable was actually previously illustrated in the pendulum example where the elements of the state of the pendulum ( $\theta, \dot{\theta}$ ) could be described in linguistic terms such as “negative large,” “positive small,” etc. Linguistic variables allow linguistic terms to represent the approximate condition of the state of the system to be represented by fuzzy numbers. As illustrated in the pendulum example, the utility of linguistic variables is that they are an effective means to “translate” human expertise germane to a controls application into appropriate fuzzy rules utilized in a fuzzy controller.

The inference system typically utilized in fuzzy controllers is best illustrated by developing the so-called standard additive model [Kosko, 1997] utilizing the Mamdani inference system, which is the framework underlying most fuzzy controllers (and was the framework of the pendulum controller example above). The standard additive model is illustrated in [Figure 14.20](#) [Kosko, 1997].

Central to this system is a set of if-then rules, which require some basic fuzzy logic and inference. Considering the linguistic variables that represent the fuzzy numbers representing the state of the pendulum, it is clear that there are the basic, or primary, terms “negative,” “zero” and “positive” and two hedges, “small” and “large.” Clearly, for other applications, different primary terms can be utilized, as well as different hedges, such as “very,” “more,” “less,” “extremely” etc.

Several operators on fuzzy numbers are useful for implementing a fuzzy inference system. In particular, a fuzzy number can be concentrated or dilated according to

$$A^k(x) = (A(x))^k \tag{14.16}$$

where it is the concentration operator if  $k > 1$  or the dilation operator if  $k < 1$  that can be utilized to represent the linguistic hedges “very” and “more or less,” respectively. Also, the operator “not” and the relations “and” and “or” are related to the definitions of complement, intersection and union as follows:

1. Not A      $\neg A(x) = \bar{A}(x) = 1 - A(x)$
2. A and B     $(A \textbf{ and } B)(x) = (A \cap B)(x)$
3. A or B      $(A \textbf{ or } B)(x) = (A \cup B)(x)$

Note that the definitions of “and” and “or” are not unique, as the definitions of the complement, intersection and union are not unique. Thus, any of the possible definitions of intersection and union can be used to implement the logical “and” or logical “or.”

An example of one way to evaluate the multiconditional approximate reasoning inference system in the standard additive model typical for fuzzy controllers is as follows. Given a measured state variable,  $x$ , it may be “fuzzified” to account for measurement uncertainty. (Such a fuzzification was not considered in the pendulum example—in that case, the degree of membership of the crisp state value was used). As illustrated in Figure 14.32, if a measurement from a sensor is  $x$ , then the fuzzified set,  $X(x)$ , may be defined to account for sensor uncertainty, where the shape of the membership function defining the fuzzy set  $X(x)$  depends upon the type of uncertainty expected from the sensor. Then the degree of consistency between the fuzzified state measurement and a fuzzy set  $A_i$  is computed as the height of the intersection between  $X(x)$  and  $A_i(x)$ . This is essentially determining the degree to which “if  $X$  is  $A_i$ ,” is satisfied. Because there are various means to compute the intersection of two fuzzy sets, the value of this degree of consistency will depend upon the definition of intersection utilized. In particular, if the standard intersection is utilized, then the degree of consistency is given by:

$$r_i(X) = \sup_x \min[X(x), A_i(x)] \tag{14.17}$$

where the “min” function computes the standard intersection, and the “sup” function determines its maximum value, as is illustrated for two arbitrary fuzzy sets in Figure 14.33. Note that this is simply a generalization of utilizing the degree of membership of a crisp value, as the degree of membership is the supremum

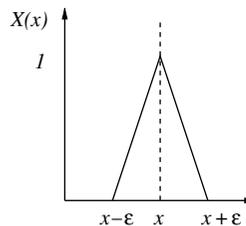

FIGURE 14.32 Fuzzifying a crisp variable.

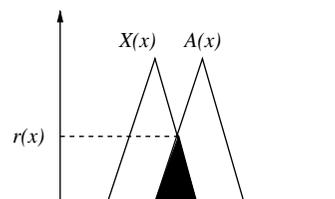

FIGURE 14.33 Degree of consistency between fuzzy sets  $X(x)$  and  $A(x)$ .

of the intersection of the line representing the crisp value of the variable and the fuzzy set, as is illustrated, for example, in [Figure 14.21](#).

Having determined the degree to which “if  $X$  is  $A_i$ ” is satisfied, the result of “then  $Y$  is  $B_i$ ” must be determined. The most common (and apparently most effective) technique was illustrated in the pendulum example. This technique is to let the resulting fuzzy set,  $B'$ , be determined according to  $B' = \min[r_i, B]$  which is simply the “clipping” approach illustrated in the pendulum example.

The overall general formulation to do so is as follows. Given an if–then rule, if “ $X$  is  $A$ , then  $Y$  is  $B$ ,” where  $X$  and  $Y$  are fuzzy sets representing the state of linguistic variables, the task is to determine the application of this rule to a fuzzy set  $A'$  which is not necessarily identical to  $A$  to determine the appropriate conclusion,  $B'$ , as illustrated in the following chart:

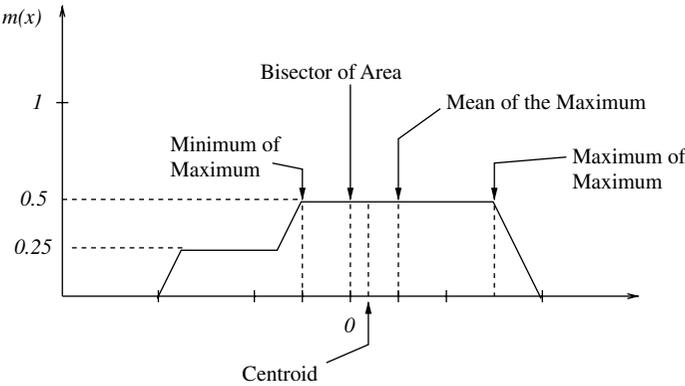

Rule:            If  $X$  is  $A$ , then  $Y$  is  $B$ .  
 Fact:             $X$  is  $A'$ .  
 Conclusion:     $Y$  is  $B'$ .

It is important to note that the “min” operator utilized to determine the degree of consistency neither satisfies the rules of classical (Boolean) logic when reduced to the crisp case [Terano, 1992] nor does it satisfy all the axioms that may be generated as reasonable extensions of the classical case [Klir and Yuan, 1995]. Possibilities other than the “min” operator as fuzzy implications include  $\max[1 - A(x), \min[A(x), B(y)]]$  (due to Zadeh), or  $\min[1, 1 - A(x) + B(x)]$  (the Lukasiewicz implication). A list of such fuzzy implications, as well as a full exposition regarding their properties can be found in Klir (1995) or Jang et al. (1997). A more basic presentation is in Terano (1992) or Jang et al. (1997). From a controls perspective, note that “very good results are obtained” from the more general implications, but that Mamdani (1974), attempting to actually control a steam engine, “obtained excellent results from the max–min compositions” illustrated. A complete and rigorous exposition of fuzzy logic is based upon considerations of fuzzy relations and fuzzy implications, which are beyond the scope of this section. The interested reader is referred to the references.

The final step is defuzzification, where, as is typical, there are various alternative approaches to the centroid method presented in the pendulum example. In particular, in addition to the centroid, the following are possible methods for defuzzification:

1. Bisector of area
2. Mean of the maximum
3. Smallest of maximum
4. Largest of maximum

These concepts are illustrated in [Figure 14.34](#).

**FIGURE 14.34** Defuzzification methods.

### 14.4.5 Alternative Inference Systems

The Mamdani inference system considered so far in this presentation is not the only inference system utilized in fuzzy control applications. In particular, the so-called TSK fuzzy model (named for Takagi, Sugeno and Kang [Jang et al., 1997]) is an alternative model which has the advantage that it does not require defuzzification of the output, which can possibly be computationally costly.

In particular, in the TSK model, fuzzy rules are of the form “if  $X$  is  $A$  and  $Y$  is  $B$ , then  $z = f(x, y)$ .” In contrast to the Mamdani model, the output of the rules is a function, as opposed to a fuzzy set. For the pendulum example, possible TSK rules may include:

1. If the pendulum angle is zero and the angular velocity is zero, then  $u = 0$ .
2. If the pendulum angle is positive and small and the angular velocity is zero, then  $u = 0.5\theta$ .
3. If the pendulum angle is positive and large and the angular velocity is zero, then  $u = 0.7\theta$ .
4. If the pendulum angle is positive and small and the pendulum angular velocity is negative and small, then  $u = 0.4\theta + 0.6\dot{\theta}$ .

As indicated, defuzzification of the outputs is not required, but the outputs from each of the rules still need to be combined. Two possible alternatives are often employed: weighted average, and weighted sum.

For the weighted average, if  $z_1$  and  $z_2$  are the output functions for two rules, and  $r_1$  and  $r_2$  are the degrees of consistency between the input data and antecedent fuzzy sets,  $A_1$  and  $A_2$ , then the output is computed as:

$$u = \frac{r_1 z_1 + r_2 z_2}{r_1 + r_2} \quad (14.18)$$

If the weighted sum is used, then simply:

$$u = r_1 z_1 + r_2 z_2 \quad (14.19)$$

A final control paradigm briefly summarized here is model-based fuzzy control, which considers the design of fuzzy rules given the (nonlinear) model of the system to be controlled, which is in contrast with the heuristic approach of the traditional fuzzy logic control paradigm outlined above. The advantage of this approach is that it makes use of analytical model information that may be available but is completely ignored in the standard fuzzy control paradigm.

At least two different forms of model based fuzzy control paradigms exist: the so-called Takagi–Sugeno fuzzy logic controllers (TSFLCs) and sliding-mode fuzzy logic controllers (SMFLCs). For TSFLCs, rules are determined by considering the dynamics of the system in various “fuzzy regimes” of the state space and determining appropriate (linear) control laws at the center of each of these fuzzy regimes. SMFLC rules can be determined by considering the distance between the state vector and a desired “sliding surface.” For further details, the reader is referred to Palm et al. (1997).

### 14.4.6 Other Applications

Finally, although feedback control is the primary application of fuzzy logic, it certainly is not the exclusive application. Other applications include identification and classification techniques such as handwriting recognition [Yen and Langari, 1999], robotics and intelligent agents [Yen and Langari, 1999], database information retrieval [Yen and Langari, 1999], nonlinear system identification and adaptive noise cancellation [Jang et al., 1997], modeling [Babuska, 1998], PID controller tuning [Yen and Langari, 1999], process control and analysis [Ruan, 1997] and traffic control [Dubois, 1980].

## 14.5 Conclusions

---

We have reviewed some of the major soft computing (SC) techniques used for complex systems. Due to limitations of space, SC has been described here only in outline. The purpose has been to show the way the methods work and the possible range of applications and to interest the reader in these new technologies. SC techniques are not model based so are most suitable for applications for which first-principles-based approaches are either not possible or too slow. There are many such instances in the control area for which soft computing is especially appropriate. As MEMS devices are in the frontiers of hardware, many of the issues related to their understanding are still not completely clear and the model equations cannot always be computed quickly enough for real-time control purposes. It is possible, then, that SC techniques could lend a hand to the use of these devices in real applications.

## Acknowledgments

---

M.S. wishes to thank his colleagues K.T. Yang and R.L. McClain and his students X. Zhao, G. Díaz, A. Pacheco-Vega and W. Franco for collaboration on artificial neural networks and genetic algorithms. He also thanks D.K. Dorini of BRDG-TNDR for sponsoring the research and CONACyT (Mexico) and the Organization of American States for support of the students. B.G. would like to thank Neil Petroff for his many thoughtful comments and suggestions concerning the section on fuzzy logic and fuzzy control.

## Defining Terms

### Neural Networks

**Activation function:** The input–output relation of a single neuron.

**Artificial neural network (ANN):** A network of neurons used for computational purposes, as opposed to the natural neural networks in humans and animals.

**Backpropagation:** A specific error correction technique that enables weights and biases to be adjusted during training.

**Bias:** A characteristic of each neuron that determines the threshold at which it will fire.

**Configuration:** The arrangement of neurons and layers in an artificial neural network.

**Feedforward artificial neural network:** A kind of network in which the information flows in one direction from the input to the output.

**Hidden layer:** A layer of the network in between the input and output.

**Layer:** A slice of the feedforward artificial neural network with several neurons in it.

**Learning rate:** A coefficient that controls how fast the weights and biases change during training.

**Multilayer network:** A network with three or more layers of neurons.

**Neurocontrol:** Control by means of an artificial neural network.

**Neuron:** The smallest, single computational unit; also called a node.

**Node:** See neuron.

**Output layer:** The layer of the network in which the information goes out.

**Synaptic weight:** Same as weight.

**Training:** A procedure by which weights and biases are adjusted.

**Weight:** A characteristic of every interneuronal connection that defines it.

### Genetic Algorithms

**Binary string:** A series of zeros and ones that may represent a number.

**Crossover:** An operation between two strings in which part of each string is detached from its original and interchanged with the other.

**Evolutionary algorithm:** An algorithm that changes in some probabilistic way according to the results being obtained.

**Fitness:** A numerical quantity that characterizes how good a proposed solution is.  
**Genetic algorithm:** An optimization algorithm that uses the principles of evolution in a specific way.  
**Global optimum:** The best in some predefined sense among a possibly infinite set of possibilities.  
**Gradient-based optimization:** Optimization methods that use derivatives of functions.  
**Local optimum:** The best in some predefined sense in an infinitesimally small neighborhood.  
**Mutation:** The operation in which a bit of a binary string changes from zero to one or vice versa.  
**Offspring:** The pair of strings produced from parents belonging to the old generation.  
**Parents:** The pair of strings in the old generation that produces a pair of offspring in the new.  
**Population size:** The number of candidate strings in a given generation.

## Fuzzy Logic

**Additive fuzzy system:** A fuzzy logic inference system used frequently in feedback control applications.  
**Crisp set:** A “standard” set wherein an element must either be a member of the set or not a member of the set.  
**Defuzzification:** The process by which a crisp value is obtained from a fuzzy set.  
**Fuzzification:** The process by which the degree of membership of the state of a system is determined in various fuzzy sets.  
**Fuzzy control:** A feedback control method utilizing concepts from fuzzy logic.  
**Fuzzy logic:** A logical inference system based upon fuzzy set theory.  
**Fuzzy set:** A generalization of “standard” set theory wherein the degree of membership of an element to the set has a continuous range of values.  
**Linguistic variable:** A qualitative variable described quantitatively by a fuzzy set.  
**Mamdani inference system:** A feedback control approach that facilitates the application of human intuition or expertise to feedback control systems by the use of fuzzy set theory and if–then rules.  
**Membership function:** The function describing the degree of membership an element has in a fuzzy set.  
**T-conorm:** An operator used to define in mathematically general terms the union of two fuzzy sets.  
**T-norm:** An operator used to define in mathematically general terms the intersection of two fuzzy sets.

## **For Further Information**

For neural networks, the monographs by Schalkoff (1997) and Haykin (1999) are very good for beginners. For more advanced readers, the list of references in this chapter can be consulted for papers pertaining to specific areas. For genetic algorithms, the books by Goldberg (1989), Michalewicz (1992) and Mitchell (1997) are recommended for beginners. There are many excellent fuzzy control texts; however, the authors found Kosko (1997) and Passino and Yurkovich (1998) particularly clear and useful. Texts with indepth and complete developments of fuzzy logic include Klir and Yuan (1995) and Jang et al. (1997).

### 15.1 Introduction

---

Without question, one of the most exciting technological developments during the last decade of the 20th century was the field of microelectromechanical systems (MEMS). MEMS consists of microfabricated mechanical and electrical structures working in concert for perception and control of the local environment. It was no accident that the development of MEMS accelerated rapidly during the 1990s, as the field was able to take advantage of innovations created during the integrated circuit revolution of the 1960s to the 1980s, in terms of processes, equipment and materials. A well-rounded understanding of MEMS requires a mature knowledge of the materials used to construct the devices, as the material properties of each component can influence device performance. Because the fabrication of MEMS structures often depends on the use of structural, sacrificial and masking materials on a common substrate, issues related to etch selectivity, adhesion, microstructure and a host of other properties are important design considerations. A discussion of the materials used in MEMS is really a discussion of the material systems used in MEMS, as the fabrication technologies rarely utilize a single material, but rather a collection of materials, each providing a critical function. It is in this light that this chapter is constructed. This chapter does not attempt to present a comprehensive review of all materials used in MEMS because the list of materials is just too long. It does, however, detail a selection of material systems that illustrate the importance of viewing MEMS in terms of material systems as opposed to individual materials.

## 15.2 Single-Crystal Silicon

---

Use of silicon (Si) as a material for microfabricated sensors can be traced to 1954, when the first paper describing the piezoresistive effect in germanium (Ge) and Si was published [Smith, 1954]. The results of this study suggested that strain gauges made from these materials could be 10 to 20 times larger than those for conventional metal strain gauges, which eventually led to the commercial development of Si strain gauges in the late 1950s. Throughout the 1960s and early 1970s, techniques to mechanically and chemically micromachine Si substrates into miniature, flexible mechanical structures on which the strain gauges could be fabricated were developed and ultimately led to commercially viable, high-volume production of Si-based pressure sensors in the mid 1970s. These lesser known developments in Si microfabrication technology happened concurrently with more popular developments in the areas of Si-based solid-state devices and integrated-circuit (IC) technologies that have revolutionized modern life. The conjoining of Si IC processing with Si micromachining techniques during the 1980s marked the advent of MEMS, and positioned Si as the primary material for MEMS.

There is little question that Si is the most widely known semiconducting material in use today. Single-crystal Si has a diamond (cubic) crystal structure. It has an electronic band gap of 1.1 eV, and, like many semiconducting materials, it can be doped with impurities to alter its conductivity. Phosphorus (P) is a common dopant for n-type Si and boron (B) is commonly used to produce p-type Si. A solid-phase oxide (SiO<sub>2</sub>) that is chemically stable under most conditions can readily be grown on Si surfaces. Mechanically, Si is a brittle material with a Young's modulus of about 190 GPa, a value that is comparable to steel (210 GPa). Si is among the most abundant elements on Earth that can readily be refined from sand to produce electronic-grade material. Mature industrial processes exist for the low-cost production of single-crystal Si wafered substrates that have large surface areas (>8-in. diameter) and very low defect densities.

For MEMS applications, single-crystal Si serves several key functions. Single-crystal Si is perhaps the most versatile material for bulk micromachining, owing to the availability of well-characterized anisotropic etches and etch-mask materials. For surface micromachining applications, single-crystal Si substrates are used as mechanical platforms on which device structures are fabricated, whether they are made from Si or other materials. In the case of Si-based integrated MEMS devices, single-crystal Si is the primary electronic material from which the IC devices are fabricated.

Bulk micromachining of Si uses wet and dry etching techniques in conjunction with etch masks and etch stops to sculpt micromechanical devices from the Si substrate. From the materials perspective, two key capabilities make bulk micromachining a viable technology: (1) the availability of anisotropic etchants such as ethylene-diamine pyrocatechol (EDP) and potassium hydroxide (KOH), which preferentially etch single-crystal Si along select crystal planes; and (2) the availability of Si-compatible etch-mask and etch-stop materials that can be used in conjunction with the etch chemistries to protect select regions of the substrate from removal.

One of the most important characteristics of etching is the directionality (or profile) of the etching process. If the etch rate in all directions is equal, the process is said to be *isotropic*. By comparison, etch processes that are *anisotropic* generally have etch rates in the direction perpendicular to the wafer surface that are much larger than the lateral etch rates. It should be noted that an "anisotropic" sidewall profile could also be produced in virtually any Si substrate by deep reactive ion etching, ion beam milling or laser drilling.

Isotropic etching of a semiconductor in liquid reagents is commonly used for removal of work-damaged surfaces, creation of structures in single-crystal slices, and patterning single-crystal or polycrystalline semiconductor films. For isotropic etching of Si, the most commonly used etchants are mixtures of hydrofluoric (HF) and nitric (HNO<sub>3</sub>) acid in water or acetic acid (CH<sub>3</sub>COOH), usually called the HNA etching system.

Anisotropic Si etchants attack the (100) and (110) crystal planes significantly faster than the (111) crystal planes. For example, the (100) to (111) etch-rate ratio is about 400:1 for a typical KOH/water etch solution. Silicon dioxide (SiO<sub>2</sub>), silicon nitride (Si<sub>3</sub>N<sub>4</sub>) and some metallic thin films (e.g., Cr, Au) provide good etch masks for most Si anisotropic etchants. In structures requiring long etching times in KOH, Si<sub>3</sub>N<sub>4</sub> is the preferred masking material, due to its chemical durability.

In terms of etch stops, heavily B-doped Si ( $>7 \times 10^{19}/\text{cm}^3$ ), commonly referred to as a p+ etch stop, is effective for some etch chemistries. Fundamentally, etching is a charge transfer process, with etch rates dependent on dopant type and concentration. Highly doped material might be expected to exhibit higher etch rates because of the greater availability of mobile carriers. This is true for isotropic etchants such as HNA, where typical etch rates are 1 to 3  $\mu\text{m}/\text{min}$  for p- or n-type dopant concentrations greater than  $10^{18}/\text{cm}^3$  and essentially zero for concentrations less than  $10^{17}/\text{cm}^3$ . On the other hand, anisotropic etchants such as EDP and KOH exhibit a much different preferential etching behavior. Si that is heavily doped with B ( $>7 \times 10^{19}/\text{cm}^3$ ) etches at a rate that is about 5 to 100 times slower than undoped Si when etched in KOH and 250 times slower when etched in EDP. Etch stops formed by the p+ technique are often less than 10  $\mu\text{m}$  thick, as the B doping is often done by diffusion. Using high diffusion temperatures (e.g., 1175°C) and long diffusion times (e.g., 15 to 20 hours), thick ( $\sim 20 \mu\text{m}$ ) p+ etch stop layers can be created. It is also possible to create a p+ etch stop below the Si surface using ion implantation; however, the implant depth is limited to a few microns and a high-energy/high-current ion accelerator is required for implantation. While techniques are available to grow a B-doped Si epitaxial layer on top of a p+ etch stop to increase the thickness of the final structure, this is seldom utilized due to the expense of the epitaxial process step.

Due to the high concentration of B, p+ Si has a high density of defects. These defects are generated as a result of stresses created in the Si lattice due to the fact that B is a smaller atom than Si. Studies of p+ Si report that stress in the resultant films can either be tensile [Ding et al., 1990] or compressive [Maseeh and Senturia, 1990]. These variations may be due to post-processing steps. For instance, thermal oxidation can significantly modify the residual stress distribution in the near-surface region of p+ Si films, thereby changing the overall stress in the film. In addition to the generation of crystalline defects, the high concentration of dopants in the p+ etch-stops prevents the fabrication of electronic devices in these layers. Despite some of these shortcomings, the p+ etch-stop technique is widely used in Si bulk micromachining due to its effectiveness and simplicity.

A large number of dry etch processes are available to pattern single-crystal Si. The process spectrum ranges from physical etching via sputtering and ion milling to chemical plasma etching. Two processes, reactive ion etching (RIE) and reactive ion beam etching (RIBE) combine aspects of both physical and chemical etching. In general, dry etch processes utilize a plasma of ionized gases, along with neutral particles to remove material from the etch surface. Details regarding the physical processes involved in dry etching can be found elsewhere [Wolfe and Tauber, 1999].

Reactive ion etching is the most commonly used dry etch process to pattern Si. In general, fluorinated compounds such as  $\text{CF}_4$ ,  $\text{SF}_6$  and  $\text{NF}_3$  or chlorinated compounds such as  $\text{CCl}_4$  or  $\text{Cl}_2$  sometimes mixed with  $\text{He}$ ,  $\text{O}_2$  or  $\text{H}_2$  are used. The RIE process is highly directional, thereby enabling direct pattern transfer from the masking material to the etched Si surface. The selection of masking material is dependent on the etch chemistry and the desired etch depth. For MEMS applications, photoresist and  $\text{SiO}_2$  thin films are often used. Si etch rates in RIE processes are typically less than 1  $\mu\text{m}/\text{min}$ , so dry etching is mostly used to pattern layers on the order of several microns in thickness. The plasmas selectively etch Si relative to  $\text{Si}_3\text{N}_4$  or  $\text{SiO}_2$ , so these materials can be used as etch masks or etch-stop layers. Recent development of deep reactive ion etching processes has extended Si etch depths well beyond several hundred microns, thereby enabling a multitude of new designs for bulk micromachined structures.

## 15.3 Polysilicon

Without doubt the most common material system for the fabrication of surface micromachined MEMS devices utilizes polycrystalline Si (polysilicon) as the primary structural material,  $\text{SiO}_2$  as the sacrificial material and  $\text{Si}_3\text{N}_4$  for electrical isolation of device structures. Heavy reliance on this material system stems in part from the fact these three materials find uses in the fabrication of ICs and, as a result, film deposition and etching technologies are readily and widely available. Like single-crystal Si, polysilicon can be doped during or after film deposition using standard IC processing techniques.  $\text{SiO}_2$  can be grown or deposited over a broad temperature range (e.g., 200 to 1150°C) to meet various process and material

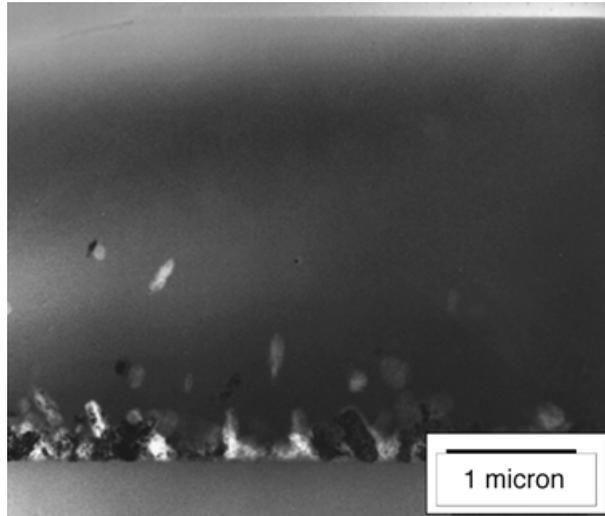

requirements. SiO<sub>2</sub> is readily dissolvable in hydrofluoric acid (HF), an IC-compatible chemical, without etching the polysilicon structural material [Adams, 1988]. HF does not wet bare Si surfaces; as a result, it is automatically rejected from microscopic cavities in between polysilicon layers after a SiO<sub>2</sub> sacrificial layer is completely dissolved.

For surface micromachined structures, polysilicon is an attractive material because it has mechanical properties that are comparable to single-crystal Si, the required processing technology has been developed for IC applications, and it is resistant to SiO<sub>2</sub> etchants. In other words, polysilicon surface micromachining leverages on the significant capital investment made by the IC industry in the important areas of film deposition, patterning and material characterization.

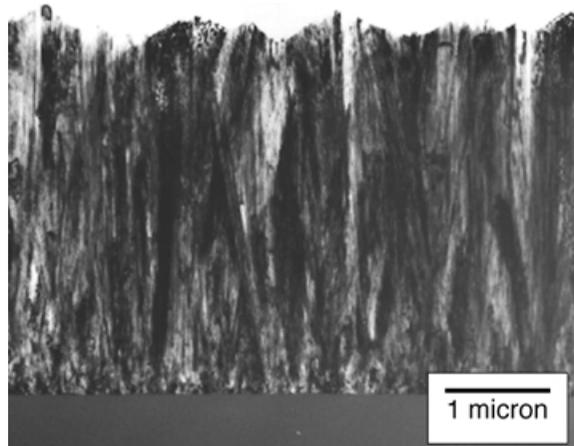

For MEMS and IC applications, polysilicon thin films are commonly deposited by a process known as low-pressure chemical vapor deposition (LPCVD). This deposition technique was first commercialized in the mid-1970s [Rosler, 1977] and has since been a standard process in the microelectronics industry. The typical polysilicon LPCVD reactor (or furnace) is based on a hot-wall, resistance-heated, horizontal, fused-silica tube design. The temperature of the wafers in the furnace is maintained by heating the tube using resistive heating elements. The furnaces are equipped with quartz boats that have closely spaced, vertically oriented slots that hold the wafers. The close spacing requires that the deposition process be performed in the reaction-limited regime to obtain uniform deposition across each wafer surface. In the reaction-limited deposition regime, the deposition rate is determined by the reaction rate of the reacting species on the substrate surface, as opposed to the arrival rate of the reacting species to the surface (which is the diffusion-controlled regime). The relationship between the deposition rate and the substrate temperature in the reaction-limited regime is exponential; therefore, precise temperature control of the reaction chamber is required. Operating in the reaction-limited regime facilitates conformal deposition of the film over the substrate topography, an important aspect of multilayer surface micromachining. Commercial equipment is available to accommodate furnace loads exceeding 100 wafers.

Typical deposition conditions utilize temperatures from 580 to 650°C and pressures ranging from 100 to 400 mtorr. The most commonly used source gas is silane (SiH<sub>4</sub>), which readily decomposes into Si on substrates heated to these temperatures. Gas flow rates depend on the tube diameter and other conditions. For processes performed at 630°C, the polysilicon deposition rate is about 100 Å/min. The gas inlets are typically at the load door end of the tube, with the outlet to the vacuum pump located at the opposite end. For door injection systems, depletion of the source gas occurs along the length of the tube. To keep the deposition rate uniform, a temperature gradient is maintained along the tube so that the increased deposition rate associated with higher substrate temperatures offsets the reduction due to gas depletion. Typical temperature gradients range from 5 to 15°C along the tube length. Some systems incorporate an injector inside the tube to allow for the additional supply of source gas to offset depletion effects. In this case, the temperature gradient along the tube is zero. This is an important modification, as the microstructure and physical properties of the deposited polysilicon are a function of the deposition temperature.

Polysilicon is made up of small single-crystal domains called *grains*, whose orientations and/or alignment vary with respect to each other. The roughness often observed on polysilicon surfaces is due to the granular nature of polysilicon. The microstructure of the as-deposited polysilicon is a function of the deposition conditions [Kamins, 1998]. For typical LPCVD processes (e.g., 100% SiH<sub>4</sub> source gas, 200 mtorr deposition pressure), the amorphous-to-polycrystalline transition temperature is about 570°C, with amorphous films deposited below this temperature (Figure 15.1) and polycrystalline films above this temperature (Figure 15.2). As the deposition temperature increases significantly above 570°C, the grain structure of the as-deposited polysilicon films changes in dramatic fashion. For example, at 600°C, the grains are very fine and equiaxed, while at 625°C, the grains are larger and have a columnar structure that is aligned perpendicular to the plane of the substrate [Kamins, 1998]. In general, the grain size tends to increase with film thickness across the entire range of deposition temperatures. As with grain size, the crystalline orientation of the polysilicon grains is dependent on the deposition temperature. For example, under standard LPCVD conditions (100% SiH<sub>4</sub>, 200 mtorr), the crystal orientation of polysilicon is predominantly (110) for substrate temperatures between 600 and 650°C. In contrast, the (100) orientation is dominant for substrate temperatures between 650 and 700°C.

**FIGURE 15.1** TEM micrograph of an amorphous Si film deposited at 570°C.

**FIGURE 15.2** TEM micrograph of a polysilicon film deposited at 620°C.

During the fabrication of micromechanical devices, polysilicon films typically undergo one or more high-temperature processing steps (e.g., doping, thermal oxidation, annealing) after deposition. These high-temperature steps can cause recrystallization of the polysilicon grains, leading to a reorientation of the film and a significant increase in average grain size. Consequently, the polysilicon surface roughness increases with the increase in grain size, an undesirable outcome from a fabrication point of view because surface roughness limits pattern resolution. Smooth surfaces are desired for many mechanical structures, as defects associated with surface roughness can act as initiating points of structural failure. To address these concerns, chemical-mechanical polishing processes that reduce surface roughness with minimal film removal can be used.

Three phenomena influence the growth of polysilicon grains, namely strain-induced growth, grain-boundary growth, and impurity drag [Kamins, 1998]. If the dominant driving force for grain growth is the release of stored strain energy caused by such things as doping or mechanical deformation (wafer warpage), grain growth will increase linearly with increasing annealing time. To minimize the energy associated with grain boundaries, the grains tend to grow in a way that minimizes the grain boundary area.

This driving force is inversely proportional to the radius of curvature of the grain boundary, and the growth rate is proportional to the square root of the annealing time. Heavy P-doping causes significant grain growth at temperatures as low as 900°C because P increases grain boundary mobility. If other impurities are incorporated in the grain boundaries, they may retard grain growth, which then results in the growth rate being proportional to the cube root of the annealing time.

Thermal oxidation of polysilicon is carried out in a manner essentially identical to that of single-crystal Si. The oxidation rate of undoped polysilicon is typically between that of (100)- and (111)-oriented single-crystal Si. Heavily P-doped polysilicon oxidizes at a rate significantly higher than undoped polysilicon. However, this impurity-enhanced oxidation effect is smaller in polysilicon than in single-crystal Si. The effect is most noticeable at lower oxidation temperatures (<1000°C). Like single-crystal Si, oxidation of polysilicon can be modeled by using process simulation software. For first-order estimates, however, the oxidation rate of (100) Si can be used to estimate the oxidation rate of polysilicon.

The resistivity of polysilicon can be modified by impurity doping using the methods developed for single-crystal doping. Polysilicon doping can be achieved during deposition (called *in situ* doping) or after film deposition either by diffusion or ion implantation. *In situ* doping is achieved by adding reaction gases such as diborane (B<sub>2</sub>H<sub>6</sub>) and phosphine (PH<sub>3</sub>) to the Si-containing source gas. The addition of dopants during the deposition process not only affects the conductivity of the as-deposited films, but also affects the deposition rate. Relative to the deposition of undoped polysilicon, the addition of P reduces the deposition rate while the addition of B increases the deposition rate. *In situ* doping can be used to produce conductive films with uniform doping profiles through the film thickness without the need for high-temperature steps commonly associated with diffusion or ion implantation. Nonuniform doping through the thickness of a polysilicon film can lead to microstructural variations in the thickness direction that can result in stress gradients in the films and subsequent bending of released structural components. In addition, minimizing the maximum required temperature and duration of high-temperature processing steps is important for the fabrication of micromechanical components on wafers that contain temperature-sensitive layers.

The primary disadvantage of *in situ* doping is the complexity of the deposition process. The control of film thickness, deposition rate, and deposition uniformity is more complicated than the process used to deposit undoped polysilicon films, in part because a second gas with a different set of temperature- and pressure-related reaction parameters is included. Additionally, the cleanliness standards of the reactor are more demanding for the doped furnace. Therefore, many MEMS fabrication facilities use diffusion-based doping processes. Diffusion is an effective method for doping polysilicon films, especially for very heavy doping (e.g., resistivities of 10<sup>-4</sup> Ω-cm) of thick (>2 μm) films. However, diffusion is a high-temperature process, typically from 900 to 1000°C. Therefore, fabrication processes that require long diffusion times to achieve uniform doping at significant depths may not be compatible with pre-MEMS, complementary metal-oxide-semiconductor (CMOS) integration schemes. Like *in situ* doping, diffusion processes must be performed properly to ensure that the dopant distribution through the film thickness is uniform, so that dopant-related variations in the mechanical properties through the film thickness are minimized. As will be discussed below, the use of doped oxide sacrificial layers relaxes some of the concerns associated with doping the film uniformly by diffusion, because the sacrificial doped SiO<sub>2</sub> can also be used as a diffusion source. Phosphorous, which is the most commonly used dopant in polysilicon MEMS, diffuses significantly faster in polysilicon than in single-crystal Si, due primarily to enhanced diffusion rates along grain boundaries. The diffusivity in polysilicon thin films (i.e., small equiaxed grains) is about 1 × 10<sup>12</sup> cm<sup>2</sup>/s.

Ion implantation is also used to dope polysilicon films. The implantation energy is typically adjusted so that the peak of the concentration profile is near the midpoint of the film. When necessary, several implant steps are performed at various energies in order to distribute the dopant uniformly through the thickness of the film. A high-temperature anneal step is usually required to electrically activate the implanted dopant, as well as to repair implant-related damage in the polysilicon film. In general, the resistivity of implanted polysilicon films is not as low as films doped by diffusion. In addition, the need for specialized implantation equipment limits the use of this method in polysilicon MEMS.

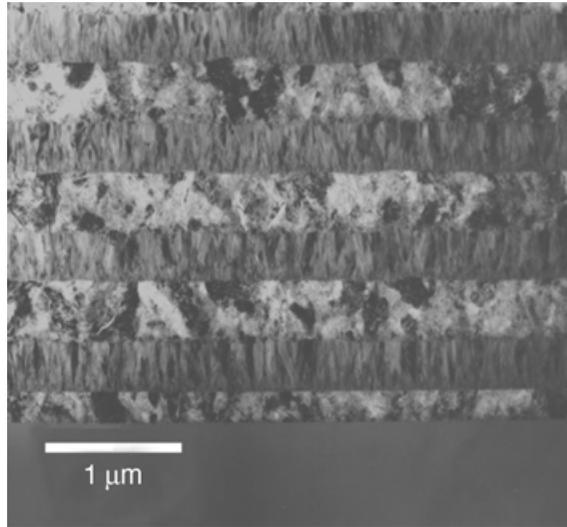

The electrical properties of polysilicon depend strongly on the grain structure of the film. The grain boundaries provide a potential barrier to the moving charge carriers, thus affecting the conductivity of the films. For P-doped polysilicon, the resistivity decreases as the amount of P increases for concentrations up to about  $1 \times 10^{21}/\text{cm}^3$ . Above this value, the resistivity reaches a plateau of about  $4 \times 10^4 \Omega\text{-cm}$  after a  $1000^\circ\text{C}$  anneal. The maximum mobility for such a highly P-doped polysilicon is about  $30 \text{ cm}^2/\text{Vs}$ . Grain boundary and ionized impurity scattering are important factors limiting the mobility [Kamins, 1988].

The thermal conductivity of polysilicon is a strong function of the grain structure of the film [Kamins 1998]. For fine-grain films, the thermal conductivity is about 0.30 to 0.35 W/cm-K, which is about 20 to 25% of the single-crystal value. For thick films with large grains, the thermal conductivity ranges between 50 and 85% of the single-crystal value.

In general, thin films are generally under a state of stress, commonly referred to as *residual stress*, and polysilicon is no exception. In polysilicon micromechanical structures, the residual stress in the films can greatly affect the performance of the device. Like the electrical and thermal properties of polysilicon, the as-deposited residual stress in polysilicon films depends on microstructure. In general, as-deposited polysilicon films have compressive residual stresses, although reports regarding polysilicon films with tensile stress can be found in the literature [Kim et al., 1998]. The highest compressive stresses are found in amorphous Si films and polysilicon films with a strong, columnar (110) texture. For films with fine-grained microstructures, the stress tends to be tensile. For the same deposition conditions, thick polysilicon films tend to have lower residual stress values than thin films, especially true for films with a columnar microstructure. Annealing can be used to reduce the compressive stress in as-deposited polysilicon films. For polysilicon films doped with phosphorus by diffusion, a decrease in the magnitude of compressive stress has been correlated with grain growth [Kamins, 1998]. For polysilicon films deposited at  $650^\circ\text{C}$ , the compressive residual stress is typically on the order of  $5 \times 10^9$  to  $10 \times 10^9 \text{ dyne/cm}^2$ . However, these stresses can be reduced to less than  $10^8 \text{ dyne/cm}^2$  by annealing the films at high temperature ( $1000^\circ\text{C}$ ) in a  $\text{N}_2$  ambient [Guckel et al., 1985; Howe and Muller, 1983]. Compressive stresses in fine-grained polysilicon films deposited at  $580^\circ\text{C}$  (100-Å grain size) can be reduced from  $1.5 \times 10^{10}$  to less than  $10^8 \text{ dyne/cm}^2$  by annealing above  $1000^\circ\text{C}$ , or even made to be tensile ( $5 \times 10^9 \text{ dynes/cm}^2$ ) by annealing at temperatures between 650 and  $850^\circ\text{C}$  [Guckel et al., 1988]. Recent advances in the area of rapid thermal annealing (RTA) as applied to polysilicon indicate that RTA is a fast and effective method of stress reduction in polysilicon films. For polysilicon films deposited at  $620^\circ\text{C}$  with compressive stresses of about 340 MPa, a 10-s anneal at  $1100^\circ\text{C}$  was sufficient to completely relieve the stress [Zhang et al., 1998].

A second approach, called the *multipoly process*, has recently been developed to address issues related to residual stress [Yang et al., 2000]. As the name implies, the multipoly process is a deposition method to produce a polysilicon-based multilayer structure where the composite has a predetermined stress level. The multilayer structure is comprised of alternating tensile and compressive polysilicon layers deposited sequentially. The overall stress of the composite is simply the superposition of the stress in each individual layer. The tensile layers consist of fine-grained polysilicon grown at a temperature of  $570^\circ\text{C}$  while the compressive layers are made up of polysilicon deposited at  $615^\circ\text{C}$  and having a columnar microstructure. The overall stress in the composite film depends on the number of alternating layers and the thickness of each layer. With the proper set of parameters, a composite polysilicon film can be deposited with a near-zero residual stress. Moreover, despite the fact that the composite has a clearly changing microstructure through the thickness of the film, the stress gradient is also nearly zero. The clear advantage of the multipoly process lies in the fact that stress reduction can be achieved without the need for high-temperature annealing, a considerable advantage for polysilicon MEMS processes with on-chip CMOS integration. A transmission electron microscopy (TEM) micrograph of a multipoly structure is shown in [Figure 15.3](#).

Conventional techniques to deposit polysilicon films for MEMS applications utilize LPCVD systems with deposition rates that limit the maximum film thickness to roughly  $5 \mu\text{m}$ . Many device designs, however, require thick structural layers that are not readily achievable using LPCVD processes. For these devices, wafer bonding and etchback techniques are often used to produce thick ( $>10 \mu\text{m}$ ) single-crystal Si films on sacrificial substrate layers. There is, however, a deposition technique to produce thick polysilicon films on sacrificial substrates. These thick polysilicon films are called *epi-poly* films because

**FIGURE 15.3** TEM micrograph of a polysilicon multilayer film created using the multipoly process.

epitaxial Si reactors are used to deposit these films using a high-temperature process. Unlike conventional LPCVD polysilicon deposition processes which have deposition rates of  $100 \text{ \AA}/\text{min}$ , epi-poly processes have deposition rates on the order of  $1 \text{ }\mu\text{m}/\text{min}$  [Gennissen et al., 1997]. The high deposition rates are a result of the deposition conditions used—specifically, much higher substrate temperatures ( $>1000^\circ\text{C}$ ) and deposition pressures ( $>50 \text{ torr}$ ). The polysilicon films are usually deposited on  $\text{SiO}_2$  sacrificial substrate layers and have been used in the fabrication of mechanical properties test structures [Lange et al., 1996; Gennissen et al., 1997; Greek et al., 1999], thermal actuators [Gennissen et al., 1997], electrostatically actuated accelerometers [Gennissen et al., 1997] and gryoscopes [Funk et al., 1999]. An LPCVD polysilicon seed layer is used in order to control nucleation, grain size and surface roughness. In general, the microstructure and residual stress of epi-poly films is related to deposition conditions, with compressive films having a mixture of (110) and (311) grains [Lange et al., 1996; Greek et al., 1999] and tensile films having a random mix of (110), (100), (111) and (311) grains [Lange et al., 1996]. The Young's modulus of epi-poly measured from micromachined test structures is comparable to LPCVD polysilicon [Greek et al., 1999].

Porous Si is a “type” of Si finding applications in MEMS technology. Porous Si is made by room-temperature electrochemical etching of Si in HF. Under normal conditions, Si is not etched by HF, hence its widespread use as an etchant of sacrificial oxide in polysilicon surface micromachining. In an electrochemical circuit using an HF-based solution, however, positive charge carriers (holes) at the Si surface facilitate the exchange of F atoms with the H atoms terminating the Si surface bonds. The exchange continues with the exchange of subsurface bonds, leading to the eventual removal of the fluorinated Si. The quality of the etched surface is related to the density of holes at the surface which is controlled by the applied current density. For high current densities, the density of holes is high and the etched surface is smooth. For low current density, the density of holes is low and they are clustered in highly localized regions associated with surface defects. The surface defects become enlarged by etching, leading to the formation of pores. Pore size and density are related to the type of Si used and the conditions of the electrochemical cell. Both single-crystal and polycrystalline Si can be converted to porous Si, with porosities of up to 80% possible.

The large surface-to-volume ratios make porous Si attractive for many MEMS applications. As one might expect, use of porous Si has been proposed for a number of gaseous and liquid applications, including filter membranes and absorbing layers for chemical and mass sensing [Anderson et al., 1994]. The large surface-to-volume ratio also permits the use of porous Si as the starting material for the formation

of thick thermal oxides, as the proper pore size can be selected to account for the volume expansion of the thermal oxide. When single-crystal substrates are used in the formation of porous Si films, the unetched material remains single crystalline, thus providing the appropriate template for epitaxial growth. It has been shown that CVD coatings will not penetrate the porous regions, but rather overcoat the pores at the surface [Lang et al., 1995]. The formation of localized, surface-micromachinable, Si on insulator structures is possible by simply combining electrochemical etching, epitaxial growth, dry etching (to create access holes) and thermal oxidation. A third, MEMS-related application is the direct use of porous Si as a sacrificial layer in polysilicon and single-crystalline Si surface micromachining. The process involves the electrical isolation of the structural Si layer either by the formation of pn-junctions through selective doping or by use of electrically insulating thin films [Lang, 1995]. In essence the formation of pores only occurs on electrically charged surfaces. A weak Si etchant aggressively attacks the porous regions with little damage to the structural Si layers. Porous Si may be an attractive option for micromachining processes that are chemically stable in HF but are tolerant of high-temperature processing steps.

With the possible exception of porous Si, all of the above-mentioned processes to prepare polysilicon for MEMS applications utilize substrate temperatures in excess of 570°C, either during film deposition or in subsequent stress-relieving annealing steps. Such high-temperature processing restricts the use of non-Si derivative materials, such as aluminum for metallization and polymers for sacrificial layers, both of which are relatively straightforward to deposit and pattern and would be of great benefit to polysilicon micromachining if they could be used throughout the process. Work in developing low-temperature deposition processes for polysilicon has focused on sputter deposition techniques [Abe and Reed, 1996; Honer and Kovacs, 2000]. Early work [Abe and Reed, 1996] emphasized the ability to deposit very smooth (25-Å roughness average) films at reasonable deposition rates (191 Å/min) and with low residual compressive stresses. The process involved DC magnetron sputtering from a Si target using an Ar sputtering gas, a chamber pressure of 5 mtorr and a power of 100 W. The substrates consisted of thermally oxidized Si wafers. The authors reported that a post-deposition anneal at 700°C in N<sub>2</sub> for 2 hr was performed to crystallize the deposited film and perhaps lower the stress. A second group [Honer and Kovacs, 2000] sought to develop a polymer-friendly, Si-based, surface-micromachining process. The Si films were sputter-deposited on polyimide sacrificial layers. To improve the conductivity of the micromachined Si structures, the sputtered Si films were sandwiched between two TiW cladding layers. The device structures were released by etching the polyimide in a O<sub>2</sub> plasma. The processing step with the highest temperature was the polyimide cure, which was performed for 1 hr at 350°C. To test the robustness of the process, sputter-deposited Si microstructures were fabricated on substrates containing CMOS devices. As expected from thermal budget considerations, the authors reported no measurable degradation of device performance.

## 15.4 Silicon Dioxide

---

SiO<sub>2</sub> can be grown thermally on Si substrates as well as also deposited using a variety of processes to satisfy a wide range of different requirements. In polysilicon surface micromachining, SiO<sub>2</sub> is used as a sacrificial material, as it can be easily dissolved using etchants that do not attack polysilicon. In a less prominent role, SiO<sub>2</sub> is used as an etch mask for dry etching of thick polysilicon films, as it is chemically resistant to dry polysilicon etch chemistries.

The SiO<sub>2</sub> growth and deposition processes most widely used in polysilicon surface micromachining are thermal oxidation and LPCVD. Thermal oxidation of Si is performed at high temperatures (e.g., 900 to 1000°C) in the presence of oxygen or steam. Because thermal oxidation is a self-limiting process (i.e., the oxide growth rate decreases with increasing film thickness), the maximum practical film thickness that can be obtained is about 2 μm, which for many sacrificial applications is sufficient.

SiO<sub>2</sub> films for MEMS applications can also be deposited using an LPCVD process known as low-temperature oxidation (LTO). In general, LPCVD provides a means for depositing thick (>2 μm) SiO<sub>2</sub> films at temperatures much lower than thermal oxidation. Not only are LTO films deposited at low temperatures, but the films also have a higher etch rate in HF than thermal oxides which results in

significantly faster releases of polysilicon surface-micromachined devices. An advantage of the LPCVD processes is that dopant gases can be included in the flow of source gases in order to dope the as-deposited SiO<sub>2</sub> films. One such example is the incorporation of P to form phosphosilicate glass (PSG). PSG is formed using the same deposition process as LTO, with PH<sub>3</sub> added to dope the glass with a P content ranging from 2 to 8 wt%. PSG has an even higher etch rate in HF than LTO, further facilitating the release of polysilicon surface-micromachined components. PSG flows at high temperatures (e.g., 1000 to 1100°C) which can be exploited to create a smooth surface topography. Additionally, PSG layers sandwiching a polysilicon film can be used as a P doping source, improving the uniformity of diffusion-based doping.

Phosphosilicate glass and LTO films are deposited in hot-wall, low-pressure, fused-silica reactors in a manner similar to the systems described previously for polysilicon. Typical deposition rates are about 100 Å/min. Precursor gases include SiH<sub>4</sub> as a Si source, O<sub>2</sub> as an oxygen source and, in the case of PSG, PH<sub>3</sub> as a source of phosphorus. Because SiH<sub>4</sub> is pyrophoric (i.e., spontaneously combusts in the presence of O<sub>2</sub>), door injection of the deposition gases would result in a large depletion of the gases at deposition temperatures of 400 to 500°C and nonuniform deposition along the tube. Therefore, the gases are introduced in the furnace through injectors distributed along the length of the tube. The wafers are placed vertically in caged boats to ensure uniform gas transport to the wafers. In the caged boats, two wafers are placed back to back in each slot, thus minimizing the deposition of SiO<sub>2</sub> on the back of the wafers. The typical load of an LTO system is over 100 wafers.

Low-temperature oxidation and PSG films are typically deposited at temperatures of 425 to 450°C and pressures ranging from 200 to 400 mtorr. The low deposition temperatures result in LTO and PSG films that are slightly less dense than thermal oxides due to incorporation of hydrogen in the films. LTO films can, however, be densified by an annealing step at high temperature (1000°C). The low density of LTO and PSG films is partially responsible for the increased etch rate in HF, which makes them attractive sacrificial materials for polysilicon surface micromachining. LTO and PSG deposition processes are not typically conformal to nonplanar surfaces because the low substrate temperatures result in low surface migration of reacting species. Step coverage is, however, sufficient for many polysilicon surface-micromachining applications, although deposited films tend to thin at the bottom surfaces of deep trenches and therefore must be thoroughly characterized for each application.

The dissolution of the sacrificial SiO<sub>2</sub> to release free-standing structures is a critical step in polysilicon surface micromachining. Typically, 49% (by weight) HF is used for the release process. To pattern oxide films using wet chemistries, etching in buffered HF (28 ml 49% HF, 170 ml H<sub>2</sub>O, 113 g NH<sub>4</sub>F), also known as buffered oxide etch (BOE), is common for large structures. A third wet etchant, known as P-etch, is traditionally used to selectively remove PSG over undoped oxide (e.g., to deglaze a wafer straight from a diffusion furnace).

Thermal SiO<sub>2</sub>, LTO, and PSG are electrical insulators suitable for many MEMS applications. The dielectric constants of thermal oxide and LTO are 3.9 and 4.3, respectively. The dielectric strength of thermal SiO<sub>2</sub> is  $1.1 \times 10^6$  V/cm, and for LTO it is about 80% that of thermal SiO<sub>2</sub> [Ghandhi, 1983]. Thermal SiO<sub>2</sub> is in compression with a stress level of about  $3 \times 10^9$  dyne/cm<sup>2</sup> [Ghandhi, 1983]. For LTO, however, the as-deposited residual stress is tensile, with a magnitude of about  $1$  to  $4 \times 10^9$  dyne/cm<sup>2</sup> [Ghandhi, 1983]. The addition of phosphorous to LTO (i.e., PSG) decreases the tensile residual stress to about  $10^8$  dyne/cm<sup>2</sup> for a phosphorus concentration of 8% [Pilskin, 1977]. These data are representative of oxide films deposited directly on Si substrates under typical conditions; however, the final value of the stress in an oxide film can be a strong function of the process parameters as well as any post-processing steps.

A recent report documents the development of another low-pressure process, known as plasma-enhanced chemical vapor deposition (PECVD), for MEMS applications. The objective was to deposit low-stress, very thick (10 to 20 μm) SiO<sub>2</sub> films for insulating layers in micromachined gas turbine engines [Zhang et al., 2000]. PECVD was selected, in part, because it offers the possibility to deposit films of the desired thickness at a reasonable deposition rate. The process used a conventional parallel plate reactor with tetraethylorthosilicate (TEOS), a commonly used precursor in LPCVD processes, as the source gas.

As expected, the authors found that film stress is related to the concentration of dissolved gases in the film and that annealed films tend to suffer from cracking. By using a thin  $\text{Si}_3\text{N}_4$  film in conjunction with the thick  $\text{SiO}_2$  film, conditions were found where a low-stress, crack-free  $\text{SiO}_2$  film could be produced.

Two other materials in the  $\text{SiO}_2$  family are receiving increasing attention from MEMS fabricators, especially now that the material systems have expanded beyond conventional Si processing. The first of these is crystalline quartz. The chemical composition of quartz is  $\text{SiO}_2$ . Quartz is optically transparent and, like its amorphous counterpart, quartz is electrically insulating. However, the crystalline nature of quartz gives it piezoelectric properties that have been exploited for many years in electronic circuitry. Like single-crystal Si, quartz substrates are available as high-quality, large-area wafers. Also like single-crystal Si, quartz can be bulk micromachined using anisotropic etchants based on heated HF and ammonium fluoride ( $\text{NH}_4\text{F}$ ) solutions, albeit the structural shapes that can be etched into quartz do not resemble the shapes that can be etched into Si. A short review of the basics of quartz etching and its applications to the fabrication of a micromachined acceleration sensor can be found in Danel et al. (1990).

A second  $\text{SiO}_2$ -related material that has found utility in MEMS is spin-on-glass (SOG), which is used in thin-film form as a planarization dielectric material in IC processing. As the name implies, SOG is applied to a substrate by spin coating. The material is polymer based with a viscosity suitable for spin-coating, and once dispensed at room temperature on the spinning substrate, it is cured at elevated temperatures to form a solid thin film. Two recent publications illustrate the potential uses of SOG in MEMS. In the first example, SOG was developed as a thick-film sacrificial molding material to pattern thick polysilicon films [Yasseen et al., 1999]. The authors reported a process to produce SOG films that were 20  $\mu\text{m}$  thick, complete with a chemical-mechanical polishing (CMP) procedure and etching techniques. The thick SOG films were patterned into molds that were filled with 10- $\mu\text{m}$ -thick LPCVD polysilicon films, planarized by selective CMP and subsequently dissolved in a  $\text{HCl}:\text{HF}:\text{H}_2\text{O}$  wet etchant to reveal the patterned polysilicon structures. The cured SOG films were completely compatible with the polysilicon deposition process, indicating that SOG could be used to produce MEMS devices with extremely large gaps between structural layers. In the second example, high-aspect-ratio channel-plate microstructures were fabricated from SOG [Liu et al., 1999]. The process required the use of molds to create the structures. Electroplated nickel (Ni) was used as the molding material, with Ni channel plate molds fabricated using a conventional LIGA process. The Ni molds are then filled with SOG, and the sacrificial Ni molds are removed in a reverse electroplating process. In this case, the fabricated SOG structures were over 100  $\mu\text{m}$  tall, essentially bulk micromachined structures fabricated using a sacrificial molding material system.

## 15.5 Silicon Nitride

$\text{Si}_3\text{N}_4$  is widely used in MEMS for electrical isolation, surface passivation, etch masking and as a mechanical material. Two deposition methods are commonly used to deposit  $\text{Si}_3\text{N}_4$  thin films: LPCVD and PECVD. PECVD  $\text{Si}_3\text{N}_4$  is generally nonstoichiometric and may contain significant concentrations of hydrogen. Use of PECVD  $\text{Si}_3\text{N}_4$  in micromachining applications is somewhat limited because its etch rate in HF can be high (e.g., often higher than that of thermally grown  $\text{SiO}_2$ ) due to the porosity of the film. However, PECVD offers the potential to deposit nearly stress-free  $\text{Si}_3\text{N}_4$  films, an attractive property for many MEMS applications, especially in the area of encapsulation and packaging. Unlike its PECVD counterpart, LPCVD  $\text{Si}_3\text{N}_4$  is extremely resistant to chemical attack, thereby making it the material of choice for many Si bulk and surface micromachining applications. LPCVD  $\text{Si}_3\text{N}_4$  is commonly used as an insulating layer to isolate device structures from the substrate and from other device structures, because it is a good insulator with a resistivity of  $10^{16}$   $\Omega\text{-cm}$  and a field breakdown limit of  $10^7$  V/cm.

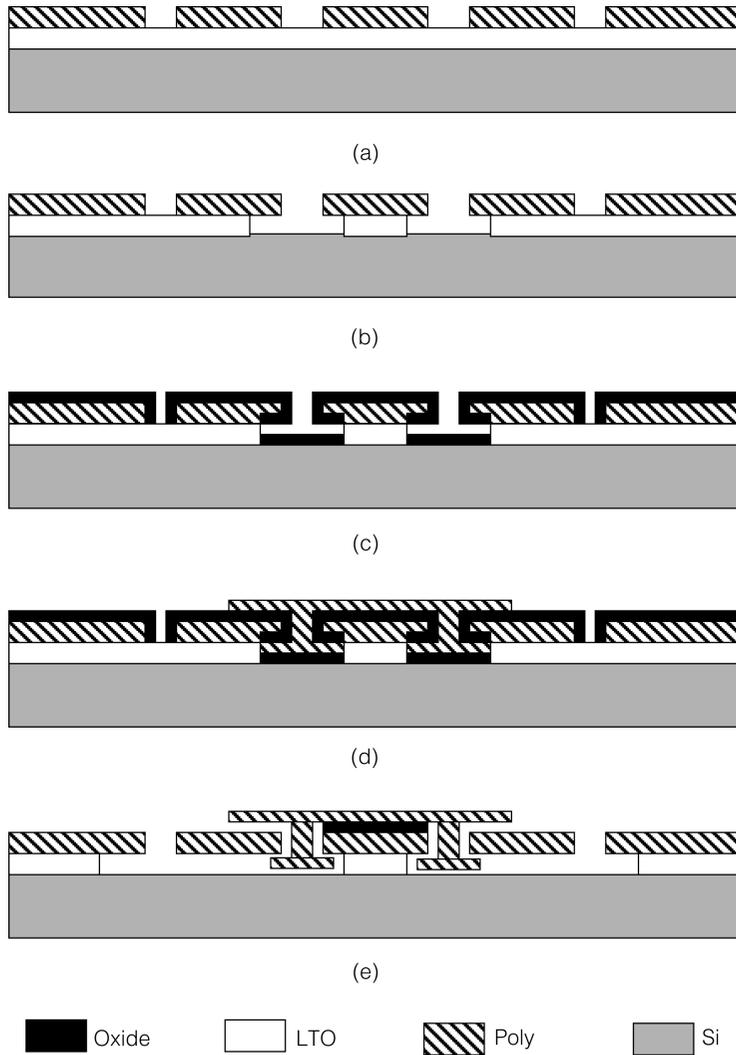

The LPCVD  $\text{Si}_3\text{N}_4$  films are deposited in horizontal furnaces similar to those used for polysilicon deposition. Typical deposition temperatures and pressures range between 700 and 900°C and 200 to 500 mtorr, respectively. A typical deposition rate is about 30 Å/min. The standard source gases are dichlorosilane ( $\text{SiH}_2\text{Cl}_2$ ) and ammonia ( $\text{NH}_3$ ).  $\text{SiH}_2\text{Cl}_2$  is used in place of  $\text{SiH}_4$  because it produces films with a higher degree of thickness uniformity at the required deposition temperature and it allows the wafers

to be spaced close together, thus increasing the number of wafers per furnace load. To produce stoichiometric  $\text{Si}_3\text{N}_4$ , a  $\text{NH}_3$ -to- $\text{SiH}_2\text{Cl}_2$  ratio of 10:1 is commonly used. The standard furnace configuration uses door injection of the source gases with a temperature gradient along the tube axis to accommodate for the gas depletion effects. LPCVD  $\text{Si}_3\text{N}_4$  films deposited between 700 and 900°C are amorphous; therefore, the material properties do not vary significantly along the length of tube despite the temperature gradient. As with polysilicon deposition, a typical furnace can accommodate over 100 wafers. Because  $\text{Si}_3\text{N}_4$  is deposited in the reaction-limited regime, film is deposited on both sides of each wafer with equal thickness.

The residual stress in stoichiometric  $\text{Si}_3\text{N}_4$  is large and tensile, with a magnitude of about  $10^{10}$  dyne/cm<sup>2</sup>. Such a large residual stress limits the practical thickness of a deposited  $\text{Si}_3\text{N}_4$  film to a few thousand angstroms because thicker films tend to crack. Nevertheless, stoichiometric  $\text{Si}_3\text{N}_4$  films have been used as mechanical support structures and electrical insulating layers in piezoresistive pressure sensors [Folkmer et al., 1995]. To reduce the residual stress, thus enabling the use of thick  $\text{Si}_3\text{N}_4$  films for applications that require durable, chemically resistant membranes, nonstoichiometric silicon nitride ( $\text{Si}_x\text{N}_y$ ) films can be deposited by LPCVD. These films, often referred to as Si-rich or low-stress nitride, are intentionally deposited with an excess of Si by simply decreasing the  $\text{NH}_3$  to  $\text{SiH}_2\text{Cl}_2$  ratio in the reaction furnace. For a  $\text{NH}_3$ -to- $\text{SiH}_2\text{Cl}_2$  ratio of 1:6 at a deposition temperature of 850°C and pressure of 500 mtorr, the as-deposited films are nearly stress free [Sekimoto et al., 1982]. The increase in Si content not only leads to a reduction in tensile stress, but also decreases the etch rate of the film in HF. As a result, low-stress silicon nitride films have replaced stoichiometric  $\text{Si}_3\text{N}_4$  in many MEMS applications and even have enabled the development of fabrication techniques that would otherwise not be feasible with stoichiometric  $\text{Si}_3\text{N}_4$ . For example, low-stress silicon nitride has been successfully used as a structural material in a surface micromachining process that uses polysilicon as the sacrificial material [Monk et al., 1993]. In this case, Si anisotropic etchants such as KOH and EDP were used for dissolving the sacrificial polysilicon. A second low-stress nitride surface micromachining process used PSG as a sacrificial layer, which was removed using a HF-based solution [French et al., 1997]. Of course, wide use of  $\text{Si}_3\text{N}_4$  as a MEMS material is restricted by its dielectric properties; however, its Young's modulus (146 GPa) is on par with Si (~190 GPa), making it an attractive material for mechanical components.

The essential interactions between substrate, electrical isolation layer, sacrificial layers, and structural layers are best illustrated by examining the critical steps in a multilevel surface micromachining process. The example used here (shown in Figure 15.4) is the fabrication of a Si micromotor using a technique called the *rapid prototyping process*. The rapid prototyping process utilizes three deposition and three photolithography steps to implement flange-bearing, side-drive micromotors such as in the SEM of Figure 15.5. The device consists of heavily P-doped LPCVD polysilicon structural components deposited on a Si wafer, using LTO both as a sacrificial layer and as an electrical isolation layer. Initially, a 2.4- $\mu\text{m}$ -thick LTO film is deposited on the Si substrate. A 2- $\mu\text{m}$ -thick doped polysilicon layer is then deposited on the LTO film. Photolithography and RIE steps are then performed to define the rotor, stator and rotor/stator gap. To fabricate the flange, a sacrificial mold is created by etching into the LTO film with an isotropic etchant, then partially oxidizing the polysilicon rotor and stator structures to form what is called the *bearing clearance oxide*. This oxidation step also forms the bottom of the bearing flange mold. A 1- to 2- $\mu\text{m}$ -thick, heavily doped polysilicon film is then deposited and patterned by photolithography and RIE to form the bearing. At this point, the structural components of the micromotor are completely formed, and all that remains is to release the rotor by etching the sacrificial oxide in HF and performing an appropriate drying procedure (detailed later in this chapter). In this example, the LTO film serves three purposes: It is the sacrificial underlayer for the free-spinning rotor, it comprises part of the flange mold, and it serves as an insulating anchor for the stators and bearing post. Likewise, the thermal oxide serves as a mold and electrical isolation layer. The material properties of LTO and thermal oxide allow for these films to be used as they are in the rapid prototyping process, thus enabling the fabrication of multilayer structures with a minimum of processing steps.

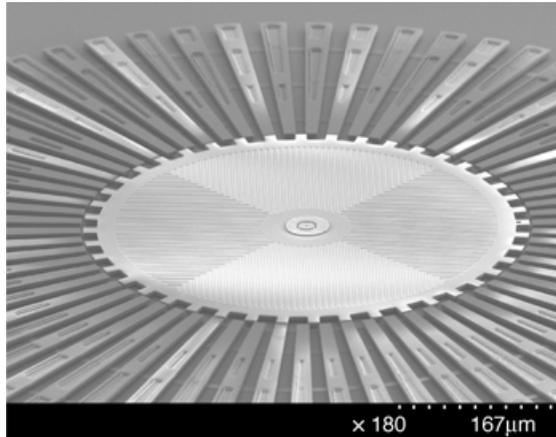

Without question,  $\text{SiO}_2$  is an excellent sacrificial material for polysilicon surface micromachining; however, other materials could also be used. In terms of chemical properties, aluminum (Al) would

**FIGURE 15.4** Cross-sectional schematics of the rapid prototyping process used to fabricate polysilicon micromotors by surface micromachining: (a) after the rotor/stator etch, (b) after the flange mold etch, (c) after the bearing clearance oxidation step, (d) after the bearing etch, and (e) after the release step.

certainly be a satisfactory candidate as a sacrificial layer, as it can be dissolved in acidic-based Al etchants that do not etch polysilicon. However, the thermal properties tell a different story. LPCVD polysilicon is often deposited at temperatures between 580 and 630°C, which are excessively close to the Al melting temperature at the deposition pressure. Independent of the temperature incompatibility, polysilicon is often used as the gate material in MOS processes. As a result, for MEMS and IC processes that share the same LPCVD polysilicon furnace, as might be the case for an integrated MEMS process, it would be inadvisable to put Al-coated wafers in a polysilicon furnace due to cross-contamination considerations.

The release process associated with polysilicon surface micromachining is simple in principle but can be complicated in practice. The objective is to completely dissolve the sacrificial oxide from beneath the freestanding components without etching the polysilicon structural components. The wafers/dies are simply immersed in the appropriate solution for a period of time sufficient to release all desired parts. This is done with various concentrations of electronic-grade HF, including BOE, as the etch rates of SiO<sub>2</sub> and polysilicon are significantly different. It has been observed, however, that during the HF release step,

**FIGURE 15.5** SEM micrograph of a polysilicon micromotor fabricated using the rapid prototyping process.

the mechanical properties of polysilicon, including residual stress, Young's modulus and fracture strain, can be affected [Walker et al., 1991]. In general, the modulus and fracture strain of polysilicon decreases with increasing time of exposure to HF and with increasing HF concentration. This decrease in the modulus and fracture strain indicates a degradation of the film mechanical integrity. To minimize the HF release time, structures are designed with access holes and cuts of sufficient size to facilitate the flow of HF to the sacrificial oxide. In this manner, polysilicon structures can be released without appreciable degradation to film properties and hence device performance.

Following the HF release step, the devices must be rinsed and dried. A simple process includes rinses in deionized (DI) water then in methanol, followed by a drying step using  $N_2$ . The primary difficulty with the wet release process is that surface tension forces, which are related to the surface properties of the material, tend to pull the micromechanical parts toward the substrate as the devices are immersed and pulled out of the solutions. Release processes that avoid the surface tension problem by using frozen alcohols that are sublimated at the final rinse step have been developed [Guckel et al., 1990]. Processes based on the use of supercritical fluids [Mulhern et al., 1993], such as  $CO_2$  at  $35^\circ C$  and 1100 psi, to extinguish surface tension effects vanish are now commonplace in many MEMS facilities.

## 15.6 Germanium-Based Materials

Germanium (Ge) has a long history in the development of semiconducting materials, dating back to the development of the earliest transistors. The same is true in the development of micromachined transducers and the early work on the piezoresistive effect in semiconducting materials [Smith, 1954]. Development of Ge for microelectronic devices may have continued if only a water-insoluble oxide could be formed on Ge surfaces. Nonetheless, there is a renewed interest in Ge for micromachined devices, especially for devices that require use of low-temperature processes.

Thin polycrystalline Ge (poly-Ge) films can be deposited by LPCVD at temperatures much lower than polysilicon, namely,  $325^\circ C$  at a pressure of 300 mtorr on Si, Ge or SiGe substrates [Li et al., 1999]. Ge does not nucleate on  $SiO_2$  surfaces, which prohibits use of thermal oxides and LTO films as sacrificial substrate layers but does enable use of these films as sacrificial molds, as selective growth using  $SiO_2$  masking films is possible. Residual stress in poly-Ge films deposited on Si substrates is about 125 MPa compressive, which can be reduced to nearly zero after a 30-s anneal at  $600^\circ C$ . Poly-Ge is essentially impervious to KOH, tetramethyl ammonium hydroxide (TMAH) and BOE, making it an ideal masking and etch-stop material in Si micromachining. In fact, the combination of low residual stress and inertness to Si anisotropic etches enables the fabrication of Ge membranes on Si substrates [Li et al., 1999]. The mechanical properties of poly-Ge are comparable with polysilicon, with a Young's modulus measured at

132 GPa and a fracture stress ranging between 1.5 GPa and 3.0 GPa [Franke et al., 1999]. Poly-Ge can also be used as a sacrificial layer. Typical wet etchants are based on mixtures of  $\text{HNO}_3$ ,  $\text{H}_2\text{O}$  and  $\text{HCl}$  and  $\text{H}_2\text{O}$ ,  $\text{H}_2\text{O}_2$  and  $\text{HCl}$ , as well as the RCA SC-1 cleaning solution. These mixtures do not etch Si,  $\text{SiO}_2$ ,  $\text{Si}_3\text{N}_4$  and  $\text{Si}_x\text{N}_y$ , thereby enabling the use of poly-Ge as a sacrificial substrate layer in polysilicon surface micromachining. Using the above-mentioned techniques, poly-Ge-based thermistors and  $\text{Si}_3\text{N}_4$ -membrane-based pressure sensors using poly-Ge sacrificial layers have been fabricated [Li et al., 1999]. In addition, poly-Ge microstructures, such as lateral resonant structures, have been fabricated on Si substrates containing CMOS structures with no process-related degradation in performance, thus showing the advantages of low deposition temperatures and compatible wet chemical etching techniques [Franke et al., 1999].

SiGe is an alloy of Si and Ge and has recently received attention for its usefulness in microelectronics; therefore, deposition technologies for SiGe thin films are readily available. While the requirements for SiGe-based electronic devices require single-crystal material, the requirements for MEMS are much less restrictive, allowing for the use of polycrystalline material in many applications. Polycrystalline SiGe (poly-SiGe) films retain many properties comparable to polysilicon but can be deposited at lower substrate temperatures. Deposition processes include LPCVD, atmospheric pressure chemical vapor deposition (APCVD) and RTCVD (rapid thermal CVD) using  $\text{SiH}_4$  and  $\text{GeH}_4$  as precursor gases. Deposition temperature range from  $450^\circ\text{C}$  for LPCVD [Franke et al., 2000] to  $625^\circ\text{C}$  for RTCVD [Sedky et al., 1998]. The LPCVD processes can be performed in horizontal furnace tubes similar in configuration and size to those used for the deposition of polysilicon films. In general, the deposition temperature is related to the concentration of Ge in the films, with higher Ge concentration resulting in lower deposition temperatures. Like polysilicon, poly-SiGe can be doped with B and P to modify its conductivity. In fact, it has been reported that as-deposited, *in situ*, B-doped poly-SiGe films have a resistivity of  $1.8 \text{ m}\Omega\text{-cm}$  [Franke et al., 2000].

Poly-SiGe can be deposited on a number of sacrificial substrates, including  $\text{SiO}_2$  [Sedky et al., 1998], PSG [Franke et al., 1999] and poly-Ge [Franke et al., 1999], which, as detailed in previous sections of this chapter, can also be deposited at relatively low processing temperatures. For films rich in Ge, a thin polysilicon seed layer is sometimes used on  $\text{SiO}_2$  surfaces, as Ge does not readily nucleate on oxide surfaces. Because poly-SiGe is an alloy, variations in film stoichiometry can result in changes in physical properties. For instance, attack of poly-SiGe by  $\text{H}_2\text{O}_2$ , a main component in some Ge etchants, becomes problematic for Ge concentrations over 70%. As with most CVD thin films, residual stress is dependent on the substrate used and the deposition conditions; however, for *in situ* B-doped films, the as-deposited stresses are quite low at 10 MPa compressive [Franke et al., 2000].

In many respects, fabrication of devices made from poly-SiGe thin films follows processing methods used in polysilicon micromachining, as Si and Ge are quite compatible. The poly-SiGe/poly-Ge material system is particularly attractive for surface micromachining, as it is possible to use  $\text{H}_2\text{O}_2$  as a release agent. It has been reported that in  $\text{H}_2\text{O}_2$ , poly-Ge etches at a rate of  $0.4 \mu\text{m}/\text{min}$ , while poly-SiGe with Ge concentrations below 80% have no observable etch rate after 40 hr [Heck et al., 1999]. The ability to use  $\text{H}_2\text{O}_2$  as a sacrificial etchant makes the poly-SiGe and poly-Ge combination perhaps the ideal material system for surface micromachining. To this end, several interesting devices have been fabricated from poly-SiGe. Due to the conformal nature of the poly-SiGe coating, poly-SiGe-based, high-aspect-ratio structural elements, such as gimbal/microactuator structures made using the Hexil process [Heck et al., 1999], can readily be fabricated. Capitalizing on the low substrate temperatures associated with the deposition of poly-SiGe and poly-Ge thin films, an integrated MEMS fabrication process on Si wafers has been demonstrated [Franke et al., 2000]. In this process, CMOS structures are first fabricated into standard Si wafers. Poly-SiGe thin-film mechanical structures are surface micromachined atop the CMOS devices using a poly-Ge sacrificial layer and  $\text{H}_2\text{O}_2$  as an etchant. A significant advantage of this design lies in the fact that the MEMS structure is positioned directly above the CMOS structure, thus significantly reducing the parasitic capacitance and contact resistance characteristic of interconnects associated with the side-by-side integration schemes often used in integrated polysilicon MEMS. Use of  $\text{H}_2\text{O}_2$  as the sacrificial etchant means that no special protective layers are required to protect the underlying CMOS layer during release. Clearly, the unique properties of the poly-SiGe/poly-Ge material system, used in conjunction with the Si/ $\text{SiO}_2$  material system, enable fabrication of integrated MEMS that minimizes interconnect distances and potentially increases device performance.

## 15.7 Metals

---

Metals are used in many different capacities, ranging from hard etch masks and thin film conducting interconnects to structural elements in microsensors and microactuators. Metallic thin films can be deposited using a wide range of deposition techniques, the most common being evaporation, sputtering, CVD and electroplating. Such a wide range of deposition methods makes metal thin films one of the most versatile classes of materials used in MEMS devices. A complete review would constitute a chapter in itself; the following illustrative examples are included to give the reader an idea of how different metal thin films can be used.

Aluminum (Al) is probably the most widely used metal in micrfabricated devices. In MEMS, Al thin films can be used in conjunction with polymers such as polyimide because the films can be sputter-deposited at low temperatures. In most cases, Al is used as a structural layer; however, Al can be used as a sacrificial layer, as well. The polyimide/aluminum combination as structural and sacrificial materials, respectively, has also been demonstrated to be effective for surface micromachining [Schmidt et al., 1988; Mahadevan et al., 1990]. In this case, acid-based Al etchants can be used to dissolve the Al sacrificial layer. A unique feature of this material system is that polyimide is significantly more compliant than polysilicon and silicon nitride (e.g., its elastic modulus is nearly 50 times smaller). At the same time, polyimide can withstand large strains (up to 100% for some chemistries) before fracture. Finally, because both polyimide and Al can be processed at low temperatures (e.g., below 400°C), this material system can be used subsequent to the fabrication of ICs on the wafer. A drawback of polyimide is its viscoelastic properties (i.e., it creeps).

Tungsten (deposited by CVD) as a structural material and silicon dioxide as a sacrificial material have also been used for surface micromachining [Chen and MacDonald, 1991]. In this case, HF is used for removing the sacrificial oxide. In conjunction with high-aspect-ratio processes, nickel and copper are being used as structural layers with polyimide and other metals (e.g., chromium) as the sacrificial layers. The study of many of these material systems has been either limited or is just in the preliminary stages; as a result, their benefits are yet to be determined.

Metal thin films are among the most versatile MEMS materials, as alloys of certain metallic elements exhibit a behavior known as the shape-memory effect. The shape-memory effect relies on the reversible transformation from a ductile martensite phase to a stiff austenite phase upon the application of heat. The reversible nature of this phase change allows the shape-memory effect to be used as an actuation mechanism. Moreover, it has been found that high forces and strains can be generated from shape-memory thin films at reasonable power inputs, thus enabling shape memory actuation to be used in MEMS-based microfluidic devices such as microvalves and micropumps. Alloys of Ti and Ni, collectively known as TiNi, are among the most popular shape-memory alloys owing to their high actuation work densities (reported to be up to 50 MJ/m<sup>3</sup>) and large bandwidth (up to 0.1 kHz) [Shih et al., 2001]. TiNi is also attractive because conventional sputtering techniques can be employed to deposit thin films of the alloy, as detailed in a recent report [Shih et al., 2001]. In this study, TiNi films deposited by two methods—co-sputtering elemental Ti and Ni targets and co-sputtering TiNi alloy and elemental Ti targets—were compared for use in microfabricated shape-memory actuators. In each case, the objective was to establish conditions so that films with the proper stoichiometry, and hence phase transition temperature, could be maintained. The sputtering tool was equipped with a substrate heater in order to deposit films on heated substrates as well as to anneal the films in vacuum after deposition. It was reported that co-sputtering from TiNi and Ti targets produced better films than co-sputtering from Ni and Ti targets, due to process variations related to roughening of the Ni target. The TiNi/Ti co-sputtering process has been successfully used as an actuation material in a silicon spring-based microvalve [Hahm et al., 2000].

Use of thin-film metal alloys in magnetic actuator systems is yet another example of the versatility of metallic materials in MEMS. From a physical perspective, magnetic actuation is fundamentally the same in the microscopic and macroscopic domains, with the main difference being that process constraints limit the design options of microscale devices. Magnetic actuation in microdevices generally requires the magnetic layers to be relatively thick (tens to hundreds of microns), so as to create structures that can

be used to generate magnetic fields of sufficient strength to generate the desired actuation. To this end, magnetic materials are often deposited by thick-film methods such as electroplating. The thicknesses of these layers often exceeds what can feasibly be patterned by etching, so plating is often conducted in microfabricated molds usually made from X-ray-sensitive materials such as polymethylmethacrylate (PMMA). The PMMA mold thickness can exceed several hundred microns, so X-rays are used as the exposure source. In some cases, a thin-film seed layer is deposited by sputtering or other conventional means before the plating process begins. At the completion of the plating process, the mold is dissolved, freeing the metallic component. This process, commonly known as LIGA, has been used to produce high-aspect-ratio structures such as microgears from NiFe magnetic alloys [Leith and Schwartz, 1999]. LIGA is not restricted to the creation of magnetic actuator structures and, in fact, has been used to make such structures as Ni fuel atomizers [Rajan et al., 1999]. In this application, Ni was selected for its desirable chemical, wear and temperature properties, not its magnetic properties.

## 15.8 Silicon Carbide

---

Use of Si as a mechanical and electrical material has enabled the development of MEMS for a wide range of applications. Of course, use of MEMS is restricted by the physical properties of the material, which in the case of Si-based MEMS limits the devices to operating temperatures of about 200°C in low-wear and benign chemical environments. Therefore, alternate materials are necessary to extend the usefulness of MEMS to areas classified as “harsh environments.” In a broad sense, harsh environments include all conditions where use of Si is prohibited by its electrical, mechanical and chemical properties. These would include high-temperature, high-radiation, high-wear and highly acidic and basic chemical environments. To be a direct replacement for Si in such applications, the material would have to be a chemically inert, extremely hard, temperature-insensitive, micromachinable semiconductor. These requirements pose significant fabrication challenges, as micromachining requires the use of chemical and mechanical processes to remove unwanted material. In general, a class of wide bandgap semiconductors that includes silicon carbide (SiC) and diamond embodies the electrical, mechanical and chemical properties required for many harsh environment applications, but until recently these materials found little usefulness in MEMS because the necessary micromachining processes did not exist. The following two sections review the development of SiC and diamond for MEMS applications.

SiC has long been recognized as a semiconductor with potential for use in high-temperature and high-power electronics. SiC is a material that is polymorphic, meaning that it exists in multiple crystalline structures, each sharing a common stoichiometry. SiC exists in three main polytypes: cubic, hexagonal and rhombohedral. The cubic polytype, called 3C-SiC, has an electronic bandgap of 2.3 eV, which is over twice that of Si. Numerous hexagonal and rhombohedral polytypes have been identified, the two most common being the 4H-SiC and 6H-SiC hexagonal polytypes. The electronic bandgap of 4H- and 6H-SiC is even higher than 3C-SiC, being 2.9 and 3.2 eV, respectively. SiC in general has a high thermal conductivity, ranging from 3.2 to 4.9 W/cm-K, and a high breakdown field ( $30 \times 10^5$  V/cm). SiC films can be doped to create n- and p-type material. The stiffness of SiC is quite large relative to Si, with measured Young's modulus values in the range of 300 to 700 GPa, which makes it very attractive for micromachined resonators and filters, as the resonant frequency increases with increasing modulus. SiC is not etched in any wet chemistries commonly used in Si micromachining. SiC can be etched in strong bases like KOH, but only at temperatures in excess of 600°C. SiC is a material that does not melt, but rather sublimates at temperatures in excess of 1800°C. Single-crystal 4H- and 6H-SiC wafers are commercially available, although they are smaller (3-in. diameter) and much more expensive than Si. With this list of properties, it is little wonder why SiC is being actively researched for MEMS applications.

SiC thin films can be grown or deposited using a number of different techniques. For high-quality single-crystal films, APCVD and LPCVD processes are most commonly employed. The high crystal quality is achieved by homoepitaxial growth of 4H- and 6H-SiC films on substrates of like crystal type. These processes usually employ dual precursors to supply Si and C, with the common sources being SiH<sub>4</sub> and C<sub>3</sub>H<sub>8</sub>. Typical epitaxial growth temperatures range from 1500 to 1700°C. Epitaxial films with p- or

n-type conductivity can be grown using such dopants as Al and B for p-type films and N or P for n-type films. In fact, doping with N is so effective at modifying the conductivity that growth of undoped SiC is virtually impossible because the concentrations of residual N in these deposition systems can be quite high. At these temperatures, the crystal quality of the epilayers is sufficient for the fabrication of electronic device structures.

Both APCVD and LPCVD can be used to deposit the only known polytype to grow epitaxially on a non-SiC substrate, namely 3C-SiC on Si. Heteroepitaxy is possible because 3C-SiC and Si have similar lattice structures. The growth process involves two key steps. The first step, called *carbonization*, involves converting the near-surface region of the Si substrate to 3C-SiC by simply exposing it to a propane/hydrogen mixture at a substrate temperature of about 1300°C. The carbonized layer forms a crystalline template on which a 3C-SiC film is grown by adding silane to the hydrogen/propane mix. A 20% lattice mismatch between Si and 3C-SiC results in the formation of crystalline defects in the 3C-SiC film. The density is highest in the carbonization layer, but it decreases with increasing thickness, although not to a level comparable with epitaxial 6H- and 4H-SiC films. Regardless, the fact that 3C-SiC does grow on Si substrates enables the use of Si bulk micromachining techniques to fabrication of a host of SiC-based MEMS structures such as pressure sensors and resonant structures.

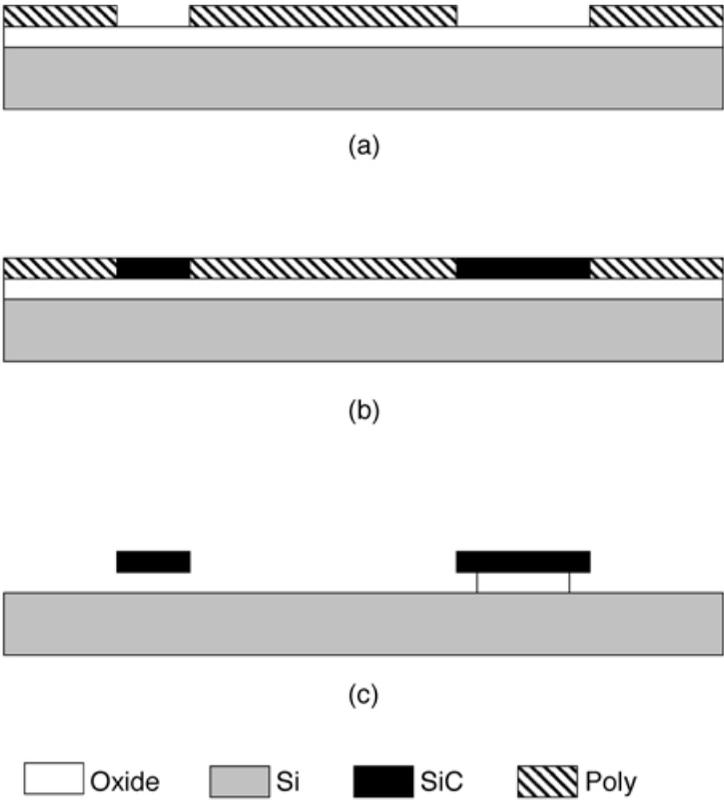

Polycrystalline SiC, hereafter referred to as poly-SiC, has proven to be a very versatile material for SiC MEMS. Unlike single-crystal versions of SiC, poly-SiC can be deposited on a variety of substrate types, including common surface micromachining materials such as polysilicon, SiO<sub>2</sub> and Si<sub>3</sub>N<sub>4</sub>. Moreover, poly-SiC can be deposited using a much wider set of processes than epitaxial films; LPCVD, APCVD, PECVD and reactive sputtering have all been used to deposit poly-SiC films. The deposition of poly-SiC requires much lower substrate temperatures than epitaxial films, ranging from roughly 500 to 1200°C. The microstructure of poly-SiC films is temperature and substrate dependent [Wu et al., 1999]. In general, grain size increases with increasing temperature. For amorphous substrates such as SiO<sub>2</sub> and Si<sub>3</sub>N<sub>4</sub>, poly-SiC films tend to be randomly oriented with equiaxed grains, with larger grains deposited on SiO<sub>2</sub> substrates. In contrast, for oriented substrates such as polysilicon, the texture of the poly-SiC film matches that of the substrate as a result of grain-to-grain epitaxy [Zorman et al., 1996]. This variation in microstructure suggests that device performance can be tailored by selecting the proper substrate and deposition conditions.

Direct bulk micromachining of SiC is very difficult, due to its outstanding chemical durability. Conventional wet chemical techniques are not effective; however, several electrochemical etch processes have been demonstrated. These techniques are selective to certain doping types, so dimensional control of the etched structures depends on the ability to form doped layers, which can only be formed by *in situ* or ion implantation processes, as solid source diffusion is not possible at reasonable processing temperatures. This constraint limits the geometrical complexity of fabricated devices. To fabricate thick (hundreds of microns), three-dimensional, high-aspect-ratio SiC structures, a molding technique has been developed [Rajan et al., 1999]. The molds are fabricated from Si substrates using deep reactive ion etching, a dry etch process that has revolutionized Si bulk micromachining. The micromachined Si molds are then filed with SiC using a combination of thin epitaxial and thick polycrystalline film CVD processes. The thin-film process, which produces 3C-SiC films with a featureless SiC/Si interface, is used to ensure that the molded structure has smooth outer surfaces. The mold-filling process coats all surfaces of the mold with a very thick SiC film. To remove the mold and free the SiC structure, the substrate is first mechanically polished to expose sections of the mold, then the substrate is immersed in a Si etchant to completely dissolve the mold. Because SiC is not attacked by Si etchants, the final SiC structure is released without the need of any special procedures. This process has been successful in the fabrication of solid SiC fuel atomizers, and a variant has been used to fabricate SiC structures in Si-based, micro, gas turbines [Lohner et al., 1999]. In both cases, the process capitalizes on the chemical inertness of SiC in conjunction with the reactivity of Si to create structures that could otherwise not be fabricated with existing technologies.

Although SiC cannot be etched using conventional wet etch techniques, thin SiC films can be patterned using conventional dry etching techniques. RIE processes using fluorinated compounds such as CHF<sub>3</sub> and SF<sub>6</sub> combined with O<sub>2</sub> and sometimes with an inert gas or H<sub>2</sub> are used. The high oxygen content in these plasmas generally prohibits the use of photoresist as a masking material; therefore, hard masks

made of metals such as Al and Ni are often used. RIE processes are generally effective patterning techniques; however, a phenomenon called *micromasking*, which results in the formation of etch-field grass, can sometimes be a problem. Nonetheless, RIE-based SiC surface-micromachining processes using polysilicon and SiO<sub>2</sub> sacrificial layers have been developed [Fleischman et al., 1996; 1998]. These processes are effective means to fabricate single-layer SiC structures, but multilayer structures are very difficult to fabricate because the etch rates of the sacrificial layers are much higher than the SiC structural layers. The lack of a robust etch stop makes critical dimensional control in the thickness direction unreliable, thus making RIE-based SiC multilayer processes impractical.

To address the materials compatibility issues facing RIE-based SiC surface micromachining in the development of a multilayer process, a micromolding process for SiC patterning on sacrificial layer substrates has been developed [Yasseen et al., 2000]. In essence, the micromolding technique is the thin film analog to the molding technique presented earlier. The cross-sectional schematic shown in Figure 15.6 illustrates the steps to fabricate a SiC lateral resonant structure. The micromolding process utilizes polysilicon and SiO<sub>2</sub> films as sacrificial molds, Si<sub>3</sub>N<sub>4</sub> as an electrical insulator, and SiO<sub>2</sub> as a sacrificial substrate. These films are deposited and patterned by conventional methods, thus leveraging the well-characterized and highly selective processes developed for polysilicon MEMS. Poly-SiC films are deposited into and onto the micromolds. Mechanical polishing with a diamond-based slurry is used to remove poly-SiC from atop the molds, then the appropriate etchant is used to dissolve the molds and sacrificial layers. An example of device structure fabricated using this method is shown in Figure 15.7. The micromolding method clearly utilizes the differences in chemical properties of the three materials in this system in a way that bypasses the difficulties associated with chemical etching of SiC.

**FIGURE 15.6** Cross-sectional schematics of the SiC micromolding process: (a) after micromold fabrication, (b) after SiC deposition and planarization, and (c) after mold and sacrificial layer release.

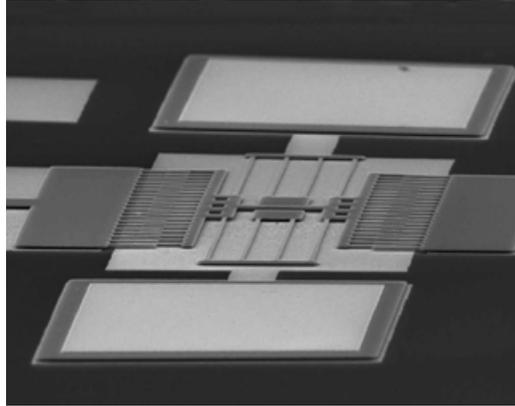

FIGURE 15.7 SEM micrograph of a SiC lateral resonant structure fabricated using the micromolding process.

## 15.9 Diamond

Along with SiC, diamond is a leading material for MEMS applications in harsh environments. It is commonly known as nature's hardest material, an ideal property for high-wear environments. Diamond has a very large electronic bandgap (5.5 eV) which is well suited for stable high-temperature operation. Diamond is a high-quality insulator with a dielectric constant of 5.5; however, it can be doped with B to create p-type conductivity. In general, diamond surfaces are chemically inert in the same environments as SiC. Diamond has a very high Young's modulus (1035 GPa), making it the ideal material for high-frequency micromachined resonators. Perhaps the only disadvantage with diamond from a materials properties perspective is that a stable oxide cannot be grown on the diamond surface. Thermal oxidation results in the formation of CO and CO<sub>2</sub>, which, of course, are gaseous substances under standard conditions. This complicates the fabrication of diamond-based electronic devices as deposited insulating thin films must be used. Operation of diamond-based sensors at high temperatures requires the use of passivation coatings to protect the diamond structures from oxidation. These limitations, however, can be overcome and do not severely restrict the use of diamond films in harsh environment applications.

Unlike SiC, fabrication of diamond MEMS structures is restricted to polycrystalline and amorphous material. Although diamond epitaxy has been demonstrated, the epi films were grown on small, irregular, single-crystalline pieces, because single-crystalline diamond wafers are not yet available. 3C-SiC thin films have been used to deposit highly oriented diamond films on Si substrates. Polycrystalline diamond films can be deposited on Si and SiO<sub>2</sub> substrates, but the surfaces often must be seeded either by damaging the surface with diamond powders or by biasing the surface with a negative charge, a process called *bias enhanced nucleation*. In general, diamond nucleates much more readily on Si surfaces than on SiO<sub>2</sub> surfaces, and this fact can be exploited to pattern diamond films into microstructures, such as a micromachined atomic force microscope (AFM) cantilever probe, using a selective growth process in conjunction with SiO<sub>2</sub> molding masks [Shibata et al., 2000]. As mentioned previously, diamond can be made insulating or semiconducting, and it is relatively straightforward to produce both types in polycrystalline diamond. This capability enables the fabrication of "all diamond" microelectromechanical structures, thus eliminating the need for Si<sub>3</sub>N<sub>4</sub> as an insulating layer.

Bulk micromachining of diamond is more difficult than SiC because electrochemical etching techniques have not been demonstrated. Using a strategy similar to that used in SiC, bulk micromachined diamond structures have been fabricated using bulk micromachined Si molds [Bjorkman et al., 1999]. The Si molds were fabricated using conventional micromachining techniques and filled with polycrystalline diamond deposited by HFCVD. The HFCVD process uses hydrogen as a carrier gas and methane as the carbon source. A hot tungsten wire is used to crack the methane into reactive species as well as to heat the substrate. The process was performed at a substrate temperature of 850 to 900°C and a pressure

of 50 mtorr. The Si substrate was seeded with diamond particles suspended in an ethanol solution prior to deposition. After diamond deposition, the top surface of the diamond structure was polished using a hot iron plate. The material removal rate was reported to be around 2  $\mu\text{m/hr}$ . After polishing, the Si mold was removed in a Si etchant, leaving behind the micromachined diamond structure. This process was used to produce all-diamond, high-aspect-ratio, capillary channels for microfluidic applications [Rangsten et al., 1999].

Surface micromachining of polycrystalline diamond thin films requires modifications of conventional micromachining practices to compensate for the nucleation and growth mechanisms of diamond thin films on sacrificial substrates. Early work in this area focused on developing thin-film patterning techniques. Conventional RIE methods are generally ineffective, so effort was focused on developing selective growth methods. One early method used selective seeding to form patterned templates for diamond nucleation. The selective seeding process was based on the lithographic patterning of photoresist mixed with diamond powders [Aslam and Schulz, 1995]. The diamond-loaded photoresist was deposited onto a Cr-coated Si wafer, exposed and then developed, leaving a patterned structure on the wafer surface. During the diamond deposition process, the photoresist rapidly evaporates, leaving behind the diamond seed particles in the desired structural shapes, which then serve as a template for diamond growth.

A second process has been developed for selective deposition directly on sacrificial substrate layers. This process combines a conventional diamond seeding technique with photolithographic patterning and etching to fabricate micromachined diamond structures using  $\text{SiO}_2$  sacrificial layers [Ramesham, 1999]. The process can be executed in one of two approaches. The first approach begins with the formation of a  $\text{SiO}_2$  layer by thermal oxidation on a Si wafer. The wafer is then seeded with diamond particles, coated with photoresist, and photolithographically patterned to form a mask for  $\text{SiO}_2$  etching. Unmasked regions of the seeded  $\text{SiO}_2$  film are then partially etched in BOE to form a surface unfavorable for diamond growth. The photoresist is then removed and a diamond film is selectively deposited. The second approach begins with an oxidized Si wafer, which is coated with photoresist. The resist is photolithographically patterned and the wafer is then seeded, with the photoresist protecting select regions of the  $\text{SiO}_2$  surface from the damage caused by the seeding process. The photoresist is removed and selective diamond deposition is performed. In each case, once the diamond film is patterned, the structures could be released using conventional means. These techniques have been used to fabricate cantilever beams and bridge structures.

A third method to surface-micromachine polycrystalline diamond films follows the conventional approach of film deposition, dry etching and release. The chemical inertness of diamond renders most conventional plasma chemistries useless for etching diamond films. Oxygen-based ion beam plasmas, however, can be used to etch diamond thin films [Yang et al., 1999]. The oxygen ion beam prohibits the use of photoresist masks, so hard masks made from metals such as Al are required. A simple ion-beam, etching-based, surface-micromachining process begins with the deposition of a  $\text{Si}_3\text{N}_4$  film on a Si wafer and is followed by the deposition of a polysilicon sacrificial layer. The polysilicon layer is seeded with a diamond slurry, and a diamond film is deposited by HFCVD. To prepare the diamond film for etching, an Al masking film is deposited and patterned. The diamond films are then etched in the  $\text{O}_2$  ion beam plasma, and the structures are released by etching the polysilicon with KOH. This process has been used to create lateral resonant structures; although the patterning process was successful, the devices were not operable because of a significant stress gradient in the film. With a greater understanding of the structure-property relationships of diamond thin films, such problems with surface micromachined structures should be solvable, thus enabling the successful fabrication of a new class of highly functional devices.

## 15.10 III–V Materials

---

Galium arsenide (GaAs), indium phosphide (InP) and other III–V compounds are attractive electronic materials for various types of sensors and optoelectronic devices. In general, III–V compounds have favorable piezoelectric and optoelectric properties, high piezoresistive constants and wide electronic bandgaps (relative to Si). In addition, III–V materials can be deposited as ternary and quaternary alloys

that have lattice constants closely matched to the binary compounds from which they are derived (e.g.,  $\text{Al}_x\text{Ga}_{1-x}\text{As}$  and GaAs), thus permitting the fabrication of a wide variety of heterostructures that facilitate device performance. Although the III–V class of materials is quite large, this section of the chapter will focus on GaAs and InP for MEMS applications.

Crystalline GaAs has a zinc-blend crystal structure. It has an electronic bandgap of 1.4 eV, enabling GaAs electronic devices to function at temperatures as high as 350°C [Hjort et al., 1994]. High-quality single-crystal wafers are commercially available, as are well-developed metallorganic chemical vapor deposition (MOCVD) and molecular beam epitaxy (MBE) growth processes for epitaxial layers of GaAs and its alloys. GaAs does not outperform Si in terms of mechanical properties; however, its stiffness and fracture toughness are still suitable for micromechanical devices. A favorable combination of mechanical and electrical properties makes GaAs attractive for certain MEMS applications.

Micromachining of GaAs is relatively straightforward, as many of its lattice-matched ternary and quaternary alloys have sufficiently varying chemical properties to allow their use as sacrificial layers. For example, the most common ternary alloy for GaAs is  $\text{Al}_x\text{Ga}_{1-x}\text{As}$ . For values of  $x \leq 0.5$ , etchants containing mixtures of HF and  $\text{H}_2\text{O}$  etch  $\text{Al}_x\text{Ga}_{1-x}\text{As}$  without attacking GaAs. In contrast, etchants consisting of  $\text{NH}_4\text{OH}$  and  $\text{H}_2\text{O}_2$  mixtures attack GaAs isotropically but do not etch  $\text{Al}_x\text{Ga}_{1-x}\text{As}$ , thereby enabling the bulk micromachining of GaAs wafers with lattice-matched etch stops. An extensive review of III–V etch processes can be found in Hjort (1996). By taking advantage of the single-crystal heterostructures that can be formed on GaAs substrates, both surface micromachined and bulk micromachined devices can be fabricated from GaAs. The list of devices is widely varying and includes comb-drive lateral resonant structures [Hjort, 1996], pressure sensors [Fobelets et al., 1994; Dehe et al., 1995b], thermopile sensors [Dehe et al., 1995a] and Fabry–Perot detectors [Dehe et al., 1998].

Micromachining of InP closely resembles the techniques used for GaAs. Many of the properties of InP are similar to GaAs in terms of crystal structure, mechanical stiffness and hardness; however, the optical properties of InP make it particularly attractive for micro-optomechanical devices to be used in the 1.3- to 1.55- $\mu\text{m}$  wavelengths [Seassal et al., 1996]. Like GaAs, single-crystal wafers of InP are readily available. Ternary and quaternary lattice-matched alloys of InP include InGaAs, InAlAs, InGaAsP and InGaAlAs compounds, and, like GaAs, some of these can be used as either etch stop and/or sacrificial layers, depending on the etch chemistry. For instance, InP structural layers deposited on  $\text{In}_{0.53}\text{Al}_{0.47}\text{As}$  sacrificial layers can be released using  $\text{C}_6\text{H}_8\text{O}_7:\text{H}_2\text{O}_2:\text{H}_2\text{O}$  etchants. At the same time, InP films and substrates can be etched in HCl: $\text{H}_2\text{O}$ -based solutions with  $\text{In}_{0.53}\text{Ga}_{0.47}\text{As}$  films as etch stops. A comprehensive list of wet chemical etchs for InP and related alloys is reviewed in Hjort (1996). Using InP-based micromachining techniques, multi-air-gap filters [Leclercq et al., 1998], bridge structures [Seassal et al., 1996] and torsional membranes [Dehe et al., 1998] have been fabricated from InP and its related alloys.

## 15.11 Piezoelectric Materials

---

Piezoelectric materials play an important role in MEMS technology, mainly for mechanical actuation but also to a lesser extent for sensing applications. In a piezoelectric material, mechanical stress polarizes the material which results in the production of an electric field. The effect also works in reverse; that is, an applied electric field acts to produce a mechanical strain. Many materials retain some sort of piezoelectric behavior, such as quartz, GaAs and ZnO, to name a few. Recent work in MEMS has focused on the development of the compound lead zirconate titanate,  $\text{Pb}(\text{Zr}_x\text{Ti}_{1-x})\text{O}_3$  (PZT). PZT is attractive because it has high piezoelectric constants that lead to high mechanical transduction.

PZT can be deposited by a wide variety of methods, including co-sputtering, CVD and sol-gel processing. Sol-gel processing has been receiving attention lately, due to being able to control the composition and the homogeneity of the deposited material over large surface areas. The sol-gel process uses liquid precursor containing Pb, Ti, Zr and O to create PZT solutions [Lee et al., 1996]. The solution is then deposited on the substrate using a spin-coating process. The substrates in this example consist of a Si wafer with a Pt/Ti/SiO<sub>2</sub> thin-film multilayer on its surface. The deposition process produces a PZT film in multilayer fashion, with each layer consisting of a spin-coated layer that is dried at 110°C for 5 min and then heat

treated at 600°C for 20 min. After building up the PZT layer to the desired thickness, the multilayer was heated at 600°C for up to 6 hr. Prior to this anneal, a PbO top layer was deposited on the PZT surface. A Au/Cr electrode was then sputter-deposited on the surface of the piezoelectric stack. This process was used to fabricate a PZT-based force sensor. Like Si, PZT films can be patterned using dry etch techniques based on chlorine chemistries, such as  $\text{Cl}_2/\text{CCl}_4$ , as well as ion beam milling using inert gases such as Ar.

## 15.12 Conclusions

---

The early development of MEMS can be attributed to the recognition of silicon as a mechanical material. The rapid expansion of MEMS over the last decade is due in part to the inclusion of new structural materials that have expanded the functionality of microfabricated devices beyond what is achievable in silicon. As shown by the examples in this chapter, the materials science of MEMS is not only about the structural layers, but also about the associated sacrificial and masking layers and how these layers interact during the fabrication process in order to realize the final device. In simple terms, MEMS is about material systems; therefore, analysis of what makes MEMS devices work (or, in many cases, not work) relies on a thorough understanding of this fact.

## For Further Information

A comprehensive review of polysilicon as a material for microelectronics and MEMS is presented in *Polycrystalline Silicon for Integrated Circuits and Displays*, 2nd ed., by Ted Kamins. The Materials Research Society holds an annual symposium on the materials science of MEMS at the Fall meetings. The proceedings from these symposia have been published as volumes 546B, 605B and 657B of the *Materials Research Society Symposium Proceedings*. Several regularly published journals contain contributed and review papers concerning materials aspects of MEMS, including: (1) *The Journal of Microelectromechanical Systems*, (2) *Journal of Micromachining and Microengineering*, (3) *Sensors and Actuators* and (4) *Sensors and Materials*. These journals are carried by most engineering and science libraries and may be accessible online.

## 16.1 Wet Bulk Micromachining: Introduction

In wet bulk micromachining, features are sculpted in the bulk of materials such as silicon, quartz, SiC, GaAs, InP, Ge and glass by orientation-dependent (anisotropic) and/or by orientation-independent (isotropic) wet etchants. The technology employs pools as tools [Harris, 1976], instead of the plasmas studied in Madou (1997, chap. 2). A vast majority of wet bulk micromachining work is based on single crystal silicon. There has been some work on quartz, some on crystalline Ge and GaAs, and a minor amount on GaP, InP and SiC. Micromachining has grown into a large discipline, comprising several tool sets for fashioning microstructures from a variety of materials. These tools are used to fabricate microstructures either in parallel or serial processes. Madou (1997, Table 7.7) summarizes these tools. It is important to evaluate all the presented micromanufacturing methods before deciding on one specific machining method optimal for the application at hand—in other words, to zero-base the technological approach [Block, B., private communication]. The principle commercial Si micromachining tools used today are the well-established wet bulk micromachining and the more recently introduced surface micromachining (see Section 16.10). A typical structure fashioned in a bulk micromachining process is shown in [Figure 16.1](#). This type of piezoresistive membrane structure, a likely base for a pressure sensor or an accelerometer, demonstrated that batch fabrication of miniature components does not need to be limited to integrated circuits (ICs). Despite all the emerging new micromachining options, Si wet bulk micromachining, being the best characterized micromachining tool, remains

**FIGURE 16.1** A wet bulk micromachining process is used to craft a membrane with piezoresistive elements. Silicon micromachining selectively thins the silicon wafer from a starting thickness of about 400  $\mu\text{m}$ . A diaphragm having a typical thickness of 20  $\mu\text{m}$  or less with precise lateral dimensions and vertical thickness control results.

most popular in industry. An emphasis in this chapter is on the wet etching process itself. Other machining steps typically used in conjunction with wet bulk micromachining, such as additive processes and bonding processes, are covered in Madou (1997, chaps. 3 and 8, respectively).

Wet bulk micromachining had its genesis in the Si IC industry, but further development will require the adaptation of many different processes and materials. To emphasize the need for micromachinists to look beyond Si as the ultimate substrate and/or building material, we have presented many examples of non-Si micromachinery throughout the book. The need to incorporate new materials and processes is especially urgent for progress in chemical sensors and micro-instrumentation which rely on non-IC materials and often are relatively large. The merging of bulk micromachining with other new fabrication tools such as surface micromachining and electroplating and the adaptation of new materials such as Ni and polyimides has fostered a powerful new, nontraditional precision engineering method. A truly multidisciplinary engineering education will be required to design miniature systems with the most appropriate building philosophy.

After a short historical note on wet bulk micromachining we begin this chapter with an introduction to the crystallography of single crystal Si and a listing of its properties, clarifying why Si is such an important sensor material. Some empirical data on wet etching are reviewed and different models for anisotropic and isotropic etching behavior follow. Then, etch stop techniques, which catapulted micromachining into an industrial manufacturing technique, are discussed. Subsequently, a discussion of problems associated with bulk micromachining such as IC incompatibility, extensive real-estate usage, and issues involving corner compensation is presented. Finally, examples of applications of wet bulk micromachining in mechanical and chemical sensors are given.

## 16.2 Historical Note

---

The earliest use of wet etching of a substrate, using a mask (wax) and etchants (acid-base), appears to be in the fifteenth century for *decorating armor* [Harris, 1976]. Engraving hand tools were not hard enough to work the armor and more powerful acid-base processes took over. By the early seventeenth century, etching to decorate arms and armor was a completely established process. Some pieces stemming from that period have been found where the chemical milling was accurate to within 0.5 mm. The masking in this traditional chemical milling was accomplished by cutting the maskant with a scribing tool and peeling the maskant off where etching was wanted. Harris (1976) describes in detail all of the improvements that, by the mid-1960s, made this type of chemical milling a valuable and reliable method of manufacturing. It is especially popular in the aerospace world. The method enables many parts to be produced more easily and cheaply than by other means and in many cases provides a means to design and produce parts and configurations not previously possible. Through the introduction of photosensitive masks by Niépce in 1822 [Madou, 1997, chap. 1], chemical milling in combination with lithography became a reality and a new level of tolerances came within reach. The more recent major applications of lithography-based chemical milling are the manufacture of printed circuit boards, started during the Second World War, and, by 1961, the fabrication of Si-integrated circuitry. Photochemical machining is also used for such precision parts as color television shadow masks, integrated circuit lead frames, light chopper and encoder discs, and decorative objects such as costume jewelry [Allen, 1986]. The geometry of a 'cut' produced when etching silicon integrated circuits is similar to the chemical-milling cut of the aerospace industry, but the many orders of magnitude difference in size and depth of the cut account for a major difference in achievable accuracy. Accordingly, the tolerances for fashioning integrated circuitry are many orders of magnitude smaller than in the chemical milling industry.

In this book we are concerned with lithography and chemical machining used in the IC industry and in microfabrication. A major difference between these two fields is in the aspect ratio (height-to-width ratio) of the features crafted. In the IC industry one deals with mostly very small, flat structures with aspect ratios of 1 to 2. In the microfabrication field, structures typically are somewhat larger and aspect ratios might be as high as 400.

**Decorating armor.** (From Harris, T. W., *Chemical Milling*, Clarendon Press, Oxford, 1976. With permission.)

Isotropic etching has been used in silicon semiconductor processing since its beginning in the early 1950s. Representative work from that period is the impressive series of papers by Robbins and Schwartz (1959, 1960) and Schwartz and Robbins (1961, 1976) on chemical isotropic etching, and Uhler's paper on electrochemical isotropic etching [Uhler, 1956]. The usual chemical isotropic etchant used for silicon was HF in combination with  $\text{HNO}_3$  with or without acetic acid or water as diluent [Robbins and Schwartz, 1959; 1960; Schwartz and Robbins, 1961; 1976]. The early work on isotropic etching in an electrochemical cell (i.e., 'electropolishing') was carried out mostly in nonaqueous solutions, avoiding black or red deposits that formed on the silicon surface in aqueous solutions [Hallas, 1971]. Turner showed that if a critical current density is exceeded, silicon can be electropolished in aqueous HF solutions without the formation of any deposits [Turner, 1958].

In the mid-1960s, the Bell Telephone Laboratories started the work on anisotropic Si etching in mixtures of, at first, KOH, water and alcohol and later in KOH and water. This need for high aspect ratio cuts in silicon arose for making dielectrically isolated structures in integrated circuits such as for beam leads. Chemical and electrochemical anisotropic etching methods were pursued [Stoller and Wolff, 1966; Stoller, 1970; Forster and Singleton, 1966; Kenney, 1967; Lepselter, 1966; 1967; Waggener, 1970; Kragness and Waggener, 1973; Waggener et al., 1967a; 1967b; Bean and Runyan, 1977]. In the mid-1970s, a new surge of activity in anisotropic etching was associated with the work on V-groove and U-groove transistors [Rodgers et al., 1976; 1977; Ammar and Rodgers, 1980].

The first use of Si as a micromechanical element can be traced back to a discovery and an idea from the mid-1950s and early 1960s, respectively. The discovery was the large piezoresistance in Si and Ge by Smith in 1954 [Smith, 1954]. The idea stems from Pfann et al. in 1961 [Pfann, 1961], who proposed a diffusion technique for the fabrication of Si piezoresistive sensors for stress, strain and pressure. As early as 1962 Tufté et al. (1962), at Honeywell, followed up on this suggestion. By using a combination of a wet isotropic etch, dry etching and oxidation processes, Tufté et al. made the first thin Si piezoresistive diaphragms, of the type shown in [Figure 16.1](#), for pressure sensors [Tufté et al., 1962]. Sensym/National Semiconductor (sold to Hawker Siddeley in 1988) became the first to make stand-alone Si sensor products

(1972). By 1974, National Semiconductor described a broad line of Si pressure transducers, in the first complete silicon pressure transducer catalog [Editorial, 1974]. Other early commercial suppliers of micromachined pressure sensor products were Foxboro/ICT, Endevco, Kulite and Honeywell's Microswitch. Other micromachined structures began to be explored by the mid- to late-1970s: Texas Instruments produced a thermal print head (1977) [Editorial, 1977]; Hewlett Packard made thermally isolated diode detectors (1980) [O'Neill, 1976]; fiberoptic alignment structures were made at Western Electric [Boivin, 1974]; and IBM produced ink jet nozzle arrays (1977) [Bassous et al., 1977]. Many **Silicon Valley microsensor companies** played and continue to play a pivotal role in the development of the market for Si sensor products.

European and Japanese companies followed the U.S. lead more than a decade later; for example, Druck Ltd. in the U.K. started exploiting Greenwood's micromachined pressure sensor in the mid-1980s [Greenwood, 1984].

Petersen's 1982 paper, extolling the excellent mechanical properties of single crystalline silicon, helped galvanize academia to get involved in Si micromachining in a major way [Petersen, 1982]. Before that time most efforts had played out in industry and practical needs were driving the technology (market pull). The new generation of micromachined devices often constitutes gadgetry only, and the field is perceived by many as a technology looking for applications (technology push). It has been estimated that

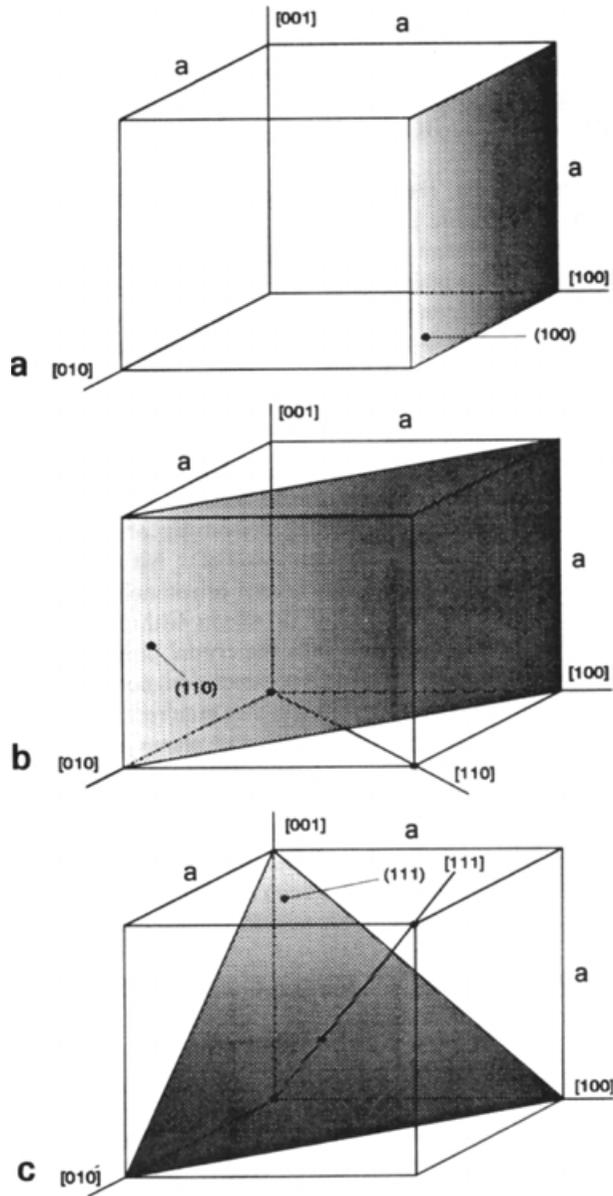

FIGURE 16.2 Miller indices in a cubic lattice: planes and axes. Shaded planes are: a (100), b (110), c (111).

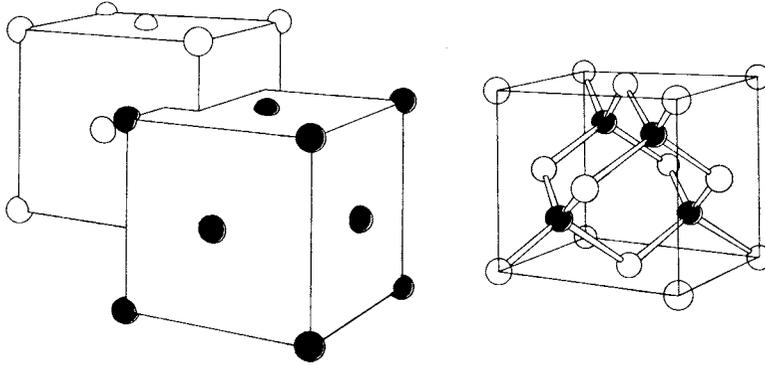

today there are more than 10,000 scientists worldwide involved in Si sensor research and development [Middlehoek and Dauderstadt, 1994]. In order to justify the continued investment, it has become an absolute priority to understand the intended applications better and to be able to select a more specific micromachining tool set intelligently and to identify large market applications [Madou, 1997, chap. 10].

## 16.3 Silicon Crystallography

### 16.3.1 Miller Indices

The periodic arrangement of atoms in a crystal is called the lattice. The unit cell in a lattice is a segment representative of the entire lattice. For each unit cell, basis vectors ( $a_1$ ,  $a_2$  and  $a_3$ ) can be defined such that

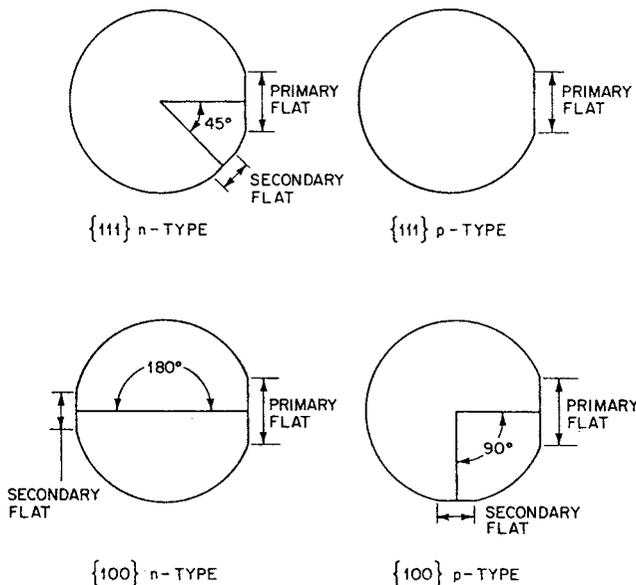

**FIGURE 16.4** The diamond-type lattice can be constructed from two interpenetrating face-centered cubic unit cells. Si forms four covalent bonds, making tetrahedrons.

silicon. The latter has been observed after ion-implantation [Tan et al., 1981] and hot indentation [Eremenko and Nikitenko, 1972].

When ordering silicon wafers, the crystal orientation must be specified. The most common orientations used in the IC industry are the  $\langle 100 \rangle$  and  $\langle 111 \rangle$  orientation; in micromachining,  $\langle 110 \rangle$  wafers are used quite often as well. The  $\langle 110 \rangle$  wafers break or cleave much more cleanly than other orientations. In fact, it is the only major plane that can be cleaved with exactly perpendicular edges. The  $\langle 111 \rangle$  wafers are used less, as they cannot be etched anisotropically except when using laser-assisted etching [Alavi et al., 1992]. On a  $\langle 100 \rangle$  wafer, the  $\langle 110 \rangle$  direction is often made evident by a flat segment, also called an orientation flat. The precision on the flat is about  $3^\circ$ . The position of the flat on  $\langle 110 \rangle$ -oriented wafers varies from manufacturer to manufacturer, but often parallels a  $\langle 111 \rangle$  direction. Flat areas help orientation determination, placement of slices in cassettes and fabrication equipment (large primary flat), and help identify orientation and conductivity type (smaller secondary flat; see Madou [1997, chap. 3, Si growth]). Primary and secondary flats on  $\langle 111 \rangle$  and  $\langle 100 \rangle$  silicon wafers are indicated in Figure 16.5.

**FIGURE 16.5** Primary and secondary flats on silicon wafers.

### 16.3.3 Geometric Relationships between Some Important Planes in the Silicon Lattice

To better appreciate the different three-dimensional shapes resulting from anisotropically etched single crystal Si (SCS) and to better understand the section further below on corner compensation, some of the more important geometric relationships between different planes within the Si lattice need further clarification. We will consider only silicon wafers with a (100) or a (110) as the surface planes. We will also accept, for now, that in anisotropic alkaline etchants the {111} planes, which have the highest atom-packing density, are nonetching compared to the other planes. As the {111} planes are essentially not attacked by the etchant, the sidewalls of an etched pit in SCS will ultimately be bounded by this type of plane, given that the etch time is long enough for features bounded by other planes to be etched away. The types of planes introduced initially depend on the geometry and the orientation of the mask features.

#### 16.3.3.1 [100]-Oriented Silicon

In Figure 16.6, the unity cell of a silicon lattice is shown together with the correct orientation of a [100]-type wafer relative to this cell [Peeters, 1994]. It can be seen from this figure that intersections of the nonetching {111} planes with the {100} planes (e.g., the wafer surface) are mutually perpendicular and lying along the  $\langle 110 \rangle$  orientations. Provided a mask opening (say, a rectangle or a square) is accurately aligned with the primary orientation flat, i.e., the [110] direction, only {111} planes will be introduced as sidewalls from the very beginning of the etch. Since the nonetching character of the {111} planes renders an exceptional degree of predictability to the recess features, this is the mask arrangement most often utilized in commercial applications. During etching, truncated pyramids (square mask) or truncated V-grooves (rectangular mask) deepen but do not widen (Figure 16.7). The edges in these structures are  $\langle 110 \rangle$  directions, the ribs are  $\langle 211 \rangle$  directions, the sidewalls are {111} planes and the bottom is a (100) plane parallel with the wafer surface. After prolonged etching, the {111} family of planes is exposed down to their common intersection and the (100) bottom plane disappears, creating a pyramidal pit (square mask) or a V-groove (rectangular mask) (Figure 16.7). As shown in Figure 16.7, no underetching of the

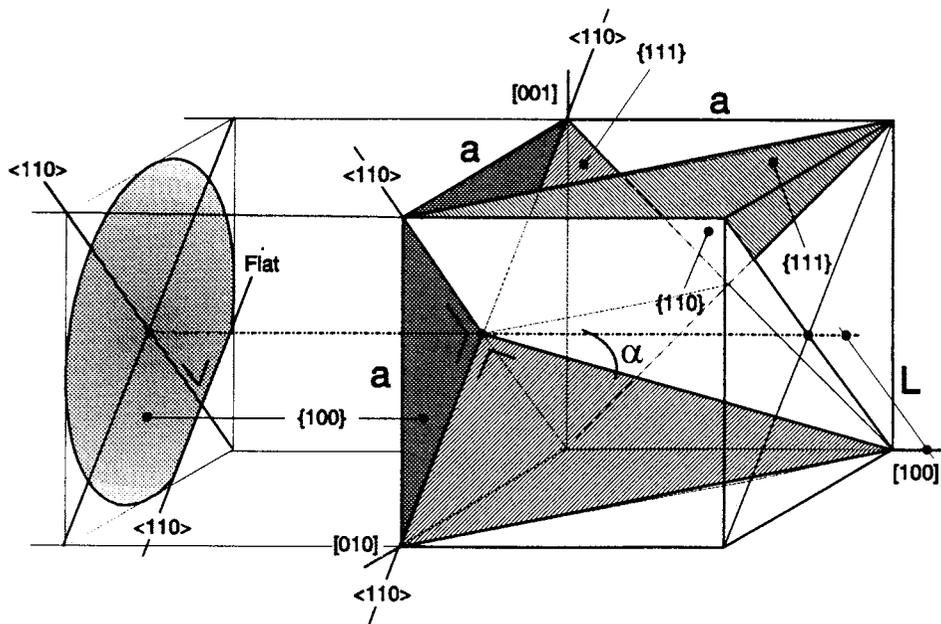

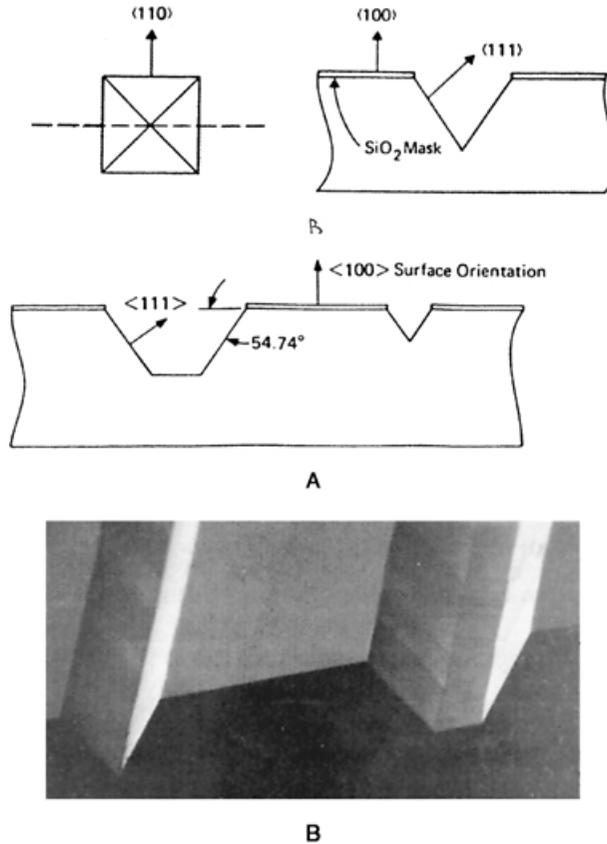

FIGURE 16.6 (100) silicon wafer with reference to the unity cube and its relevant planes. (From Peeters, E., *Process Development for 3D Silicon Microstructures with Application to Mechanical Sensor Design*, KUL, Belgium, 1994. With permission.)

**FIGURE 16.7** Anisotropically etched features in a (100) wafer with (A) Square mask (schematic) and (B) Rectangular mask (scanning electron microscope micrograph of resulting actual V- and U-grooves).

etch mask is observed, due to the perfect alignment of the concave oxide mask opening with the <110> direction. Misalignment still results in pyramidal pits, but the mask will be undercut. For a mask opening with arbitrary geometry and orientation (for example, a circle) and for sufficiently long etch times, the anisotropically etched recess in a {100} wafer is pyramidal with a base perfectly circumscribing the circular mask opening [Peeters, 1994]. Convex corners (>180°) in a mask opening will always be completely undercut by the etchant after sufficiently long etch times. This can be disadvantageous (for example, when attempting to create a mesa rather than a pit) or it can be advantageous for undercutting suspended cantilevers or bridges. In the section of this chapter on corner compensation, the issue of undercutting will be addressed in detail. The slope of the sidewalls in a cross section perpendicular to the wafer surface and to the wafer flat is determined by the angle  $\alpha$  as in Figure 16.6 depicting the off-normal angle of the intersection of a (111) sidewall and a (110) cross-cutting plane, and can be calculated from:

$$\tan \alpha = \frac{L}{a} \quad (16.1)$$

with  $L = a \times \frac{\sqrt{2}}{2}$  or  $\alpha = \arctan \frac{\sqrt{2}}{2} = 35.26^\circ$ , or  $54.74^\circ$  for the complementary angle. The tolerance on this slope is determined by the alignment accuracy of the wafer surface with respect to the (100) plane. Wafer manufacturers typically specify this misalignment to  $1^\circ$  ( $0.5^\circ$  in the best cases).

The width of the rectangular or square cavity bottom plane,  $W_0$ , in Figure 16.8, aligned with the <110> directions, is completely defined by the etch depth,  $z$ , the mask opening,  $W_m$ , and the above-calculated sidewall slope:

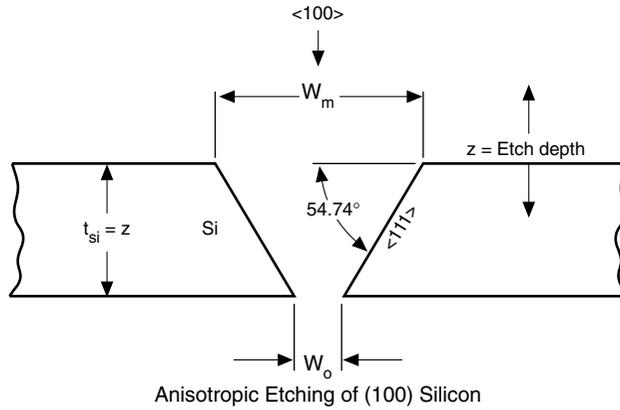

FIGURE 16.8 Relation of bottom cavity plane width with mask opening width.

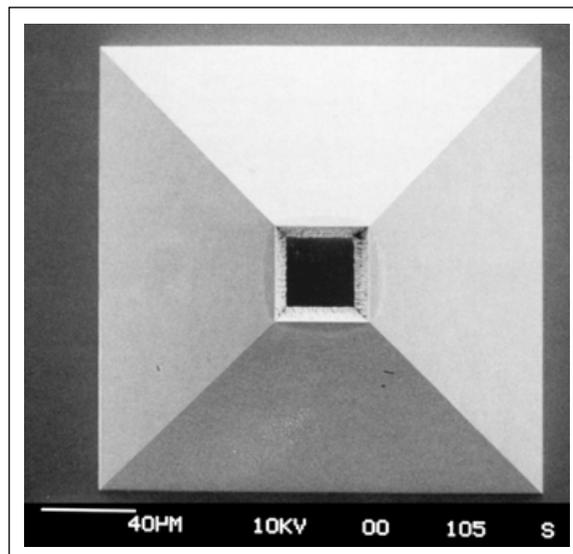

$$W_o = W_m - 2 \cotan(54.74^\circ) z$$

or

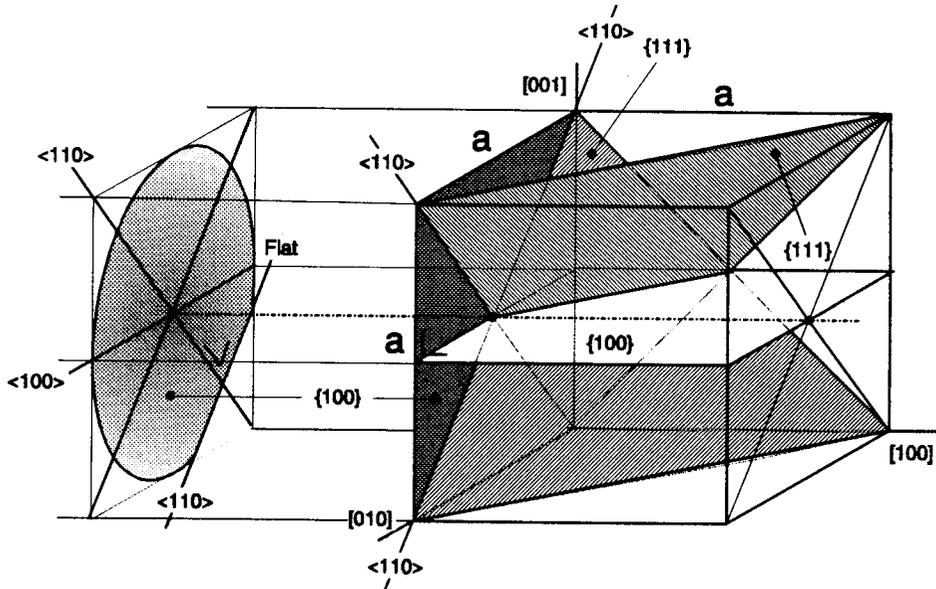

$$W_o = W_m - \sqrt{2} z \tag{16.2}$$

The larger the opening in the mask, the deeper the point at which the {111} sidewalls of the pit intersect. The etch stop at the {111} sidewalls' intersection occurs when the depth is about 0.7 times the mask opening. If the oxide opening is wide enough,  $W_m > 849 \mu\text{m}$  (for a typical 6-in. wafer with thickness  $t_{si} = z = 600 \mu\text{m}$ ), the {111} planes do not intersect within the wafer. The etched pit in this particular case extends all the way through the wafer, creating a **small orifice** or **via**. If a high density of such vias through the Si is required, the wafer must be made very thin.

Corners in an anisotropically etched recess are defined by the intersection of crystallographic planes, and the resulting corner radius is essentially zero. This implies that the size of a silicon diaphragm is very well defined, but it also introduces a considerable stress concentration factor. The influence of the zero corner radius on the yield load of diaphragms can be studied with finite element analysis (FEA).

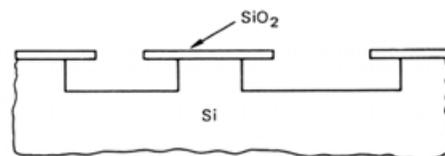

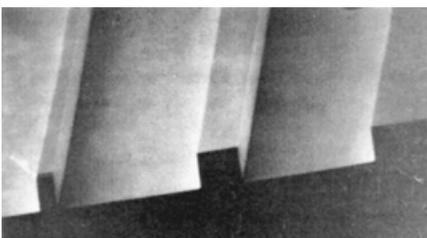

Orifice (A via through Si wafer).

**FIGURE 16.9** (100) silicon wafer with  $\langle 100 \rangle$  mask-aligned features introduces vertical sidewalls. (From Peeters, E., *Process Development for 3D Silicon Microstructures with Application to Mechanical Sensor Design*, KUL, Belgium, 1994. With permission.)

One way to obtain vertical sidewalls instead of  $54.7^\circ$  sidewalls using a [100]-oriented Si wafer is illustrated in Figure 16.9. It can be seen in this figure that there are {100} planes perpendicular to the wafer surface and that their intersections with the wafer surface are  $\langle 100 \rangle$  directions. These  $\langle 100 \rangle$  directions enclose a  $45^\circ$  angle with the wafer flat (i.e., the  $\langle 110 \rangle$  directions). By aligning the mask opening with these  $\langle 100 \rangle$  orientations, {100} facets are initially introduced as sidewalls. The {110} planes etch faster than the {100} planes and are not introduced. As the bottom and sidewall planes are all from the same {100} group, lateral underetch equals the vertical etch rate and rectangular channels, bounded by slower etching {100} planes, result (Figure 16.10). Since the top of the etched channels is exposed to the etchant longer than the bottom, one might have expected the channels in Figure 16.10 to be wider at the top than at the bottom. With some minor corrections in Peeters' derivation [Peeters, 1994], we can use his explanation for why the sidewalls stay vertical. Assume the width of the mask opening to be  $W_m$ . At a given depth,  $z$ , into the wafer, the underlying Si is no longer masked by  $W_m$ , but rather by the intersection of the previously formed {100} facets with the bottom surface. The width of this new mask is larger than the lithography mask  $W_m$  by the amount the latter is being undercut. Let's call the new mask width  $W_2$  the effective mask width at a depth  $z$ . The relation

**FIGURE 16.10** Vertical sidewalls in a (100) wafer.

between  $W_m$  and  $W_z$  is given by the lateral etch rate of a {100} facet and the time that facet was exposed to the etchant at depth  $z$ , i.e.:

$$W_z = W_m + 2R_{xy}\Delta t_z \quad (16.3)$$

where  $R_{xy}$  is the lateral underetch rate (i.e., etch rate in the x-y plane) and  $\Delta t_z$  the etch time at depth  $z$ . The underetching,  $U_z$ , of the effective mask opening  $W_z$  is given by:

$$U_z = TR_{xy} - R_{xy}\Delta t_z \quad (16.4)$$

where  $T$  is the total etch time so far. The width of the etched pit,  $W_{tot}$ , at depth  $z$  is further given by the sum of  $W_m$  and twice the underetching for that depth:

$$W_{tot} = W_z + 2U_z = W_m + 2TR_{xy} \quad (16.5)$$

Or, since  $T$  can also be written as the measured total etch depth  $z$  divided by the vertical etch rate  $R_z$ , Eq. (16.5) can be rewritten as

$$\begin{aligned} W_{tot} &= W_m + 2z(R_{xy}/R_z) \quad \text{or since } R_{xy} = R_z, \\ W_{tot} &= W_m + 2z \end{aligned} \quad (16.6)$$

The width of the etched recess is therefore equal to the photolithographic mask width plus twice the etch depth—independent of that etch depth, in other words; the walls remain vertical independent of the depth  $z$ .

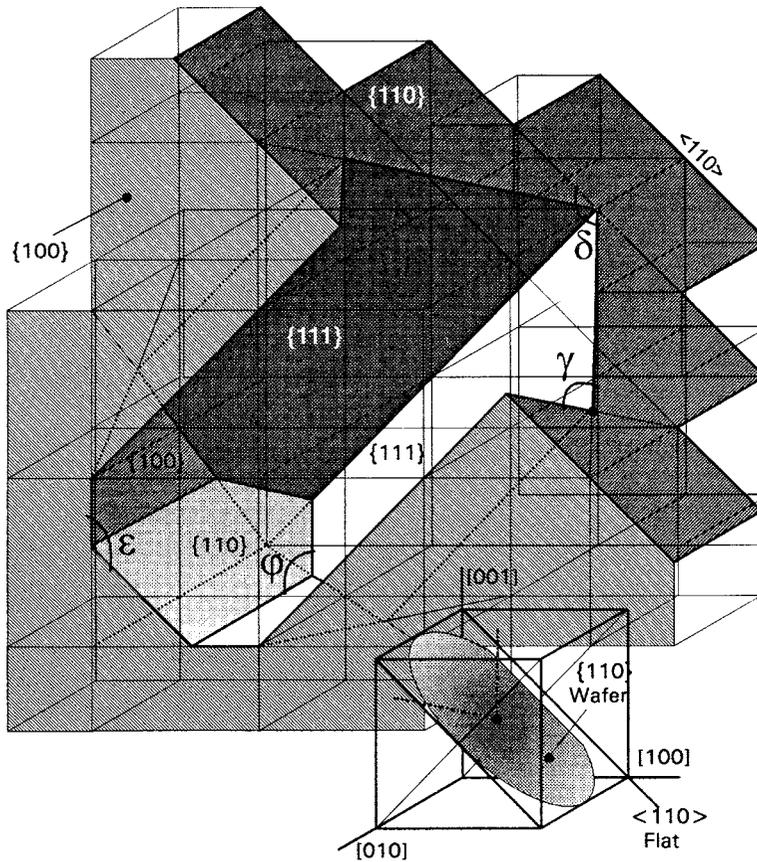

For sufficiently long etch times, {111} facets take over eventually from the vertical {100} facets. These inward sloping {111} facets are first introduced at the corners of a rectangular mask and grow larger at the expense of the vertical sidewalls until the latter ultimately disappear altogether. Alignment of mask features with the <100> directions in order to obtain vertical sidewalls in {100} wafers, therefore, is not very useful for the fabrication of diaphragms. However, it can be very effective for anticipating the undercutting of convex corners on {100} wafers. This useful aspect will be revisited when discussing corner compensation.

### 16.3.3.2 [110]-Oriented Silicon

In [Figure 16.11](#), we show a unit cell of Si properly aligned with the surface of a (110) Si wafer. This drawing will enable us to predict the shape of an anisotropically etched recess on the basis of elementary geometric crystallography. Whereas the intersections of the {111} planes with the (100) wafer surface are mutually perpendicular, here they enclose an angle  $\gamma$  in the (110) plane. Moreover, the intersections are not parallel (<110>) or perpendicular (<100>) to the main wafer flat (assumed to be <110> in this case), but rather enclose angles  $\delta$  or  $\delta + \gamma$ . It follows that a mask opening that will not be undercut (i.e., oriented such that resulting feature sidewalls are exclusively made up by {111} planes) cannot be a rectangle aligned with the flat, but must be a parallelogram skewed by  $\gamma - 90^\circ$  and  $\delta$  degrees off-axis. The angles  $\gamma$  and  $\delta$  are calculated as follows [[Peeters, 1994](#)] (see [Figures 16.11](#) and [16.12](#)):

$$\tan \beta = \frac{\frac{1}{2}a\frac{\sqrt{2}}{2}}{\frac{a}{2}} = \frac{\sqrt{2}}{2} \quad (16.7)$$

**FIGURE 16.12** (110) silicon wafer with anisotropically etched recess inscribed in the Si lattice.  $\gamma = 109.47^\circ$ ;  $\delta = 125.26^\circ$ ;  $\phi = 144.74^\circ$ ; and  $\epsilon = 45^\circ$ . (From Peeters, E., *Process Development for 3D Silicon Microstructures with Application to Mechanical Sensor Design*, KUL, Belgium, 1994. With permission.)

to understand corner compensation schemes (see below). Moreover, all processes for providing dielectric isolation require that the silicon be separated into discrete regions. To achieve a high component density with anisotropic etches on (100) wafers, the silicon must be made very thin because of the aspect ratio limitations due to the sloping walls (see above). With vertical sidewall etching in a (100) wafer, the etch mask is undercut in all directions to a distance approximately equal to the depth of the etching. Vertical etching in (110) surfaces relaxes the etching requirement dramatically and enables more densely packed

**TABLE 16.1** Selection of Wafer Type

[100] Orientation	[110] Orientation
Inward sloping walls ( $54.74^\circ$ )	Vertical {111} walls
The sloping walls cause a lot of lost real estate	Narrow trenches with high aspect ratio are possible
Flat bottom parallel to surface is ideal for membrane fabrication	Multifaceted cavity bottom ({110} and {100} planes) makes for a poor diaphragm
Bridges perpendicular to a V-groove bound by (111) planes cannot be underetched	Bridges perpendicular to a V-groove bound by (111) planes can be undercut
Shape and orientation of diaphragms convenient and simple to design	Shape and orientation of diaphragms awkward and more difficult to design
Diaphragm size, bounded by nonetching {111} planes, is relatively easy to control	Diaphragm size is difficult to control; the <100> edges are not defined by nonetching planes

structures such as beam leads or image sensors. Kendall describes and predicts a wide variety of applications for (110) wafers such as fabrication of trench capacitors, vertical multi-junction solar cells, diffraction gratings, infrared interference filters, large area cathodes and filters for bacteria [Kendall, 1975; 1979].

## 16.4 Silicon as a Substrate and Structural Material

---

### 16.4.1 Silicon as Substrate

For many mechanical sensor applications, single crystal Si, based on its intrinsic mechanical stability and the feasibility of integrating sensing and electronics on the same substrate, often presents an excellent substrate choice. For chemical sensors, on the other hand, Si, with few exceptions,<sup>2</sup> is merely the substrate and the choice is not always that straightforward.

In Table 16.2, we show a performance comparison of substrate materials in terms of cost, metallization ease and machinability. Both ceramic and glass substrates are difficult to machine, and plastic substrates are not readily amenable to metallization. Silicon has the highest material cost per unit area, but this cost often can be offset by the small feature sizes possible in a silicon implementation. Si with or without passivating layers, due to its extreme flatness, relative low cost and well-established coating procedures, often is the preferred substrate especially for thin films. A lot of thin-film deposition equipment is built to accommodate Si wafers and, as other substrates are harder to accommodate, this lends Si a convenience advantage. There is also a greater flexibility in design and manufacturing with silicon technology compared to other substrates. In addition, although much more expensive, the initial capital equipment investment is not product specific. Once a first product is on line, a next generation or new products will require changes in masks and process steps but not in the equipment itself.

Disadvantages of using Si usually are most pronounced with increasing device size and low production volumes and when electronics do not need or cannot be incorporated on the same Si substrate. The latter could be either for cost reasons (e.g., in the case of disposables such as glucose sensors) or for technological reasons (e.g., the devices will be immersed in conductive liquids or they must operate at temperatures above 150°C).

An overwhelming determining factor for substrate choice is the final package of the device. A chemical sensor on an insulating substrate almost always is easier to package than a piece of Si with conductive edges in need of insulation.

Sensor packaging is so important in sensors that as a rule sensor design should start from the package rather than from the sensor. In this context, an easier to package substrate has a huge advantage. The latter is the most important reason why recent chemical sensor development in industry has retrenched from a move toward integration on silicon in the 1970s and early 1980s to a hybrid thick film on ceramic approach in the late 1980s and early 1990s. In academic circles in the U.S. chemical sensor integration with electronics continued until the late 1980s; in Europe and Japan, such efforts are still going on [Madou, 1994].

TABLE 16.2 Performance Comparison of Substrate Materials

Substrate	Cost	Metallization	Machinability
Ceramic	Medium	Fair	Poor
Plastic	Low	Poor	Fair
Silicon	High	Good	Very good
Glass	Low	Good	Poor

---

<sup>2</sup>A notable exception is the ion-sensitive field effect transistor (ISFET) where the Si space charge is modulated by the presence of chemicals for which the ISFET chemical coating is sensitive [Madou, 1997, chap. 10].

## 16.4.2 Silicon as a Structural Element in Mechanical Sensors

### 16.4.2.1 Introduction

In mechanical sensors the active structural elements convert a mechanical external input signal (force, pressure, acceleration etc.) into an electrical signal output (voltage, current or frequency). The transfer functions in mechanical devices describing this conversion are mechanical, electro-mechanical and electrical.

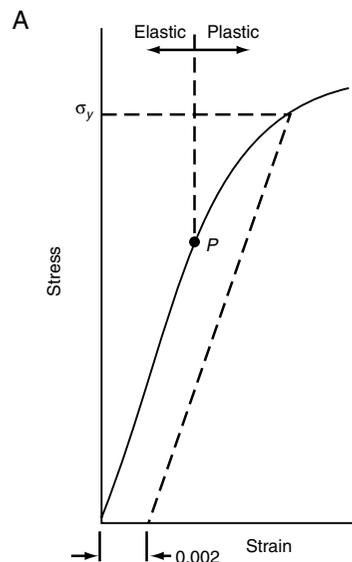

In the mechanical conversion, a given external load is concentrated and maximized in the active member of the sensor. Structurally active members are typically high-aspect-ratio elements such as suspended beams or membranes. The electromechanical conversion is the transformation of the mechanical quantity into an electrical quantity such as capacitance, resistance, charge etc. Often the electrical signal needs further electrical conversion into an output voltage, frequency or current. For electrical conversion into an output voltage, a Wheatstone bridge may be used as in the case of a piezoresistive sensor, and a charge amplifier may be used in the case of a piezoelectric sensor. To optimize all three transfer functions, detailed electrical and mechanical modeling is required. One of the most important inputs required for the mechanical models are the experimentally determined independent elasticity constants or moduli. In what follows, we describe what makes Si such an important structural element in mechanical sensors and present its elasticity constants.

### 16.4.2.2 Important Characteristics of Mechanical Structural Elements: Stress-Strain Curve and Elasticity Constants

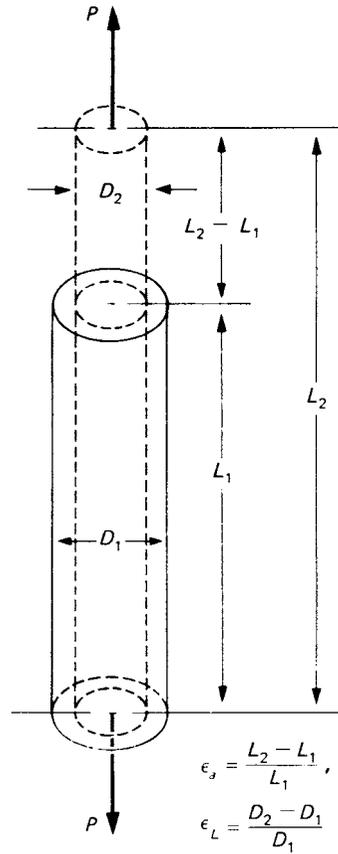

Yield, tensile strength, hardness and creep of a material all relate to the elasticity curve, i.e., the stress-strain diagram of the material as shown in Figure 16.13. For small strain values, Hooke's law applies, i.e., stress (force per unit area,  $\text{N/m}^2$ ) and strain (displacement per unit length, dimensionless) are proportional and the stress-strain curve is linear, with a slope corresponding to the elastic modulus  $E$  (Young's modulus- $\text{N/m}^2$ ). This regime as in Figure 16.13 is marked as the elastic deformation regime. For isotropic media such as amorphous and polycrystalline materials, the applied axial force per unit area or tensile stress,  $\sigma_a$ , and the axial or tensile strain,  $\epsilon_a$ , are thus related as:

$$\sigma_a = E\epsilon_a \quad (16.9)$$

with  $\epsilon_a$  given by the dimensionless ratio of  $L_2 - L_1/L_1$ , i.e., the ratio of the wire's elongation to its original length. The elastic modulus may be thought of as stiffness or a material's resistance to elastic deformation.

**FIGURE 16.13** Typical stress-strain behavior for a material showing elastic and plastic deformations, the proportional limit  $P$  and the yield strength  $\sigma_y$ , as determined using the 0.002 strain offset method (see text).

**FIGURE 16.14** Metal wire under axial or normal stress; normal stress creates both elongation and lateral contraction.

The greater the modulus, the stiffer the material. A tensile stress usually also leads to a lateral strain or contraction (Poisson effect),  $\epsilon_l$ , given by the dimensionless ratio of  $D_2 - D_1/D_1$  ( $\Delta D/D_1$ ), where  $D_1$  is the original wire diameter and  $\Delta D$  is the change in diameter under axial stress (see Figure 16.14). The Poisson ratio is the ratio of lateral over axial strain:

$$\nu = -\frac{\epsilon_l}{\epsilon_s} \tag{16.10}$$

The minus sign indicates a contraction of the material. For most materials,  $\nu$  is a constant within the elastic range. Normally, some slight volume change does accompany the deformation, and, consequently,  $\nu$  is smaller than 0.5. The magnitude of the Young's modulus ranges from  $4.1 \times 10^4$  MPa (the  $\text{N/m}^2$  unit is called the Pascal, Pa) for magnesium, to  $40.7 \times 10^4$  MPa for tungsten and 144 GPa for Invar. With increasing temperature, the elastic modulus diminishes. The Poisson ratios for aluminum and cast steel are 0.34 and 0.28, respectively. The value of  $\nu$  fluctuates for different materials over a relatively narrow range. Generally, it is on the order of 0.25 to 0.35. In extreme cases, values as low as 0.1 (certain types of concrete) and as high as 0.5 (rubber) occur. A value of 0.5 is the largest value possible. It is attained by materials during plastic flow and indicates a constant volume. For an elastic isotropic medium subjected to a triaxial state of stress, the resulting strain component in the  $x$  direction,  $\epsilon_x$ , is given by the summation of elongation and contraction:

$$\epsilon_x = \frac{1}{E}[\sigma_x - \nu(\sigma_y + \sigma_z)] \tag{16.11}$$

and so on for the  $y$  and  $z$  directions (three equations in total).

For an analysis of mechanical structures we must consider not only compressional and tensile strains but also shear strains. Whereas normal stresses create elongation plus lateral contraction with accompanying volume changes, shear stresses (e.g., by twisting a body) create shape changes without volume changes, i.e., shear strains. The one-dimensional shear strain,  $\gamma$ , is produced by the shear stress,  $\tau$  ( $\text{N/m}^2$ ). For small strains, Hooke's law may be applied again:

$$\gamma = \frac{\tau}{G} \quad (16.12)$$

where  $G$  is called the elastic shear modulus or the modulus of rigidity. For any three-dimensional state of shear stress, three equations of this type will hold. Isotropic bodies are characterized by two independent elastic constants only, since the shear modulus  $G$ , as can be shown [Chou and Pagano, 1967], relates the Young's modulus and the Poisson ratio as:

$$G = \frac{E}{2(1 + \nu)} \quad (16.13)$$

Crystal materials, whose elastic properties are anisotropic, require more than two elastic constants, the number increasing with decreasing symmetry. Cubic crystals (bcc, fcc), for example, require 3 elastic constants, hexagonal crystals require 5, and materials without symmetry require 21 [Kittel, 1976; Chou and Pagano, 1967]. The relation between stresses and strains is more complex in this case and depends greatly on the spatial orientation of these quantities with respect to the crystallographic axes. Hooke's law in the most generic form is expressed in two formulas:

$$\sigma_{ij} = E_{ijkl} \cdot \epsilon_{kl} \quad \text{and} \quad \epsilon_{ij} = S_{ijkl} \cdot \sigma_{kl} \quad (16.14)$$

where  $\sigma_{ij}$  and  $\sigma_{kl}$  are stress tensors of rank 2 expressed in  $\text{N/m}^2$ ;  $\epsilon_{ij}$  and  $\epsilon_{kl}$  are strain tensors of rank 2 and are dimensionless;  $E_{ijkl}$  is a stiffness coefficient tensor of rank 4 expressed in  $\text{N/m}^2$ ; and  $S_{ijkl}$  is a compliance coefficient tensor of rank 4 expressed in  $\text{m}^2/\text{N}$ . The first expression is analogous to Eq. (16.9) and the second expression is the inverse, giving the strains in terms of stresses. The tensor representations in Eq. (16.14) can also be represented as two matrices:

$$\sigma_m = \sum_{n=1}^6 E_{mn} \epsilon_n \quad \text{and} \quad \epsilon_m = \sum_{n=1}^6 S_{mn} \sigma_n \quad (16.15)$$

Components of tensors  $E_{ijkl}$  and  $S_{ijkl}$  are substituted by elements of the matrices  $E_{mn}$  and  $S_{mn}$ , respectively. To convert the  $ij$  indices to  $m$  and the  $kl$  indices to  $n$ , the following scheme applies:

$$\begin{aligned} 11 \rightarrow 1, 22 \rightarrow 2, 33 \rightarrow 3, 23 \text{ and } 32 \rightarrow 4, 13 \text{ and} \\ 31 \rightarrow 5, 12 \text{ and } 21 \rightarrow 6, E_{ijkl} \rightarrow E_{mn} \text{ and } S_{ijkl} \rightarrow S_{mn} \\ \text{when } m \text{ and } n = 1, 2, 3; 2 S_{ijkl} \rightarrow S_{mn} \text{ when } m \text{ or } n = \\ 4, 5, 6; 4 S_{ijkl} \rightarrow S_{mn} \text{ when } m \text{ and } n = 4, 5, 6; \sigma_{ij} \rightarrow \\ \sigma_m \text{ when } m = 1, 2, 3; \text{ and } \epsilon_{ij} \rightarrow \epsilon_m \text{ when } m = 4, 5, 6 \end{aligned}$$

With these reduced indices there are thus six equations of the type:

$$\sigma_x = E_{11}\epsilon_x + E_{12}\epsilon_y + E_{13}\epsilon_z + E_{14}\gamma_{yz} + E_{15}\gamma_{zx} + E_{16}\gamma_{xy} \quad (16.16)$$

and hence 36 moduli of elasticity or  $E_{mn}$  stiffness constants. There are also six equations of the type:

$$\epsilon_x = S_{11}\sigma_x + S_{12}\sigma_y + S_{13}\sigma_z + S_{14}\tau_{yz} + S_{15}\tau_{zx} + S_{16}\tau_{xy} \quad (16.17)$$

defining 36  $S_{mn}$  constants which are called the compliance constants; see also Madou (1997, Eq. (9.29)). It can be shown that the matrices  $E_{mn}$  and  $S_{mn}$ , each composed of 36 coefficients, are symmetrical; hence, a material without symmetry elements has 21 independent constants or moduli. Due to symmetry of crystals, several more of these may vanish until, for our isotropic medium, they number two only ( $E$  and  $\nu$ ). The stiffness coefficient and compliance coefficient matrices for cubic-lattice crystals with the vector of stress oriented along the [100] axis are given as:

$$E_{mn} = \begin{bmatrix} E_{11} & E_{12} & E_{12} & 0 & 0 & 0 \\ E_{12} & E_{11} & E_{12} & 0 & 0 & 0 \\ E_{12} & E_{12} & E_{11} & 0 & 0 & 0 \\ 0 & 0 & 0 & E_{44} & 0 & 0 \\ 0 & 0 & 0 & 0 & E_{44} & 0 \\ 0 & 0 & 0 & 0 & 0 & E_{44} \end{bmatrix} \quad S_{mn} = \begin{bmatrix} S_{11} & S_{12} & S_{12} & 0 & 0 & 0 \\ S_{12} & S_{11} & S_{12} & 0 & 0 & 0 \\ S_{12} & S_{12} & S_{11} & 0 & 0 & 0 \\ 0 & 0 & 0 & S_{44} & 0 & 0 \\ 0 & 0 & 0 & 0 & S_{44} & 0 \\ 0 & 0 & 0 & 0 & 0 & S_{44} \end{bmatrix} \quad (16.18)$$

In cubic crystals, the three remaining independent elastic moduli are usually chosen as  $E_{11}$ ,  $E_{12}$  and  $E_{44}$ . The  $S_{mn}$  values can be calculated simply from these  $E_{mn}$  values. Expressed in terms of the compliance constants, one can show that  $1/S_{11} = E = \text{Young's modulus}$ ,  $-S_{12}/S_{11} = \nu = \text{Poisson's ratio}$ , and  $1/S_{44} = G = \text{shear modulus}$ . In the case of an isotropic material, such as a metal wire, there is an additional relationship:

$$E_{44} = \frac{E_{11} - E_{12}}{2} \quad (16.19)$$

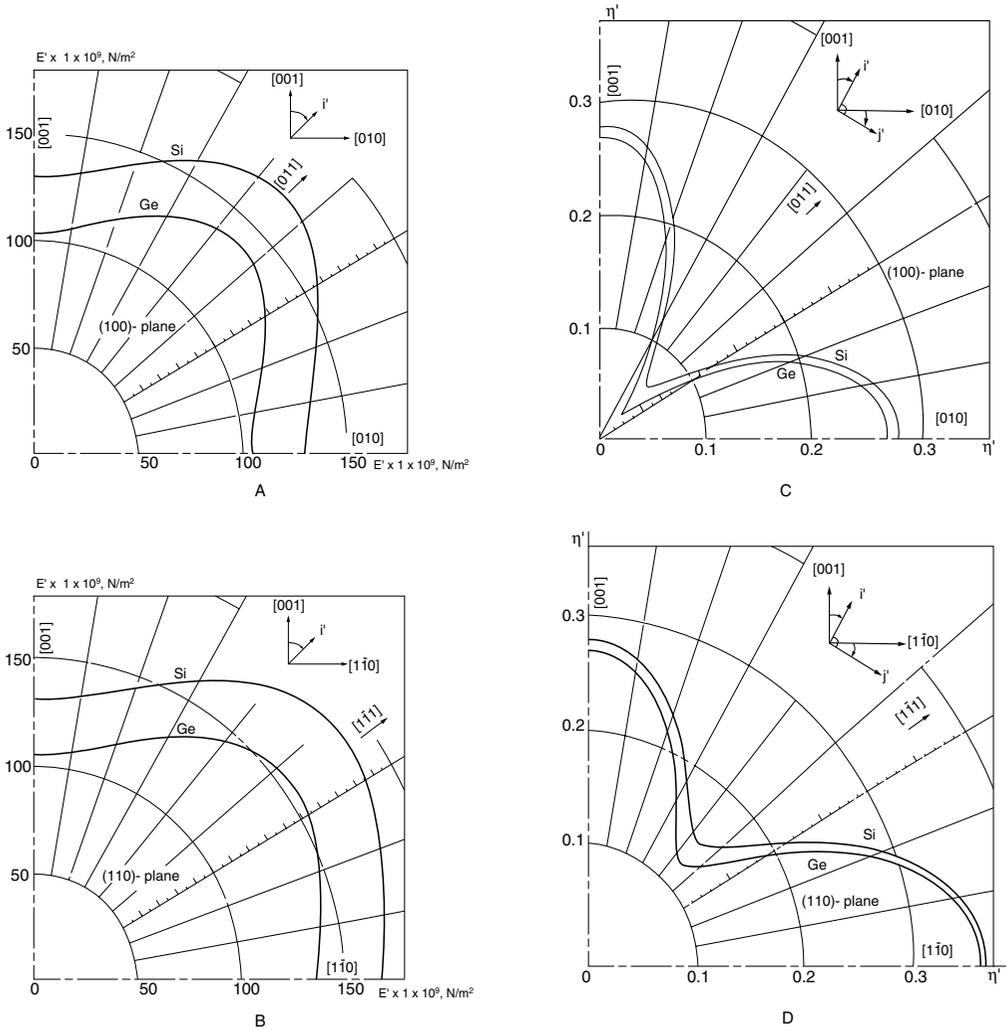

reducing the number of independent stiffness constants to two. The anisotropy coefficient  $\alpha$  is defined as:

$$\alpha = \frac{2E_{44}}{E_{11} - E_{12}} \quad (16.20)$$

making  $\alpha = 1$  for an isotropic crystal. For an anisotropic crystal, the degree of anisotropy is given by the deviation of  $\alpha$  from 1. Single crystal silicon has moderately anisotropic elastic properties [Brantley, 1973; Nikanorov et al., 1972], with  $\alpha = 1.57$ . Brantley (1973) gives the non-zero stiffness components, referred to the [100] crystal orientation as:  $E_{11} = E_{22} = E_{33} = 166 \times 10^9 \text{ N/m}^2$ ,  $E_{12} = E_{13} = E_{23} = 64 \times 10^9 \text{ N/m}^2$  and  $E_{44} = E_{55} = E_{66} = 80 \times 10^9 \text{ N/m}^2$ :

$$\begin{array}{l} \sigma_x \\ \sigma_y \\ \sigma_z \\ \tau_{xy} \\ \tau_{xz} \\ \tau_{yz} \end{array} = \begin{array}{c} \left| \begin{array}{cccccc} 166(E_{11}) & 64(E_{12}) & 64(E_{12}) & 0 & 0 & 0 \\ 64(E_{12}) & 166(E_{11}) & 64(E_{12}) & 0 & 0 & 0 \\ 64(E_{12}) & 64(E_{12}) & 166(E_{11}) & 0 & 0 & 0 \\ 0 & 0 & 0 & 80(E_{44}) & 0 & 0 \\ 0 & 0 & 0 & 0 & 80(E_{44}) & 0 \\ 0 & 0 & 0 & 0 & 0 & 80(E_{44}) \end{array} \right. \\ \times \end{array} \begin{array}{l} \epsilon_x \\ \epsilon_y \\ \epsilon_z \\ \gamma_{xy} \\ \gamma_{xz} \\ \gamma_{yz} \end{array} \quad (16.21)$$

with  $\sigma$  normal stress,  $\tau$  shear stress,  $\epsilon$  normal strain and  $\gamma$  shear strain. The values for  $E_{mn}$ , in Eq. (16.21), compare with a Young's modulus of 207 GPa for a low carbon steel. Variations on the values of the elastic constants on the order of 30%, depending on crystal orientation, must be considered; doping level (see below) and dislocation density have minor effects as well. From the stiffness coefficients the compliance coefficients of Si can be calculated as  $S_{11} = 7.68 \times 10^{-12} \text{ m}^2/\text{N}$ ,  $S_{12} = -2.14 \times 10^{-12} \text{ m}^2/\text{N}$ , and  $S_{44} = 12.6 \times 10^{-12} \text{ m}^2/\text{N}$  [Khazan, 1994]. A graphical representation of elastic constants

**FIGURE 16.15** Elasticity constants for Si and Ge. (A) Young's modulus as a function of direction in the (100) plane. (B) Young's modulus as a function of direction in the (110) plane. (C) Poisson ratio as a function of direction in the (100) plane. (D) Poisson's ratio as a function of direction in the (110) plane. (From Worthman, J. J. and R. A. Evans, *J. Appl. Phys.*, 36, 153–156, 1965. With permission.)

for different crystallographic directions in Si and Ge is given in Worthman and Evans (1965) and is reproduced in Figure 16.15. Figure 16.15A to D displays  $E$  and  $\nu$  for Ge and Si in planes (100) and (110) as functions of direction. Calculations show that  $E$ ,  $G$  and  $\nu$  are constant for any direction in the (111) plane. In other words, a plate lying in this plane can be considered as having isotropic elastic properties. A review of independent determinations of the Si stiffness coefficients, with their respective temperature coefficients, is given in Metzger and Kessler (1970). Some of the values from that review are reproduced in Table 16.3. Values for Young's modulus and the shear modulus of Si can also be found in Greenwood (1988) and are reproduced in Table 16.4 for the three technically important crystal orientations.

### 16.4.2.3 Residual Stress

Most properties, such as the Young's modulus, for lightly and highly doped silicon are identical. From Section 16.10 on, we will see that the Young's modulus for polycrystalline silicon is about 161 GPa.

**TABLE 16.3** Stiffness Coefficients and Temperature Coefficient of Stiffness for Si [Metzger and Kessler, 1970]

Stiffness Coefficients (GPa = $10^9$ N/m <sup>2</sup> )	Temperature Coefficient of Stiffness ( $\delta E/\delta T/E$ )
$E_{11} = 164.8 \pm 0.16$	$-122 \times 10^{-6}$
$E_{12} = 63.5 \pm 0.3$	$-162 \times 10^{-6}$
$E_{44} = 79.0 \pm 0.06$	$-97 \times 10^{-6}$

**TABLE 16.4** Derived Values for Young's Modulus and Shear Modulus for Si [Greenwood, 1988]

Miller Index for Orientation	Young's Modulus (E) (GPa)	Shear Modulus (G) (GPa)
[100]	129.5	79.0
[110]	168.0	61.7
[111]	186.5	57.5

Residual stress and associated stress gradients in highly boron doped single crystal silicon present some controversy. Highly boron-doped membranes, which are usually reported to be tensile, also have been reported compressive [Huff and Schmidt, 1992; Maseeh and Senturia, 1990]. From a simple atom-radius argument, one expects that a large number of substitutional boron atoms would create a net shrinkage of the lattice compared to pure silicon and that the residual stress would be tensile with a stress gradient corresponding to the doping gradient. That is, an etched cantilever would be expected to bend up out of the plane of the silicon wafer. Maseeh and Santuria (1990) believe that the appearance of compressive behavior in heavily boron-doped single crystal layers results from the use of an oxide etch mask. They suggest that plastic deformation of the  $p^+$  silicon beneath the compressively stressed oxide can explain the observed behavior. Ding and Ko (1991), who also found compressive behavior for nitride-covered  $p^+$  Si thin membranes, believe that the average stress in  $p^+$  silicon is indeed tensile, but great care is required to establish this fact because the combination of heavy boron doping and a high-temperature drive-in under oxidizing conditions can create an apparent reversal of both the net stress (to compressive) and of the stress gradient (opposite to the doping gradient). A proposed explanation is that at the oxide-silicon interface, a thin compressively stressed layer is formed during the drive-in which is not removed in buffered HF. It can be removed by reoxidation and etching in HF, or by etching in KOH.

#### 16.4.2.4 Yield, Tensile Strength, Hardness and Creep

As a material is deformed beyond its elasticity limit, yielding or plastic deformation—permanent, non-recoverable deformation—occurs. The point of yielding in Figure 16.13 is the point of initial departure from linearity of the stress–strain curve and is sometimes called the proportional limit indicated by a letter “P.” The Young’s modulus of mild steel is  $\pm 30,000,000$  psi,<sup>3</sup> and its proportional limit (highest stress in the elastic range) is approximately 30,000 psi. Thus, the maximum elastic strain in mild steel is about 0.001 under a condition of uniaxial stress. This gives an idea as to the magnitude of the strains we are dealing with. A convention has been established wherein a straight line is constructed parallel to the elastic portion of the stress–strain curve at some specified strain offset, usually 0.002. The stress corresponding to the intersection of this line and the stress–strain curve as it bends over in the plastic region is defined as the yield strength,  $\sigma_y$  (see Figure 16.13). The magnitude of the yield strength of a material

<sup>3</sup>In the sensor area it is still mandatory to be versatile in the different unit systems especially with regards to expressing units for quantities such as pressure and stress. In this book we are using mostly Pascal, Pa (=N/m<sup>2</sup>), but in industry it is still customary to use psi when dealing with metal properties, torr when dealing with vacuum systems, and dyne/cm<sup>2</sup> when dealing with surface tension.

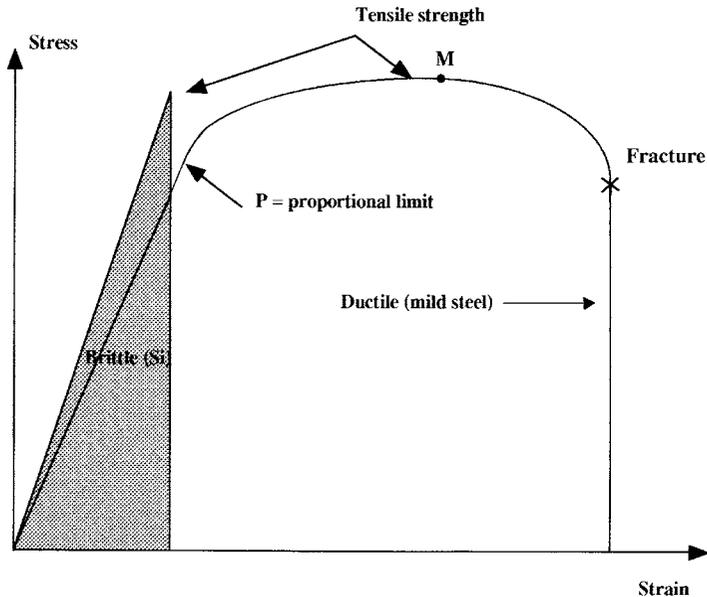

FIGURE 16.16 Stress–strain curve. Tensile strength of a metal is the stress at the maximum of this curve. Abrupt brittle fracture of a high modulus material with no plastic deformation region like Si is indicated as well.

is a measure of its resistance to plastic deformation. Yield strengths may range from 35 MPa (5000 psi) for a soft and weak aluminum to over 1400 MPa (200,000 psi) for high strength steels. The tensile strength is the stress at the maximum of the stress–strain curve (Figure 16.16). This corresponds to the maximum stress that can be sustained by a structure in tension; if the stress is applied and maintained, fracture will result. Both tensile strength and hardness are indicators of a metal’s resistance to plastic deformation. Consequently, they are roughly proportional [Callister, 1985]. Material deformation occurring at elevated temperatures and static material stresses is termed creep. It is defined as a time-dependent and permanent deformation of materials when subjected to a constant load or stress.

Silicon exhibits no plastic deformation or creep below 800°C; therefore, Si sensors are inherently very insensitive to fatigue failure when subjected to high cyclic loads. Silicon sensors have actually been cycled in excess of 100 million cycles with no observed failures. This ability to survive a very large number of duty cycles is due to the fact that there is no energy absorbing or heat generating mechanism due to intergranular slip or movement of dislocations in silicon at room temperature. However, single crystal Si, as a brittle material, will yield catastrophically, when stress beyond the yield limit is applied, rather than deform plastically as metals do (see Figure 16.16). At room temperature, high modulus materials such as Si, SiO<sub>2</sub> and Si<sub>3</sub>N<sub>4</sub> often exhibit linear-elastic behavior at lower strain and transition abruptly to brittle–fracture behavior at higher strain. Plastic deformation in metals is based on stress-induced dislocation generation in the grain boundaries and a subsequent dislocation migration that results in a macroscopic deformation from inter-grain shifts in the material. No grain boundaries exist in single crystal silicon (SCS), and plastic deformation can only occur through migration of the defects originally present in the lattice or of those that are generated at the surface. As the number of these defects is very low in SCS, the material can be considered a perfect elastic material at normal temperatures. Perfect elasticity implies proportionality between stress and strain (i.e., load and flexure) and the absence of irreversibilities or mechanical hysteresis. The absence of plastic behavior also accounts for the extremely low mechanical losses in SCS, which enable the fabrication of resonating structures that exhibit exceptionally high Q-factors. Values of up to 10<sup>8</sup> in vacuum have been reported. At elevated temperatures, and with metals and polymers at ordinary temperatures, complex behavior in the stress–strain curve can occur. Considerable plasticity can be induced in SCS at elevated temperatures (>800°C), when the mobility of defects in the

lattice is substantially increased. Huff and Schmidt (1992) actually report a pressure switch exhibiting hysteresis based on buckling of plastically deformed silicon membranes. To eliminate plastic deformation of Si wafers, it is important that during high temperature steps the presence of films that could stress or even warp the wafer in an asymmetric way, typically oxides or nitrides, be avoided.

#### 16.4.2.5 Piezoresistivity in Silicon

Piezoresistance is the fractional change in bulk resistivity induced by small mechanical stresses applied to a material. Most materials exhibit piezoresistivity, but the effect is particularly important in some semiconductors (more than an order of magnitude higher than that of metals). Monocrystalline silicon has a high piezoresistivity and, combined with its excellent mechanical and electronic properties, makes a superb material for the conversion of mechanical deformation into an electrical signal. Actually, the history of silicon-based sensors started with the discovery of the piezoresistance effect in Si and Ge more than four decades ago [Smith, 1954]. The two main classes of piezoresistive sensors are membrane-type structures (typically pressure and flow sensors) and cantilever beams (typically acceleration sensors) with in-diffused resistors (boron, arsenic or phosphorus) strategically placed in zones of maximum stress.

For a three-dimensional anisotropic crystal, the electrical field vector ( $E$ ) is related to the current vector ( $i$ ) by a 3-by-3 resistivity tensor [Khazan, 1994]. Experimentally the nine coefficients are always found to reduce to six, and the symmetric tensor is given by:

$$\begin{bmatrix} E_1 \\ E_2 \\ E_3 \end{bmatrix} = \begin{bmatrix} \rho_1 & \rho_6 & \rho_5 \\ \rho_6 & \rho_2 & \rho_4 \\ \rho_5 & \rho_4 & \rho_3 \end{bmatrix} \cdot \begin{bmatrix} i_1 \\ i_2 \\ i_3 \end{bmatrix} \quad (16.22)$$

For the cubic Si lattice, with the axes aligned with the  $\langle 100 \rangle$  axes,  $\rho_1$ ,  $\rho_2$  and  $\rho_3$  define the dependence of the electric field on the current along the same direction (one of the  $\langle 100 \rangle$  directions);  $\rho_4$ ,  $\rho_5$  and  $\rho_6$  are cross-resistivities, relating the electric field to the current along a perpendicular direction.

The six resistivity components in Eq. (16.22) depend on the normal ( $\sigma$ ) and shear ( $\tau$ ) stresses in the material as defined in the preceding section. Smith (1954) was the first to measure the resistivity coefficients  $\pi_{11}$ ,  $\pi_{12}$  and  $\pi_{44}$  for Si at room temperature. Table 16.5 lists Smith's results [Smith, 1954]. The piezoresistance coefficients are largest for  $\pi_{11}$  in n-type silicon and  $\pi_{44}$  in p-type silicon, about  $-102.10^{-11}$  and  $138.10^{-11} \text{ Pa}^{-1}$ , respectively.

Resistance change can now be calculated as a function of the membrane or cantilever beam stress. The contribution to resistance changes from stresses that are longitudinal ( $\sigma_l$ ) and transverse ( $\sigma_t$ ) with respect to the current flow is given by:

$$\frac{\Delta R}{R} = \sigma_l \pi_l + \sigma_t \pi_t \quad (16.23)$$

where

$\sigma_l$  = Longitudinal stress component, i.e., stress component parallel to the direction of the current.

$\sigma_t$  = Transversal stress component, i.e., the stress component perpendicular to the direction of the current.

$\pi_l$  = Longitudinal piezoresistance coefficient.

$\pi_t$  = Transversal piezoresistance coefficient.

The piezoresistance coefficients  $\pi_l$  and  $\pi_t$  for (100) silicon as a function of crystal orientation are reproduced from Kanda in Figure 16.17A (for p-type) and B (for n-type) [Kanda, 1982]. By maximizing the expression for the stress-induced resistance change in Eq. (16.23), one optimizes the achievable sensitivity in a piezoresistive silicon sensor.

**TABLE 16.5** Resistivity and Piezoresistance at Room Temperature  
[Smith, 1954; Khazan, 1994]

	$\rho$ ( $\Omega$ cm)	$\pi_{11}^a$	$\pi_{12}^a$	$\pi_{44}^a$
p-Si	7.8	+6.6	-1.1	+138.1
n-Si	11.7	-102.2	+53.4	-13.6

<sup>a</sup> Expressed in  $10^{-12}$  cm<sup>2</sup> dyne<sup>-1</sup> or  $10^{-11}$  Pa<sup>-1</sup>.

The orientation of a membrane or beam is determined by its anisotropic fabrication. The surface of the silicon wafer is usually a (100) plane; the edges of the etched structures are intersections of (100) and (111) planes and are thus <110> directions. p-Type piezoresistors are most commonly used because the orientation of maximum piezoresistivity (<110>) happens to coincide with the edge orientation of a conventionally etched diaphragm and because the longitudinal coefficient is roughly equal in magnitude but opposite in sign as compared to the transverse coefficient (Figure 16.17A)[Peeters, 1994]. With the values in Table 16.5,  $\pi_l$  and  $\pi_t$  now can be calculated numerically for any orientation. The longitudinal piezoresistive coefficient in the <110> direction is  $\pi_l = 1/2(\pi_{11} + \pi_{12} + \pi_{44})$ . The corresponding transverse coefficient is  $\pi_t = 1/2(\pi_{11} + \pi_{12} - \pi_{44})$ . From Table 16.5 we know that, for p-type resistors,  $\pi_{44}$  is more important than the other two coefficients and Eq. (16.23) is approximated by:

$$\frac{\Delta R}{R} = \frac{\pi_{44}}{2}(\sigma_l - \sigma_t) \quad (16.24)$$

For n-type resistors,  $\pi_{44}$  can be neglected, and we obtain:

$$\frac{\Delta R}{R} = \frac{\pi_{11} + \pi_{12}}{2}(\sigma_l + \sigma_t) \quad (16.25)$$

Equations (16.24) and (16.25) are valid only for uniform stress fields or if the resistor dimensions are small compared with the membrane or beam size. When stresses vary over the resistors they have to be integrated, which is most conveniently done by computer simulation programs.

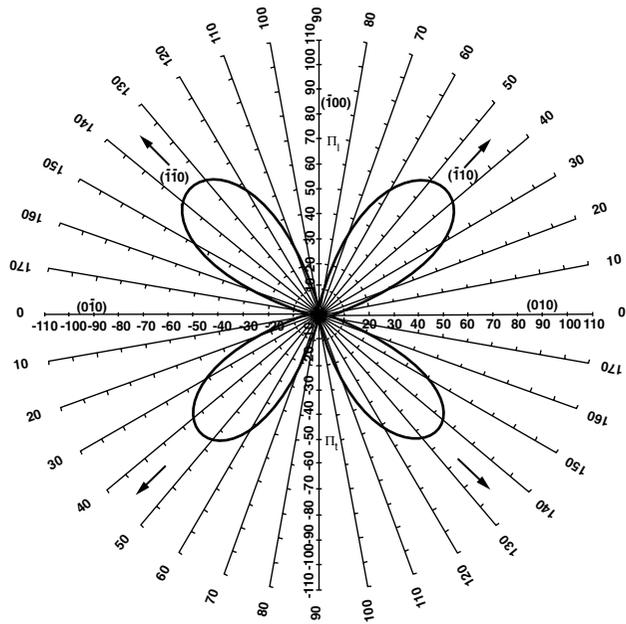

To convert the piezoresistive effect into a measurable electrical signal, a Wheatstone bridge is often used. A balanced Wheatstone bridge configuration is constructed as in Figure 16.18A by locating four p-piezoresistors midway along the edges of a square diaphragm as in Figure 16.18B (location of maximum stress). Two resistors are oriented so that they sense stress in the direction of their current axes and two are placed to sense stress perpendicular to their current flow. Two longitudinally stressed resistors (A) are balanced against two transversally stressed resistors (B); two of them increase in value and the other two decrease in value upon application of a stress. In this case, from Eq. (16.24),

$$\frac{\Delta R}{R} \approx 70 \cdot 10^{-11}(\sigma_l - \sigma_t) \quad (16.26)$$

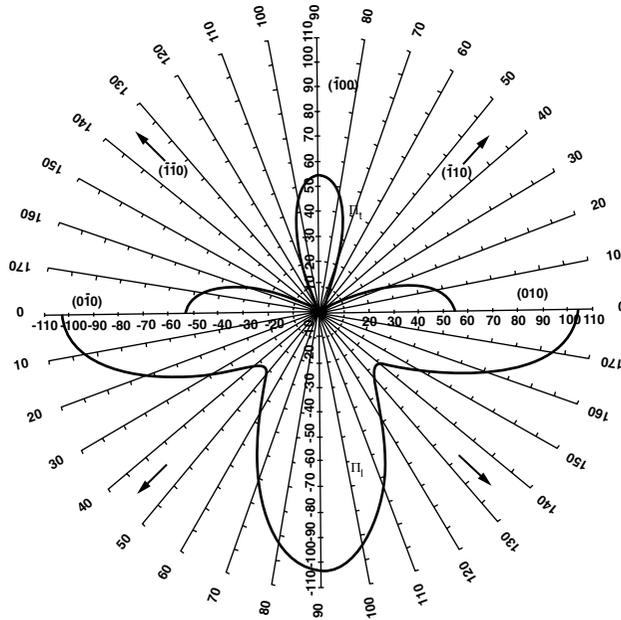

with  $\sigma$  in Pa. For a realistic stress pattern where  $\sigma_l = 10$  MPa and  $\sigma_t = 50$  MPa, Eq. (16.26) gives us a  $\Delta R/R \approx 2.8\%$  [Peeters, 1994].

By varying the diameter and thickness of the silicon diaphragms, piezoresistive sensors in the range of 0 to 200 MPa have been made. The bridge voltages are usually between 5 and 10 volts, and the sensitivity may vary from 10 mV/kPa for low pressure to 0.001 mV/kPa for high pressure sensors.

Peeters (1994) shows how a more sensitive device could be based on n-type resistors when all the n-resistors oriented along the <100> direction are subjected to an uniaxial stress pattern in the longitudinal axis, as shown in Figure 16.19. The overall maximum piezoresistivity coefficient ( $\pi_l$  in the <100> direction) is substantially higher for n-silicon than it is for p-type silicon in any direction (maximum  $\pi_l$  and  $\pi_t$  in the

(B) For n-type in the (001) plane ( $10^{-12}$  cm<sup>2</sup>/dyne). (From Kanda, Y., *IEEE Trans. Electr. Dev.*, ED-29, 64–70, 1982. With permission.)

**FIGURE 16.18** Measuring on a membrane with piezoresistors. (A) Wheatstone-bridge configuration of four in-diffused piezoresistors. The arrows indicate resistance changes when the membrane is bent downward. (B) Maximizing the piezoresistive effect with p-type resistors. The A resistors are stressed longitudinally and the B resistors are stressed transversally. (From Peeters, E., Ph.D. thesis, KUL, Belgium, 1994. With permission.)

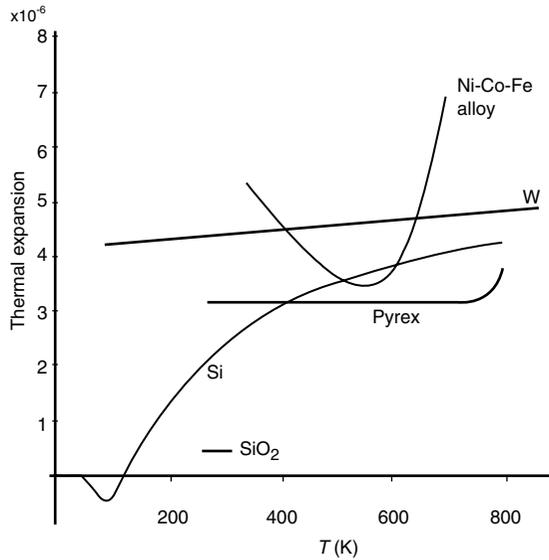

**FIGURE 16.19** Higher pressure sensitivity by strategic placement of in-diffused piezoresistors proposed by Peeters (1994). The n-resistors are stressed longitudinally with the A resistors under tensile stress, and the B resistors under compressive stress. (From Peeters, E., Ph.D. thesis, KUL, Belgium, 1994. With permission.)

<100> direction, Figure 16.17B). Exploitation of these high piezoresistivity coefficients is less obvious, though, since the resistor orientation for maximum sensitivity (<100>) is rotated over 45° with respect to the <110> edges of an anisotropically etched diaphragm. Also evident from Figure 16.17B is that a transversally stressed resistor cannot be balanced against a longitudinally stressed resistor. Peeters has circumvented these two objections by a uniaxial, longitudinal stress pattern in the rectangular diaphragm represented in Figure 16.19. With a (100) substrate and a <100> orientation (45° to wafer flat) we obtain:

$$\frac{\Delta R}{R} \approx 53 \cdot 10^{-11} \cdot \sigma_t - 102 \cdot 10^{-11} \cdot \sigma_l \quad (16.27)$$

with  $\sigma$  in Pa. Based on Eq. (16.27), with  $\sigma_t = 10$  MPa and  $\sigma_l = 50$  MPa,  $\Delta R/R \approx -4.6\%$ . In the proposed stress pattern it is important to minimize the transverse stress by making the device truly uniaxial as the

**FIGURE 16.20** Thermal expansion coefficient vs. absolute temperature. (From Greenwood, J.C., *J. Phys. E: Sci. Instrum.*, 21 1114–1128, 1988. With permission.)

longitudinal and transverse stress components have opposite effects and can even cancel out. In practice, a pressure sensor with an estimated 65% gain in pressure sensitivity over the more traditional configurations could be made in the case of an 80% uniaxiality [Peeters, 1994].

The piezoresistive effect is often described in terms of the gauge factor,  $G$ , defined as:

$$G = \frac{1}{\epsilon} \frac{\Delta R}{R} \quad (16.28)$$

which is the relative resistance change divided by the applied strain. The gauge factor of a metal strain gauge is typically around 2, for single crystal Si it is 90, and for poly-crystalline Si it is about 30 (see also Section 16.10).

#### 16.4.2.6 Thermal Properties of Silicon

In Figure 16.20, the expansion coefficient of Si, W, SiO<sub>2</sub>, Ni-Co-Fe alloy and Pyrex® is plotted vs. absolute temperature. Single crystal silicon has a high thermal conductivity (comparable with metals such as steel and aluminum) and a low thermal expansion coefficient. Its thermal expansion coefficient is closely matched to Pyrex glass but exhibits considerable temperature dependence. A good match in thermal expansion coefficient between the device wafer (e.g., Si) and the support substrate (e.g., Pyrex) is required. A poor match introduces stress, which degrades the device performance. This makes it difficult to fabricate composite structures of Pyrex and Si that are stress-free over a wide range of temperatures. Drift in silicon sensors often stems from packaging. In this respect, several types of stress-relief, subassemblies for stress-free mounting of the active silicon parts play a major role; using silicon as the support for silicon sensors is highly desirable. The latter aspect is addressed in Madou (1997, chap. 8).

Although the Si band-gap is relatively narrow, by employing silicon on insulator (SOI) wafers, high temperature sensors can be fashioned. For the latter application, relatively highly doped Si, which is relatively linear in its temperature coefficient of resistance and sensitivity over a wide range, typically is employed.

When fabricating thermally isolated structures on Si, the large thermal conductivity of Si poses a considerable problem as the major heat leak occurs through the Si material. For thermally isolated structures, machining in glass or quartz with their lower thermal conductivity represents an important alternative.

## 16.5 Wet Isotropic and Anisotropic Etching

---

### 16.5.1 Wet Isotropic and Anisotropic: Empirical Observations

#### 16.5.1.1 Introduction

Wet etching of Si is used mainly for cleaning, shaping, polishing and characterizing structural and compositional features [Uhlir, 1956]. Wet chemical etching provides a higher degree of selectivity than dry etching techniques. Wet etching often is also faster; compare a few microns to several tens of microns per minute for isotropic etchants and about 1  $\mu\text{m}/\text{min}$  for anisotropic etchants vs. 0.1  $\mu\text{m}/\text{min}$  in typical dry etching. More recently though, with ECR dry etching, rates of up to 6  $\mu\text{m}/\text{min}$  were achieved (see Madou [1997, chap. 2]). Modification of wet etchant and/or temperature can alter the selectivity to silicon dopant concentration and type and, especially when using alkaline etchants, to crystallographic orientation. Etching proceeds by reactant transport to the surface (1), surface reaction (2), and reaction product transport away from the surface (3). If (1) or (3) is rate determining, etching is diffusion limited and may be increased by stirring. If (2) is the rate-determining step, etching is reaction rate limited and depends strongly on temperature, etching material and solution composition. Diffusion-limited processes have lower activation energies (of the order of a few Kcal/mol) than reaction-rate controlled processes and therefore are relatively insensitive to temperature variations. In general, one prefers reaction rate limitation as it is easier to reproduce a temperature setting than a stirring rate. The etching apparatus needs to have both a good temperature controller and a reliable stirring facility [Kaminsky, 1985; Stoller et al., 1970].

Isotropic etchants, also polishing etchants, etch in all crystallographic directions at the same rate; they usually are acidic, such as  $\text{HF}/\text{HNO}_3/\text{CH}_3\text{COOH}$  (HNA), and lead to rounded isotropic features in single crystalline Si. They are used at room temperature or slightly above ( $<50^\circ\text{C}$ ). Historically they were the first Si etchants introduced [Robbins and Schwartz, 1959; 1960; 1961; 1976; Uhlir, 1956; Hallas, 1971; Turner, 1958; Kern, 1978; Klein and D'Stefan, 1962]. Later it was discovered that some alkaline chemicals will etch anisotropically, i.e., they etch away crystalline silicon at different rates depending on the orientation of the exposed crystal plane. Typically the pH stays above 12, while more elevated temperatures are used for these slower type etchants ( $>50^\circ\text{C}$ ). The latter type of etchants surged in importance in the late 1960s for the fabrication of dielectrically isolated structures in silicon [Stoller and Wolff, 1966; Stoller, 1970; Forster and Singleton, 1966; Kenney, 1967; Lepselter, 1966; 1967; Waggner, 1970; Kragness, 1973; Waggner et al., 1967a; 1967b; Bean and Runyan, 1977; Rodgers et al., 1977; Rodgers et al., 1976; Ammar and Rodgers, 1980; Schnable and Schmidt, 1976]. Isotropic etchants typically show diffusion limitation, while anisotropic etchants are reaction rate limited.

Preferential or selective etching (also structural etchants) usually are isotropic etchants that show some anisotropy [Kern and Deckert, 1978]. These etchants are used to produce a difference in etch rate between different materials or between compositional or structural variations of the same material on the same crystal plane. These type of etches often are the fastest and simplest techniques to delineate electrical junctions and to evaluate the structural perfection of a single crystal in terms of slip, lineage and stacking faults. The artifacts introduced by the defects etch into small pits of characteristic shape. Most of the etchants used for this purpose are acids with some oxidizing additives [Yang, 1984; Chu and Gavalier, 1965; Archer, 1982; Schimmel and Elkind, 1973; Secco d'Aragona, 1972].

#### 16.5.1.2 Isotropic Etching

##### *Usage of Isotropic Etchants*

When etching silicon with aggressive acidic etchants, rounded isotropic patterns form. The method is widely used for:

1. Removal of work-damaged surfaces
2. Rounding of sharp anisotropically etched corners (to avoid stress concentration)
3. Removing of roughness after dry or anisotropic etching

4. Creating structures or planar surfaces in single-crystal slices (thinning)
5. Patterning single-crystal, polycrystalline, or amorphous films
6. Delineation of electrical junctions and defect evaluation (with preferential isotropic etchants)

For isotropic etching of silicon, the most commonly used etchants are mixtures of nitric acid ( $\text{HNO}_3$ ) and hydrofluoric acids (HF). Water can be used as a diluent, but acetic acid ( $\text{CH}_3\text{COOH}$ ) is preferred because it prevents the dissociation of the nitric acid better and so preserves the oxidizing power of  $\text{HNO}_3$  which depends on the undissociated nitric acid species for a wide range of dilution [Robbins and Schwartz, 1960]. The etchant is called the HNA system; we will return to this etch system below.

### ***Simplified Reaction Scheme***

In acidic media, the Si etching process involves hole injection into the Si valence band by an oxidant, an electrical field, or photons. Nitric acid in the HNA system acts as an oxidant; other oxidants such as  $\text{H}_2\text{O}_2$  and  $\text{Br}_2$  also work [Tuck, 1975]. The holes attack the covalently bonded Si, oxidizing the material. Then follows a reaction of the oxidized Si fragments with  $\text{OH}^-$  and subsequent dissolution of the silicon oxidation products in HF. Consider the following reactions that describe these processes.

The holes are, in the absence of photons and an applied field, produced by  $\text{HNO}_3$ , together with water and trace impurities of  $\text{HNO}_2$ :

The holes in Reaction 16.1 are generated in an autocatalytic process;  $\text{HNO}_2$  generated in the above reaction re-enters into the further reaction with  $\text{HNO}_3$  to produce more holes. With a reaction of this type, one expects an induction period before the oxidation reaction takes off, until a steady-state concentration of  $\text{HNO}_2$  has been reached. This has been observed at low  $\text{HNO}_3$  concentrations [Tuck, 1975]. After hole injection,  $\text{OH}^-$  groups attach to the oxidized Si species to form  $\text{SiO}_2$ , liberating hydrogen in the process:

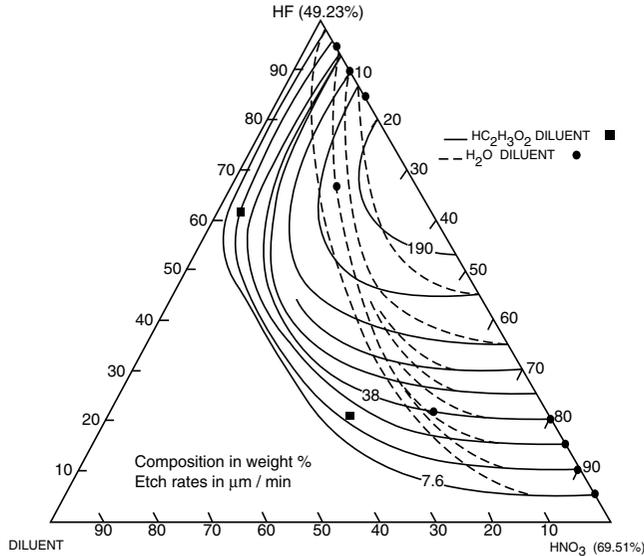

Hydrofluoric acid (HF) dissolves the  $\text{SiO}_2$  by forming the water-soluble  $\text{H}_2\text{SiF}_6$ . The overall reaction of HNA with Si looks like:

The simplification in the above reaction scheme is that only holes are assumed. In the actual Si acidic corrosion reaction, both holes and electrons are involved. The question of hole and/or electron participation in Si corrosion will be considered after the introduction of the model for the Si/electrolyte interfacial energetics. We will learn from that model that the rate-determining step in acidic etching involves hole injection in the valence band, whereas in alkaline anisotropic etching it involves electron injection in the conduction band by surface states. The reactivity of a hole injected in the valence band is significantly greater than that of an electron injected in the conduction band. The observation of isotropy in acidic etchants and anisotropy in alkaline etchants centers on this difference in reactivity.

### ***Iso-Etch Curves***

By the early 1960s, the isotropic HNA silicon etch was well characterized. Schwartz and Robbins published a series of four very detailed papers on the topic between 1959 and 1976 [Robbins and Schwartz, 1959; 1960; 1961; 1976]. Most of the material presented below is based on their work.

**FIGURE 16.21** Iso-etch curves. From Robbins and Schwartz (1960), recalculated for one-sided Si etching and expressed in  $\mu\text{m}/\text{min}$ .

HNA etching results, represented in the form of iso-etch curves, for various weight percentages of the constituents are shown in Figure 16.21. For this work, normally available concentrated acids of 49.2 wt% HF and 69.5 wt%  $\text{HNO}_3$  are used. Water as diluent is indicated by dash-line curves and acetic acid by solid-line curves. Also, as in Wong's representation [Wong, 1990], we have recalculated the curves from Schwartz et al to express the etch rate in  $\mu\text{m}/\text{min}$  and divided the authors' numbers by 2 as we are considering one-sided etching only. The highest etch rate is observed around a weight ratio HF- $\text{HNO}_3$  of 2:1 and is nearly 100 times faster than anisotropic etch rates. Adding a diluent slows down the etching. From these curves, the following characteristics of the HNA system can be summarized:

1. At high HF and low  $\text{HNO}_3$  concentrations, the iso-etch curves describe lines of constant  $\text{HNO}_3$  concentrations (parallel to the HF-diluent axis); consequently, the  $\text{HNO}_3$  concentration controls the etch rate. Etching at those concentrations tends to be difficult to initiate and exhibits an uncertain induction period (see above). In addition, it results in relatively unstable silicon surfaces proceeding to slowly grow a layer of  $\text{SiO}_2$  over a period of time. The etch is limited by the rate of oxidation, so that it tends to be orientation dependent and affected by dopant concentration, defects and catalysts (sodium nitrate often is used). In this regime the temperature influence is more pronounced, and activation energies for the etching reaction of 10 to 20 Kcal/mol have been measured.
2. At low HF and high  $\text{HNO}_3$  concentrations, iso-etch curves are lines parallel to the nitric-diluent axis, i.e., they are at constant HF composition. In this case, the etch rate is controlled by the ability of HF to remove the  $\text{SiO}_2$  as it is formed. Etches in this regime are isotropic and truly polishing, producing a bright surface with anisotropies of 1% or less (favoring the  $\langle 110 \rangle$  direction) when used on  $\langle 100 \rangle$  wafers [Wise et al., 1981]. An activation energy of 4 Kcal/mol is indicative of the diffusion limited character of the process; consequently, in this regime, temperature changes are less important.
3. In the region of maximal etch rate both reagents play an important role. The addition of acetic acid, as opposed to the addition of water, does not reduce the oxidizing power of the nitric acid until a fairly large amount of diluent has been added. Therefore, the rate contours remain parallel with lines of constant nitric acid over a considerable range of added diluent.

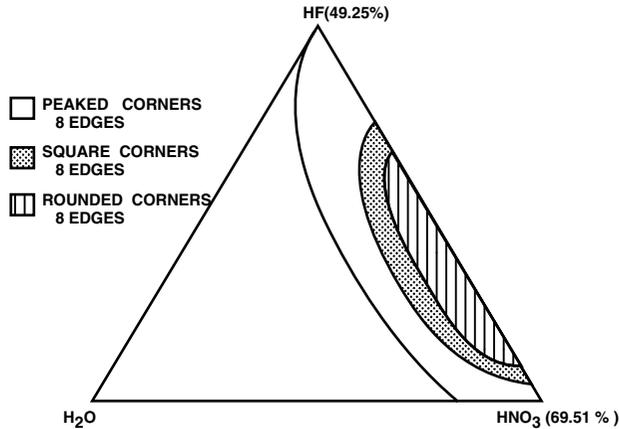

FIGURE 16.22 Topology of etched Si surfaces. (From Schwartz, B. and H. Robbins, *J. Electrochem. Soc.*, 123, 1903–1909, 1976. With permission.)

4. In the region around the HF vertex the surface reaction rate-controlled etch leads to rough, pitted Si surfaces and sharply peaked corners and edges. In moving towards the HNO<sub>3</sub> vertex, the diffusion-controlled reaction results in the development of rounded corners and edges and the rate of attack on (111) planes and (110) planes becomes identical in the polishing regime (anisotropy less than 1%; see point 2).

In Figure 16.22 we summarize how the topology of the Si surfaces depends strongly on the composition of the etch solution. Around the maximum etch rates the surfaces appear quite flat with rounded edges, and very slow etching solutions lead to rough surfaces [Schwartz and Robbins, 1976].

#### **Arrhenius Plot for Isotropic Etching**

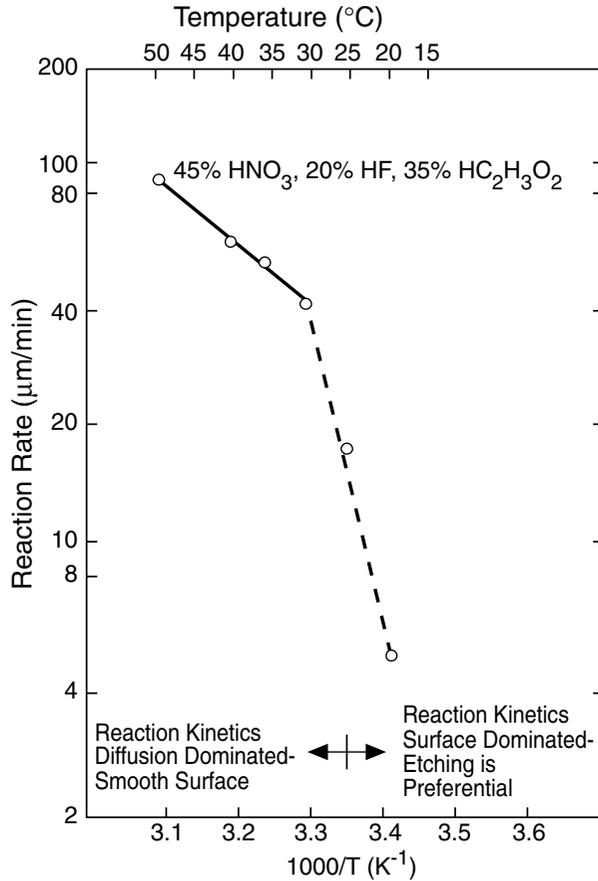

The effect of temperature on the reaction rate in the HNA system was studied in detail by Schwartz and Robbins (1961). An Arrhenius plot for etching Si in 45% HNO<sub>3</sub>, 20% HF and 35% HC<sub>2</sub>H<sub>3</sub>O<sub>2</sub>, culled from their work, is shown in Figure 16.23. Increasing the temperature increases the reaction rate. The graph shows two straight-line segments, indicating a higher activation energy below 30°C and a lower one above this temperature. In the low temperature range, etching is preferential and the activation energy is associated with the oxidation reaction. At higher temperatures the etching leads to smooth surfaces and the activation energy is lower and associated with diffusion limited dissolution of the oxide [Schwartz and Robbins, 1961].

With isotropic etchants the etchant moves downward and outwards from an opening in the mask, undercuts the mask, and enlarges the etched pit while deepening it (Figure 16.24). The resulting isotropically etched features show more symmetry and rounding when agitation accompanies the etching (the process is diffusion limited). This agitation effect is illustrated in Figure 16.24. With agitation the etched feature approaches an ideal round cup; without agitation the etched feature resembles a rounded box [Petersen, 1982]. The flatness of the bottom of the rounded box generally is poor, since the flatness is defined by agitation.

#### **Masking for Isotropic Silicon Etchants**

Acidic etchants are very fast; for example, an etch rate for Si of up to 50 μ min<sup>-1</sup> can be obtained with 66% HNO<sub>3</sub> and 34% HF (volumes of reagents in the normal concentrated form) [Kern, 1978; Kern and Deckert, 1978]. Isotropic etchants are so aggressive that the activation barriers associated with etching the different Si planes are not differentiated; all planes etch equally fast, making masking a real challenge.

Although SiO<sub>2</sub> has an appreciable etch rate of 300 to 800 Å/min in the HF:HNO<sub>3</sub> system, one likes to use thick layers of SiO<sub>2</sub> as a mask anyway, especially for shallow etching, as the oxide is so easy to form

**FIGURE 16.23** Etching Arrhenius plot. Temperature dependence of the etch rate of Si in HF:HNO<sub>3</sub>:CH<sub>3</sub>:COOH (1:4:3). (From Schwartz, B. and H. Robbins, *J. Electrochem. Soc.*, 108, 365–372, 1961. With permission.)

and pattern. A mask of nonetching Au or Si<sub>3</sub>N<sub>4</sub> is needed for deeper etching. Photoresists do not stand up to strong oxidizing agents such as HNO<sub>3</sub>, and neither does Al.

Silicon itself is soluble to a small extent in pure HF solutions; for a 48% HF, at 25°C, a rate of 0.3 Å/min was observed for n-type, 2-ohm cm (111)-Si. It was established that Si dissolution in HF is not due to oxidation by dissolved oxygen. Diluted HF etches Si at a higher rate because the reaction in aqueous solutions proceeds by oxidation of Si by OH<sup>-</sup> groups [Hu and Kerr, 1967]. A typically buffered HF (BHF) solution has been reported to etch Si at radiochemically measured rates of 0.23 to 0.45 Å/min, depending on doping type and dopant concentration [Hoffmeister, 1969].

By reducing the dopant concentration (n or p) to below 10<sup>17</sup> atoms/cm<sup>3</sup> the etch rate of Si in HNA is reduced by ~150 [Muraoka et al., 1973]. The doping dependence of the etch rate provides yet another means of patterning a Si surface (see next section). A summary of masks that can be used in acidic etching is presented in Table 16.6.

#### **Dopant Dependence of Silicon Isotropic Etchants**

The isotropic etching process is fundamentally a charge-transfer mechanism. This explains the etch rate dependence on dopant type and concentration. Typical etch rates with an HNA system (1:3:8) for n- or p-type dopant concentrations above 10<sup>18</sup> cm<sup>-3</sup> are 1 to 3  $\mu\text{m}/\text{min}$ . As presented in the preceding section, a reduction of the etch rate by 150 times is obtained in n- or p-type regions with a dopant concentration of 10<sup>17</sup> cm<sup>-3</sup> or smaller [Muraoka et al., 1973]. This presumably is due to the lower mobile carrier

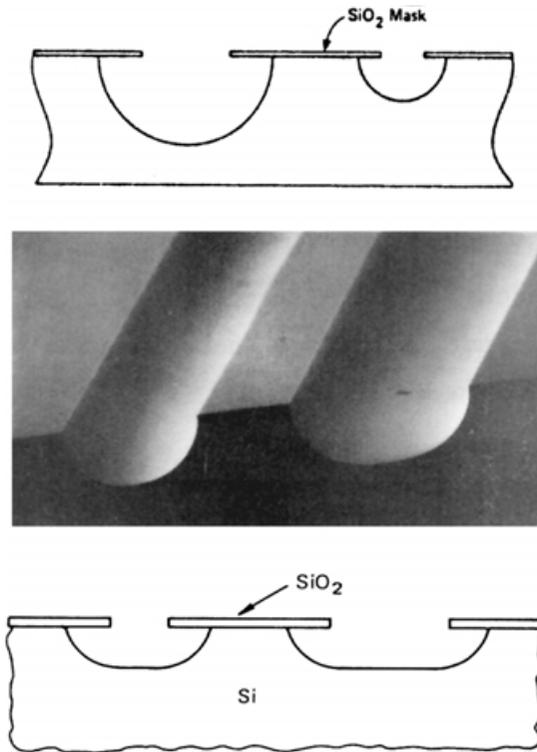

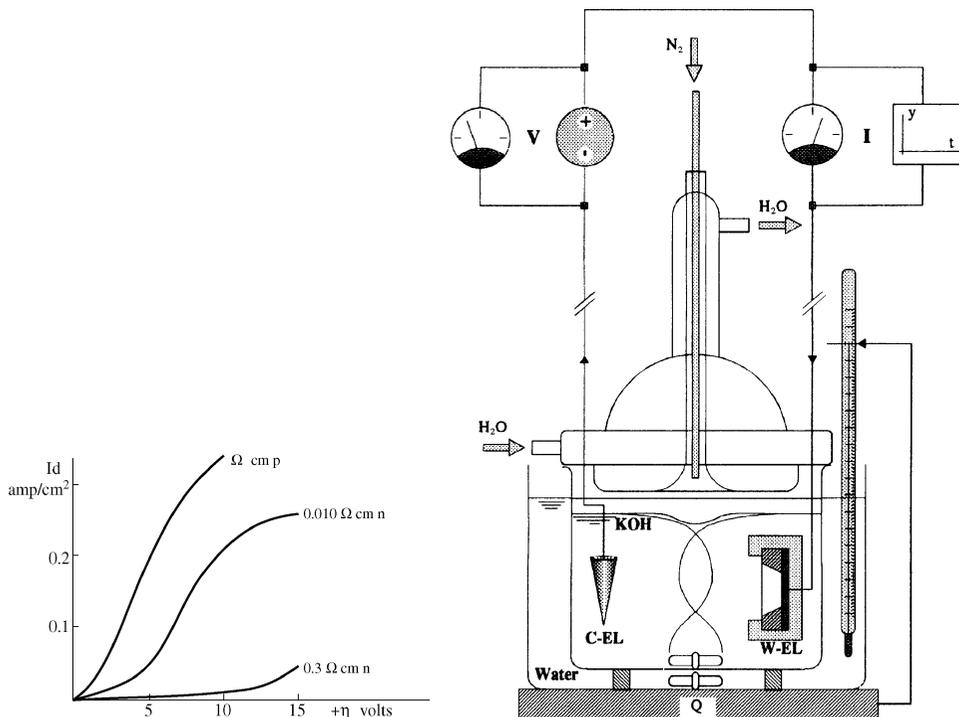

FIGURE 16.24 Isotropic etching of Si with (A) and without (B) etchant solution agitation.

TABLE 16.6 Masking Materials for Acidic Etchants<sup>a</sup>

Masking	Etchants		
	Piranha (4:1, H <sub>2</sub> O <sub>2</sub> :H <sub>2</sub> SO <sub>4</sub> )	Buffered HF (5:1 NH <sub>4</sub> F:conc. HF)	HNA
Thermal SiO <sub>2</sub>		0.1 μm/min	300–800 Å/min; limited etch time, thick layers often are used due to ease of patterning
CVD (450°C) SiO <sub>2</sub>		0.48 μm/min	0.44 μm/min
Corning 7740 glass		0.063 μ/min	1.9 μ/min
Photoresist	Attacks most organic films	Good for short while	Resists do not stand up to strong oxidizing agents like HNO <sub>3</sub> and are not used
Undoped Si, polysilicon	Forms 30 Å of SiO <sub>2</sub>	0.23 to 0.45 Å/min	Si 0.7 to 40 μm/min at room temperature; at a dopant concentration <10 <sup>17</sup> cm <sup>-3</sup> (n or p)
Black wax			Usable at room temperature
Au/Cr	Good	Good	Good

<sup>a</sup> The many variables involved necessarily means that the given numbers are approximate only.

concentration available to contribute to the charge transfer mechanisms. In any event, heavily doped silicon substrates with high conductivity can be etched more readily than lightly doped materials. Dopant-dependent isotropic etching can also be exploited in an electrochemical set-up as described in the next section. Although doping does change the chemical etch rate, attempts to exploit these differences for industrial production have failed so far [Seidel, 1989]. This situation is different in electrochemical isotropic etching (see next section).

### ***Electrochemical Isotropic Silicon Etch-Stop***

Sometimes, a high temperature or extremely aggressive chemical etching process can be replaced by an electrochemical procedure utilizing a much milder solution, thus allowing a simple photoresist mask to be employed [Kern and Deckert, 1978]. In electrochemical acidic etching, with or without illumination of the corroding Si electrode, an electrical power supply is employed to drive the chemical reaction by supplying holes to the silicon surface (W-EL see Figure 16.25). A voltage is applied across the silicon wafer and a counter electrode (C-EL usually platinum) arranged in the same etching solution. Oxidation is promoted by a positive bias applied to the silicon causing an accumulation of holes in the silicon at the silicon/electrolyte interface. Under this condition, oxidation at the surface proceeds rapidly while the oxide is readily dissolved by the HF solution. No oxidant such as  $\text{HNO}_3$  is needed to supply the holes; excess electron-hole pairs are created by the electrical field at the surface and/or by optical excitation, thereby increasing the etch rate. This technique proved successful in removing heavily doped layers, leaving behind the more lightly doped membranes in all possible dopant configurations: p on p<sup>+</sup>, p on n<sup>+</sup>, n on p<sup>+</sup>, and n on n<sup>+</sup> [Theunissen et al., 1970; Meek, 1971]. This electrochemical etch-stop technique is demonstrated in the inset of Figure 16.25 [van Dijk et al., 1970]. A 5% HF solution is used, the electrolyte cell is kept in the dark at room temperature, and the distance between the Si anode and the Pt cathode in the electrochemical cell is 1 to 5 cm. Instead of using HF, one can substitute  $\text{NH}_4\text{F}$  (5 wt%) for the electrochemical etching as described by Shengliang et al. (1987). Shengliang reports a selectivity of n-silicon to n<sup>+</sup>-silicon (0.001  $\Omega\text{cm}$ ) of 300 with the latter etchant. In the inset in Figure 16.25 the current density vs. applied voltage across the anode and cathode during dissolution is plotted. The current density is related to the dissolution rate of silicon. It can be seen that p-type and heavily doped n-type materials can be dissolved at relatively low voltages, whereas n-type silicon with a lower doping level does not

dissolve at the same low voltages. Experiments in this same set-up with homogeneously doped silicon wafers show that n-type silicon of about  $3 \cdot 10^{18} \text{ cm}^{-3}$  ( $< 0.01 \text{ } \Omega\text{cm}$ ) completely dissolves in these etching conditions, whereas n-type silicon of donor concentrations lower than  $2 \cdot 10^{16} \text{ cm}^{-3}$  ( $> 0.3 \text{ } \Omega\text{cm}$ ) barely dissolves. For p-type silicon, dissolution is initiated when the acceptor concentration is higher than  $5 \cdot 10^{15} \text{ cm}^{-3}$  ( $< 3 \text{ } \Omega\text{cm}$ ) and the dissolution rate further increases with increasing acceptor concentration. Under specific circumstances, namely high HF concentrations and low etching currents, porous Si may form [Bomchil et al., 1986].

The acidic electrochemical technique has not been used much in micromachining and is primarily used to polish surfaces. Since the etching rate increases with current density, high spots on the surface are more rapidly etched and very smooth surfaces result. The method of isotropic electrochemical etching has some major advantages which could make it a more important micromachining tool in the future. The etched surfaces are very smooth (say with an average roughness,  $R_a$ , of 7 nm), the process is room temperature and IC compatible, simpler resists schemes can be used as the process is much milder than etching in HNA, and etching can be controlled simply by switching a voltage on or off. We will pick up the discussion of anodic polishing, photo etching, and formation of porous silicon in HF solutions after gathering more insight in various etching models.

### ***Preferential Etching***

A variety of additives to the HNA system, mainly oxidants, can be included to modify the etch rate, surface finish or isotropy, rendering the etching baths preferential. It is clear that the effect of these additives will only show up in the reaction-controlled regime. Only additives that change the viscosity of the solution could modify the etch rate in the diffusion-limited regime, thereby changing the diffusion coefficient of the reactants [Tuck, 1975; Bogenschutz et al., 1967]. We will not review the effect of these additives any further; refer to [Table 16.7](#) and the cited literature for further study [Yang, 1984; Chu and Gavaler, 1965; Archer, 1982; Schimmel and Elkind, 1973; Secco d'Aragona, 1972].

### ***Problems with Isotropic Etchants***

There are several problems associated with isotropic etching of Si. First, it is difficult to mask with high precision using a desirable and simple mask such as  $\text{SiO}_2$  (etch rate is 2 to 3% of the silicon etch rate). Second, the etch rate is very agitation sensitive in addition to being temperature sensitive. This makes it difficult to control lateral as well as vertical geometries. Electrochemical isotropic etching (see above) and the development of anisotropic etchants in the late 1960s (see below) overcame many of these problems.

A comprehensive review of isotropic etchants solutions can be found in Kern and Deckert (1978). These authors also give a review of different techniques practiced in chemical etching such as immersion etching, spray etching, electrolytic etching, gas-phase etching, and molten salt etching (fusion techniques). In [Table 16.7](#) some isotropic and preferential etchants and their specific applications are listed.

## **16.5.1.3 Anisotropic Etching**

### ***Introduction***

Anisotropic etchants shape, also 'machine,' desired structures in crystalline materials. When carried out properly, anisotropic etching results in geometric shapes bounded by perfectly defined crystallographic planes. Anisotropic wet etching techniques, dating back to the 1960s at the Bell Laboratories, were developed mainly by trial and error. Going over some experimental data, before embarking upon the models, seems fitting. Moreover, we must keep in mind that for higher index planes most models fail.

[Figure 16.1](#) shows a cross-section of a typical shape formed using anisotropic etching. The thinned membranes with diffused resistors could be used for a piezoresistive pressure sensor or an accelerometer. In the usual application, the wafer is selectively thinned from a starting thickness of 300 to 500  $\mu\text{m}$  to form a diaphragm having a final thickness of 10 to 20  $\mu\text{m}$  with precisely controlled lateral dimensions and a thickness control of the order of 1  $\mu\text{m}$  or better. A typical procedure involves the steps summarized in [Table 16.8](#) [Elwenspoek et al., 1994].

**TABLE 16.7** Isotropic and Preferential Defect Etchants and Their Specific Applications

Etchant	Application	Remark
HF: 8 vol%, HNO <sub>3</sub> : 75 vol%, and CH <sub>3</sub> COOH: 17 vol%	n- and p-type Si, all planes, general etching	Planar etch; e.g., 5 μm/min at 25°C
1 part 49% HF, 1 part of (1.5 M CrO <sub>3</sub> ) (by volume)	Delineation of defects on (111), (100), and (110) Si without agitation	Yang etch <sup>a</sup>
5 vol parts nitric acid (65%), 3 vol parts HF (48%), 3 vol parts acetic acid (96%), 0.06 parts bromine	Polishing etchant used to remove damage introduced during lapping	So-called CP4 etchant; Heidenreich, U.S. Patent 2619414
HF	SiO <sub>2</sub>	Si etch rate for 48% HF at 25°C is 0.3 Å/min with n-type 2 Ω cm (111) Si
1HF, 3HNO <sub>3</sub> , 10CH <sub>3</sub> COOH (by volume)	Delineates defects in (111) Si; etches p <sup>+</sup> or n <sup>+</sup> and stops at p <sup>-</sup> or n <sup>-</sup>	Dash etch; p- and n-Si at 1300 Å/min in the [100] direction and 46 Å/min in the [111] direction at 25°C <sup>b</sup>
1HF, 1(5 M CrO <sub>3</sub> ) (by volume)	Delineates defects in (111); needs agitation; does not reveal etch pits well on (100) well	Sirtl etch <sup>c</sup>
2HF, 1(0.15 M K <sub>2</sub> Cr <sub>2</sub> O <sub>7</sub> ) (by volume)	Yields circular (100) Si dislocation etch pits; agitation reduces etch time	Secco etch <sup>d</sup>
60 ml HF, 30 ml HNO <sub>3</sub> , 30 ml (5 M CrO <sub>3</sub> ), 2 g Cu(NO <sub>3</sub> ) <sub>2</sub> , 60 ml CH <sub>3</sub> COOH, 60 ml H <sub>2</sub> O	Delineates defects in (100) and (111) Si; requires agitation	Jenkins etch <sup>e</sup>
2HF, 1 (1 M CrO <sub>3</sub> ) (by volume)	Delineates defects in (100) Si without agitation; works well on resistivities 0.6–15.0 Ωcm n- and p-types)	Schimmel etch <sup>f</sup>
2HF, 1 (1 M CrO <sub>3</sub> ), 1.5 (H <sub>2</sub> O) (by volume)	Works well on heavily doped (100) silicon	Modified Schimmel <sup>f</sup>
HF/KMnO <sub>4</sub> /CH <sub>3</sub> COOH	Epitaxial Si	
H <sub>3</sub> PO <sub>4</sub>	Si <sub>3</sub> N <sub>4</sub>	160–180°C
KOH + alcohols	Polysilicon	85°C
H <sub>3</sub> PO <sub>4</sub> /HNO <sub>3</sub> /HC <sub>2</sub> H <sub>3</sub> O <sub>2</sub>	Al	40–50°C
HNO <sub>3</sub> /BHF/water	Si and polysilicon	0.1 μm min <sup>-1</sup> for single crystal Si

**TABLE 16.8** Summary of the Process Steps Required for Anisotropic Etching of a Membrane [Elwenspoek et al., 1994]

Process	Duration	Process Temperature (°C)
Oxidation	Variable (hours)	900–1200
Spinning at 5000 rpm	20–30 sec	Room temperature
Prebake	10 min	90
Exposure	20 sec	Room temperature
Develop	1 min	Room temperature
Post-bake	20 min	120
Stripping of oxide (BHF:1:7)	±10 min	Room temperature
Stripping resist (acetone)	10–30 sec	Room temperature
RCA1 (NH <sub>3</sub> (25%) + H <sub>2</sub> O + H <sub>2</sub> O <sub>2</sub> :1:5:1)	10 min	Boiling
RCA2 (HCl + H <sub>2</sub> O + H <sub>2</sub> O <sub>2</sub> :1:6:1)	10 min	Boiling
HF-dip (2% HF)	10 sec	Room temperature
Anisotropic etch	From minutes up to one day	70–100

The development of anisotropic etchants solved the lateral dimension control lacking in isotropic etchants. Lateral mask geometries on planar photoengraved substrates can be controlled with an accuracy and reproducibility of 0.5  $\mu\text{m}$  or better, and the anisotropic nature of the etchant allows this accuracy to be translated into control of the vertical etch profile. Different etch stop techniques, needed to control the membrane thickness, are available. The invention of these etch stop techniques truly made items as shown in [Figure 16.1](#) manufacturable.

While anisotropic etchants solve the lateral control problem associated with deep etching, they are not without problems. They are slower, even in the fast etching  $\langle 100 \rangle$  direction, with etch rates of 1  $\mu\text{m}/\text{min}$  or less. That means that etching through a wafer is a time-consuming process: to etch through a 300- $\mu\text{m}$ -thick wafer one needs 5 hours. They also must be run hot to achieve these etch rates (85 to 115°C), precluding many simple masking options. Like the isotropic etchants, their etch rates are temperature sensitive; however, they are not particularly agitation sensitive, considered to be a major advantage.

### **Anisotropic Etchants**

A wide variety of etchants have been used for anisotropic etching of silicon, including alkaline aqueous solutions of KOH, NaOH, LiOH, CsOH,  $\text{NH}_4\text{OH}$ , and quaternary ammonium hydroxides, with the possible addition of alcohol. Alkaline organics such as ethylenediamine, choline (trimethyl-2-hydroxyethyl ammonium hydroxide) or hydrazine with additives such as pyrocatechol and pyrazine are employed as well. Etching of silicon occurs without the application of an external voltage and is dopant insensitive over several orders of magnitude, but in a curious contradiction to its suggested chemical nature, it has been shown to be bias dependent [Allongue et al., 1993; Palik et al., 1987]. This contradiction will be explained with the help of the chemical models presented below.

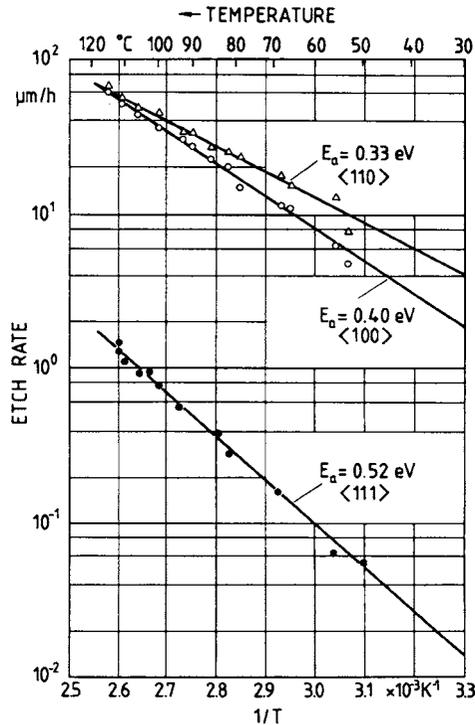

Alcohols such as propanol and isopropanol butanol typically slow the attack on Si [Linde and Austin, 1992; Price, 1973]. The role of pyrocatechol [Finne and Klein, 1967] is to speed up the etch rate through complexation of the reaction products. Additives such as pyrazine and quinone have been described as catalysts by some [Reisman et al., 1979]; but this is contested by other authors [Seidel et al., 1990]. The etch rate in anisotropic etching is reaction rate controlled and thus temperature dependent. The etch rate for all planes increases with temperature and the surface roughness decreases with increasing temperature, so etching at the higher temperatures gives the best results. In practice, etch temperatures of 80 to 85°C are used to avoid solvent evaporation and temperature gradients in the solution.

### **Arrhenius Plots for Anisotropic Etching**

A typical set of Arrhenius plots for  $\langle 100 \rangle$ ,  $\langle 110 \rangle$  and  $\langle 111 \rangle$  silicon etching in an anisotropic etchant (EDP, or ethylene-diamine/pyrocatechol) is shown in [Figure 16.26](#) [Seidel et al., 1990]. It is seen that the temperature dependence of the etch rate is quite large and is less dependent on orientation. The slope differs for the different planes, i.e.,  $(111) > (100) > (110)$ . Lower activation energies in Arrhenius plots correspond to higher etch rates. The anisotropy ratio (AR) derived from this figure is

$$\text{AR} = (hkl)_1 \text{ etch rate} / (hkl)_2 \text{ etch rate} \quad (16.29)$$

The AR is approximately 1 for isotropic etchants and can be as high as 400/200/1 for  $(110)/(100)/(111)$  in 50 wt% KOH/ $\text{H}_2\text{O}$  at 85°C. Generally, the activation energies of the etch rates of EDP are smaller than those of KOH. The (111) planes always etch slowest but the sequence for (100) and (110) can be reversed (e.g., 50/200/8 in 55 vol% ethylenediamine ED/ $\text{H}_2\text{O}$ ; also at 85°C). The (110) Si plane etches 8 times slower and the (111) 8 times faster in KOH/ $\text{H}_2\text{O}$  than in ED/ $\text{H}_2\text{O}$ , while the (100) etches at the same rate [Kendall and Guel, 1985]. Working with alcohols and other organic additives often changes the relative etching rate of the different Si planes. Along this line, Seidel et al. (1990a; 1990b) found that the decrease in etch rate by adding isopropyl alcohol to a KOH solution was 20% for  $\langle 100 \rangle$ , but almost 90% for  $\langle 110 \rangle$ . As a result of the much stronger decrease of the etch rate on a (110) surface, the etch ratio of  $(100):(110)$  is reversed.

**FIGURE 16.26** Vertical etch rates as a function of temperature for different crystal orientations: (100), (110) and (111). Etch solution is EDP (133 ml H<sub>2</sub>O, 160 g pyrocatechol, 6 g pyrazine and 1 l ED). (From Seidel, H. et al., *J. Electrochem. Soc.*, 137, 3612–3626, 1990. With permission.)

### **Important Anisotropic Etchant Systems**

In choosing an etchant, a variety of issues must be considered:

- Ease of handling
- Toxicity
- Etch rate
- Desired topology of the etched bottom surface
- IC-compatibility
- Etch stop
- Etch selectivity over other materials
- Mask material and thickness of the mask

The principal characteristics of four different anisotropic etchants are listed in [Table 16.9](#). The most commonly used are KOH [Stoller and Wolff, 1966; Stoller, 1970; Forster and Singleton, 1966; Kenney, 1967; Lepselter, 1966; 1967; Waggener, 1970; Kragness and Waggener, 1973; Waggener et al., 1967a; 1967b; Bean and Ruyan, 1977; Rodgers et al., 1976; 1977; Ammar and Rodgers, 1980; Seidel et al., 1969; 1990; Kendall and de Guel, 1985; Lee, 1990; Noworolski et al., 1995; Waggener and Dalton, 1972; Weirauch, 1975; Clemens, 1973; Bean et al., 1974; Declercq et al., 1975] and ethylene-diamine/ pyrocatechol + water (EDP) [Finne and Klein, 1967; Reisman et al., 1979; Wu et al., 1986]; hydrazine-water rarely is used [Declercq et al., 1975; Mehregany and Senturia, 1988]. More recently, quaternary ammonium hydroxide solutions such as tetraethyl ammonium hydroxide (TEAH) have become more popular [Asano et al., 1976; Tabata et al., 1990]. Each has its advantages and problems. NaOH is not used much anymore [Pugacz-Muraszkiewicz and Hammond, 1977].

**TABLE 16.9** Principal Characteristics of Four Different Anisotropic Etchants<sup>a</sup>

Etchant/Diluent/Additives/ Temperature	Etch Stop	Etch Rate (100) ( $\mu\text{m}/\text{min}$ )	Etch Rate Ratio (100)/(111)	Remarks	Mask (Etch Rate)
KOH/water, isopropyl alcohol additive, 85°C	$B > 10^{20} \text{ cm}^{-3}$ reduces etch rate by 20	1.4	400 and 600 for (110)/(111)	IC incompatible, avoid eye contact, etches oxide fast, lots of $\text{H}_2$ bubbles	Photoresist (shallow etch at room temperature); $\text{Si}_3\text{N}_4$ (not attacked); $\text{SiO}_2$ (28 Å/min)
Ethylene diamine pyrocatechol (water), pyrazine additive, 115°C	$\geq 5 \times 10^{19} \text{ cm}^{-3}$ reduces the etch rate by 50	1.25	35	Toxic, ages fast, $\text{O}_2$ must be excluded, few $\text{H}_2$ bubbles, silicates may precipitate	$\text{SiO}_2$ (2–5 Å/min); $\text{Si}_3\text{N}_4$ (1 Å/min); Ta, Au, Cr, Ag, Cu
Tetramethyl ammonium hydroxide (TMAH) (water), 90°C	$> 4 \times 10^{20} \text{ cm}^{-3}$ reduces etch rate by 40	1	From 12.5 to 50	IC compatible, easy to handle, smooth surface finish, few studies	$\text{SiO}_2$ etch rate is 4 orders of magnitude lower than (100) Si LPCVD $\text{Si}_3\text{N}_4$
$\text{N}_2\text{H}_4$ /(water), isopropyl alcohol, 115°C	$> 1.5 \times 10^{20} \text{ cm}^{-3}$ practically stops the etch	3.0	10	Toxic and explosive, okay at 50% water	$\text{SiO}_2$ (<2 Å/min) and most metallic films; does not attack Al according to some authors [Wise, 1985]

<sup>a</sup> Given the many possible variables, the data in the table are only typical examples.

Hydrazine-water is explosive at high hydrazine concentrations (rocket fuel) and is a suspected carcinogen. Its use should be avoided for safety reasons. A 50% hydrazine/water solution is stable, though, and, according to Mehregany and Senturia (1988), excellent surface quality and sharply defined corners are obtained in Si. Also on the positive side, the etchant has a very low SiO<sub>2</sub> etch rate and will not attack most metal masks except for Al, Cu and Zn. According to Wise, on the other hand, Al does not etch in hydrazine either, but the etch produces rough Si surfaces [Wise, 1985].

Ethylenediamine in EDP reportedly causes allergic respiratory sensitization, and pyrocatechol is described as a toxic corrosive. The material is also optically dense, making end-point detection harder, and it ages quickly; if the etchant reacts with oxygen, the liquid turns to a red-brown color and it loses its good properties. If cooled down after etching, one gets precipitation of silicates in the solution. Sometimes one even gets precipitation during etching, spoiling the results. When preparing the solution, the last ingredient added should be the water, since water addition causes the oxygen sensitivity. All of the above make the etchant quite difficult to handle. But, a variety of masking materials can be used in conjunction with this etchant and it is less toxic than hydrazine. No sodium or potassium contamination occurs with this compound and the etch rate of SiO<sub>2</sub> is slow. The ratio of etch rates of Si and SiO<sub>2</sub> using EDP can be as large as 5000:1 (about 2 Å/min of SiO<sub>2</sub> compared to 1 μm/min of Si) which is much larger than the ratio in KOH a ratio of as high as 400:1 has been reported [Bean, 1978]. Importantly, the etch rate slows down at a lower boron concentration than with KOH. A typical fastest-to-slowest hierarchy of Si etch rates with EDP at 85°C according to Barth (1984) is (110) > (411) > (311) > (511) > (211) > (100) > (331) > (221) > (111).

The simple KOH water system is the most popular etchant. A KOH etch, in near saturated solutions (1:1 in water by weight) at 80°C, produces a uniform and bright surface. Nonuniformity of etch rate gets considerably worse above 80°C. Plenty of bubbles are seen emerging from the Si wafer while etching in KOH. The etching selectivity between Si and SiO<sub>2</sub> is not very good in KOH, as it etches SiO<sub>2</sub> too fast. KOH is also incompatible with the IC fabrication process and can cause blindness when it gets in contact with the eyes. The etch rate for low index planes is maximal at around 4 M (see Figure 16.27A [Peeters, 1994] and Lambrechts and Sansen [1992]). The surface roughness continuously decreases with increasing concentration as can be gleaned from Figure 16.27B. Since the difference in etch rates for different KOH concentrations is small, a highly concentrated KOH (e.g., 7 M) is preferred to obtain a smooth surface on low index planes.

Except at very high concentrations of KOH, the etched (100) plane becomes rougher the longer one etches. This is thought to be due to the development of hydrogen bubbles, which hinder the transport of fresh solution to the silicon surface [Ternz, 1988]. Average roughness,  $R_a$ , is influenced strongly by fluid agitation. Stirring can reduce the  $R_a$  values over an order of magnitude, probably caused by the more efficient removal of hydrogen bubbles from the etching surface when stirring [Gravesen, 1986]. The silicon etch rate as a function of KOH concentration is shown in Figure 16.27C [Seidel et al., 1990].

Herr and Baltes (1991) found that the high-index crystal planes exhibit the highest etch rates for 6 M KOH and that for lower concentrations the etch bottoms disintegrate into microfacets. In 6 M KOH, the etch-rate order is (311) > (144) > (411) > (133) > (211) > (122). These authors could not correlate the particular etch rate sequence with the measured activation energies. This is in contrast to lower activation energies corresponding to higher etching rates for low index planes as shown in Figure 16.26. Their results obtained on large open area structures differ significantly from previous ones obtained by underetching special mask patterns. The vertical etching rates obtained here are substantially higher than the underetching rates described elsewhere, and the etch rate sequence for different planes is also significantly different. These results suggest that crevice effects may play an important role in anisotropic etching.

Besides KOH [Clark and Edell, 1987], other hydroxides have been used, including NaOH [Allongue et al., 1993; Pugacz-Muraszkiewicz and Hammond, 1977], CsOH [Clark et al., 1988] and NH<sub>4</sub>OH [Schnakenberg et al., 1990]. A major disadvantage of KOH is the presence of alkali ions, which are detrimental to the fabrication of sensitive electronic parts. Work is under way to find anisotropic etchants

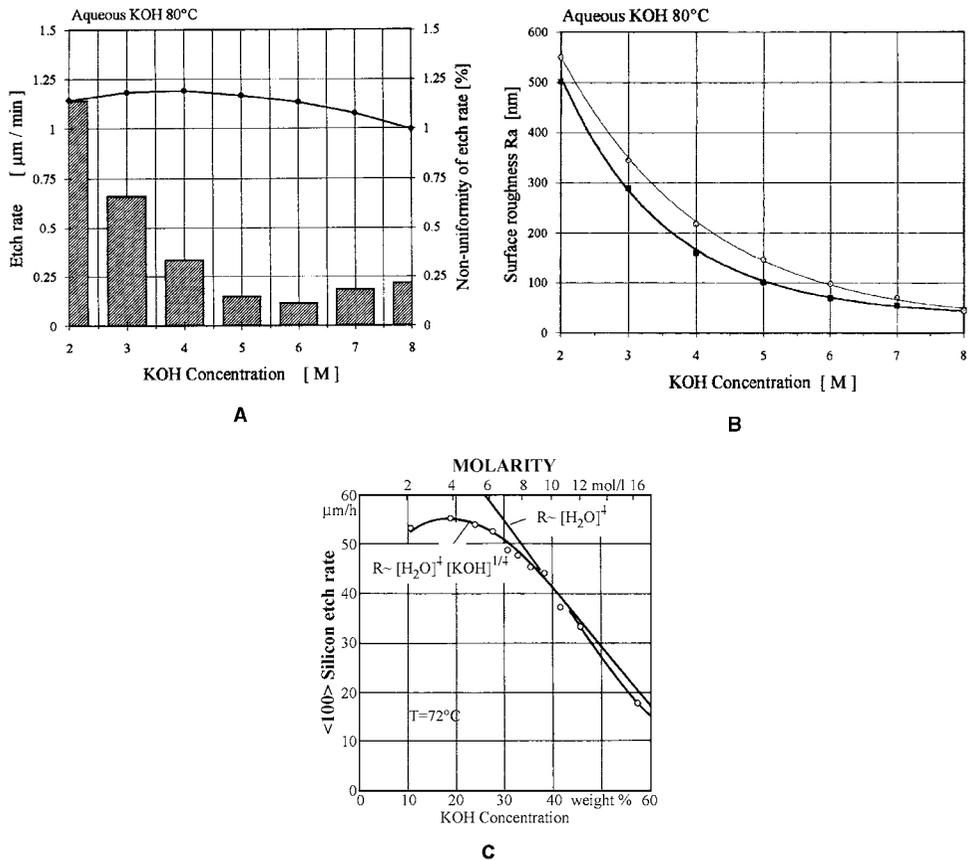

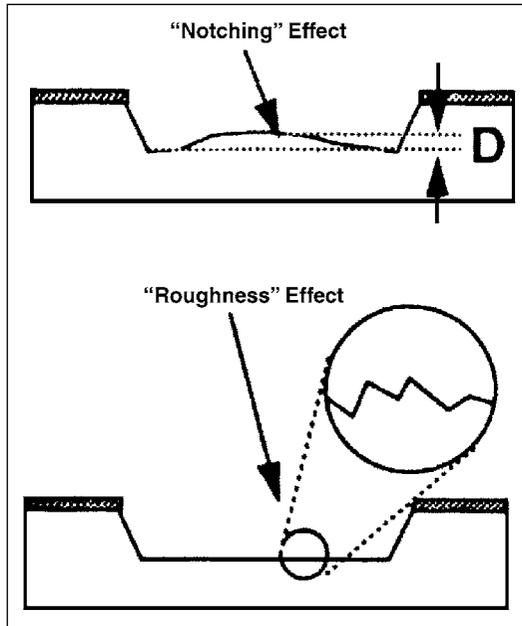

FIGURE 16.27 Anisotropic etching of silicon. (A) Silicon (100) etch rate (line) and nonuniformity of etch rate (column) in KOH at 80°C as a function of KOH concentration. The etch rate for all low index planes is maximal at around 4 M. (B) Silicon (100) surface roughness (Ra) in aqueous KOH at 80°C as a function of concentration for a 1-hour etch time (thin line) and for an etch depth of 60  $\mu\text{m}$  (thick line). (C) Silicon (100) etch rate as a function of KOH concentration at a temperature of 72°C. (A and B from Peeters, E., Ph.D. thesis, 1996, KUL, Belgium. With permission. C from Seidel et al., *J. Electrochem. Soc.*, 137, 3612–3626, 1990. With permission.)

that are more compatible with CMOS processing and that are neither toxic nor harmful. Two examples are ammonium hydroxide-water (AHW) mixtures [Schnakenberg et al., 1990] and tetramethyl ammonium hydroxide-water (TMAHW) mixtures [Tabata et al., 1990; Schnakenberg et al., 1990]. TMAHW solutions do not decompose at temperatures below 130°C, a very important feature from the viewpoint of production. They are nontoxic and can be handled easily. TMAHW solutions also exhibit excellent selectivity to silicon oxide and silicon nitride. At a solution temperature of 90°C and 22 wt% TMAH, a maximum (100) silicon etch rate of 1.0  $\mu\text{m}/\text{min}$  is observed, 1.4  $\mu\text{m}/\text{min}$  for (110) planes (this is higher than those observed with EDP, AHW, hydrazine water and tetraethyl ammonium hydroxide [TEA], but slower than those observed for KOH and an anisotropy ratio,  $\text{AR}(100)/(111)$ , of between 12.5 and 50 [Tabata et al., 1992]). From the viewpoint of fabricating various silicon sensors and actuators, a concentration above 22 wt% is preferable, since lower concentrations result in larger roughness on the etched surface. However, higher concentrations give a lower etch rate and lower etch ratio (100)/(111). Tabata (1995) also studied the etching characteristics of pH-controlled TMAHW. To obtain a low aluminum etching rate of 0.01  $\mu\text{m}/\text{min}$ , pH values below 12 for 22 wt% TMAHW were required. At those pH values the Si(100) etching rate is 0.7  $\mu\text{m}/\text{min}$ .

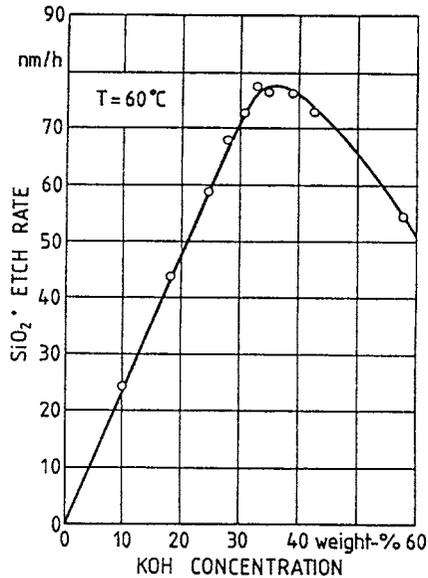

*Macroscopic roughness (notching effect) and microscopic roughness.*

### **Surface Roughness and Notching**

Anisotropic etchants frequently leave too rough a surface behind, and a slight isotropic etch is used to 'touch-up'. A distinction must be made between *macroscopic* and *microscopic roughness*. Macroscopic roughness, also referred to as notching or pillowing, results when centers of exposed areas etch with a seemingly lower average speed compared with the borders of the areas, so that the corners between sidewalls and (100) ground planes are accentuated. Membranes or double-sided clamped beams (microbridges) therefore tend to be thinner close to the clamped edges than in the center of the structure. This difference can be as large as 1 to 2  $\mu\text{m}$ , which is quite considerable if one is etching 10 to 20  $\mu\text{m}$  thick structures. Notching increases linearly with etch depth but decreases with higher concentrations of KOH. The microscopic smoothness of originally mirror-like polished wafers can also be degraded into microscopic roughness. It is this type of short-range roughness we referred to in discussing [Figure 16.27B](#) above.

### **Masking for Anisotropic Etchants**

Etching through a whole wafer (400 to 600  $\mu\text{m}$ ) takes several hours (a typical wet anisotropic etch rate being 1.1  $\mu\text{m}/\text{min}$ ), definitely not a fast process. When using KOH,  $\text{SiO}_2$  cannot be used as a masking material for features requiring that long an exposure to the etchants. The  $\text{SiO}_2$  etch rate as a function of KOH concentration at 60°C is shown in [Figure 16.28](#). There is a distinct maximum at 35 wt% KOH of nearly 80 nm/hr. The shape of this curve will be explained further below on the basis of Seidel et al.'s model. Experiments have shown that even a 1.5- $\mu\text{m}$ -thick oxide is not sufficient for the complete etching of a 380- $\mu\text{m}$ -thick wafer (6 hours) because of pinholes in the oxide [Lambrechts and Sansen, 1992]. The etch rate of thermally grown  $\text{SiO}_2$  in KOH- $\text{H}_2\text{O}$  somewhat varies and apparently depends not only on the quality of the oxide, but also on the etching container and the age of the etching solution, as well as other factors [Kendall, 1979]. The Si/ $\text{SiO}_2$  selectivity ratio at 80°C in 7 M KOH is  $30 \pm 5$ . This ratio increases with decreasing temperature; reducing the temperature from 80 to 60°C increases the selectivity ratio from 30 to 95 in 7 M KOH [Kendall, 1975]. Thermal oxides are under strong compressive stress due to the fact that in the oxide layer one silicon atom takes nearly twice as much space as in single crystalline Si (see also Madou [1997, chap. 3]). This might have severe consequences; for example, if the oxide mask is stripped on one side of the wafer, the wafer will bend. Atmospheric pressure chemical vapor deposited (APCVD)  $\text{SiO}_2$  tends to exhibit pinholes and etches much faster than thermal oxide.

**FIGURE 16.28** The SiO<sub>2</sub> etch rate in nm/hr as a function of KOH concentration at 60°C. (From Seidel, H. et al., *J. Electrochem. Soc.*, 137, 3612–3626, 1990. With permission.)

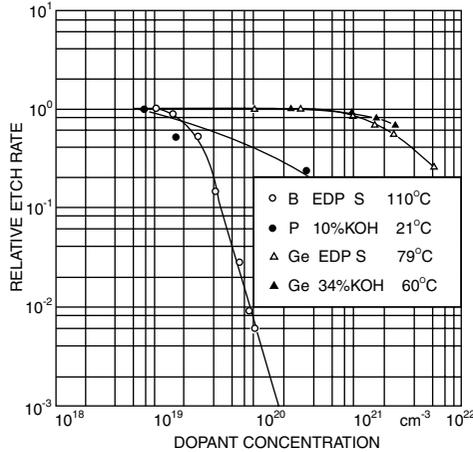

Annealing of APCVD oxide removes the pinholes but the etch rate in KOH remains greater by a factor of 2 to 3 than that of thermal oxide. Low pressure chemical vapor deposited (LPCVD) oxide is a mask material of comparable quality as thermal oxide. The etch rate of SiO<sub>2</sub> in EDP is smaller by two orders of magnitude than in KOH.

For prolonged KOH etching, a high density silicon nitride mask has to be deposited. A low pressure chemical vapor deposited (LPCVD) nitride generally serves better for this purpose than a less dense plasma deposited nitride [Puers, 1991]. With an etch rate of less than 0.1 nm/min, a 400-Å layer of LPCVD nitride suffices to mask against KOH etchant. The etch selectivity Si/Si<sub>3</sub>N<sub>4</sub> was found to be better than 10<sup>4</sup> in 7 M KOH at 80°C. The nitride also acts as a good ion-diffusion barrier, protecting sensitive electronic parts. Nitride can easily be patterned with photoresist and etched in a CF<sub>4</sub>/O<sub>2</sub>-based plasma or, in a more severe process, in H<sub>3</sub>PO<sub>4</sub> at 180°C (10 nm/min) [Buttgenbach, 1991]. Nitride films are typically under a tensile stress of about 1 × 10<sup>9</sup> Pa. If in the overall processing of the devices, nitride deposition does not pose a problem, KOH emerges as the preferential anisotropic wet etchant. For dopant dependent etching, EDP is the better etchant and generally better suited for deep etching since its oxide etch rate is negligible (<5 Å/min).

Oxide and nitride are masking for anisotropic etchants to varying degrees with both mask types being used. When these layers are used to terminate an etch in the [100] direction, a low etch rate of the mask layer allows overetching of silicon, to compensate for wafer thickness variations. A KOH solution etches SiO<sub>2</sub> at a relatively fast rate of 1.4 to 3 nm/min so that Si<sub>3</sub>N<sub>4</sub> or Au/Cr must be used as a mask against KOH for deep and long etching.

### **Backside Protection**

In many cases it is necessary to protect the backside of a wafer from an isotropic or anisotropic etchant. The backside is either mechanically or chemically protected. In the mechanical method the wafer is held in a holder, often made from Teflon. The wafer is fixed between Teflon-coated O-rings which are carefully aligned in order to avoid mechanical stress in the wafer. In the chemical method, waxes or other organic coatings are spun onto the back side of the wafer. Two wafers may be glued back-to-back for faster processing.

**FIGURE 16.29** Relative etch rate for (100) Si in EDP and KOH solutions as a function of concentration of boron, phosphorus and germanium. (From Seidel, H. et al., *J. Electrochem. Soc.*, 137, 3626–3632, 1990. With permission.)

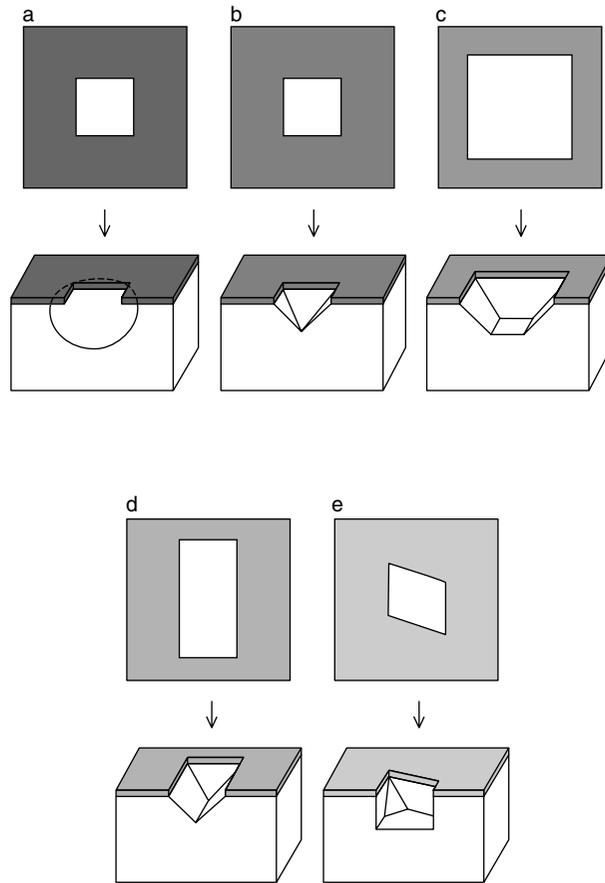

### Etch Rate and Etch Stops

The Si etch rate,  $R$ , as a function of KOH concentration at 72°C, was shown in Figure 16.27C. The etch rate has a maximum at about 20% KOH. The best fit for this experimentally determined etch rate, for most KOH concentrations, is [Seidel et al., 1990a; 1990b]

$$R = k[\text{H}_2\text{O}]^4[\text{KOH}]^{\frac{1}{4}} \quad (16.30)$$

Any model of anisotropic etching will have to explain this peculiar dependency on the water and KOH concentration, as well as the fact that all anisotropic etchant systems of Table 16.9 exhibit drastically reduced etch rates for high boron concentrations in silicon ( $\geq 5 \times 10^{19} \text{ cm}^{-3}$  solid solubility limit). Other impurities (P, Ge) also reduce the etch rate, but at much higher concentrations (see Figure 16.29 [Seidel et al., 1990]). Boron typically is incorporated using ion implantation (thin layers) or liquid/solid source deposition (thick layers  $> 1 \mu\text{m}$ ). These doped layers are used as very effective etch stop layers (see below). Hydrazine or EDP, which displays a smaller (100)-to-(111) etch rate ratio ( $\sim 35$ ) than KOH, exhibits a stronger boron concentration dependency. The etch rate in KOH is reduced by a factor of 5 to 100 for a boron concentration larger than  $10^{20} \text{ cm}^{-3}$ . When etching in EDP, the factor climbs to 250 [Bogh, 1971]. With TMAHW solutions, the Si etch rate decreases to 0.01  $\mu\text{m}/\text{min}$  for boron concentrations of about  $4 \times 10^{20} \text{ cm}^{-3}$  [Steinsland et al., 1995]. The mechanism eludes us, but Seidel et al.'s model (see below) gives the most plausible explanation for now. Some of the different mechanisms to explain etch stop effects that have been suggested follow:

1. Several observations suggest that doping leads to a more readily oxidized Si surface. Highly boron- or phosphorus-doped silicon in aqueous KOH spontaneously can form a thin passivating oxide layer [Palik et al., 1982; 1985]. The boron-oxides and -hydroxides initially generated on the silicon surface are not soluble in KOH or EDP etchants [Petersen, 1982]. The substitutional boron creates local tensile stress in the silicon, increasing the bond strength so that a passivating oxide might be more readily formed at higher boron concentrations. Boron-doped silicon has a high defect density (slip planes), encouraging oxide growth.
2. Electrons produced during oxidation of silicon are needed in a subsequent reduction step (hydrogen evolution in Reaction 16.2). When the hole density passes  $10^{19} \text{ cm}^{-3}$  these electrons combine with holes instead, thus stopping the reduction process [Palik et al., 1982]. Seidel et al.'s model follows this explanation (see below).

**FIGURE 16.30** Isotropic and anisotropic etched features in  $\langle 100 \rangle$  and  $\langle 110 \rangle$  wafers. (a) isotropic etch; (b) to (e) anisotropic etch. (a) to (d):  $\langle 100 \rangle$  oriented wafers and (e):  $\langle 110 \rangle$  oriented wafer.

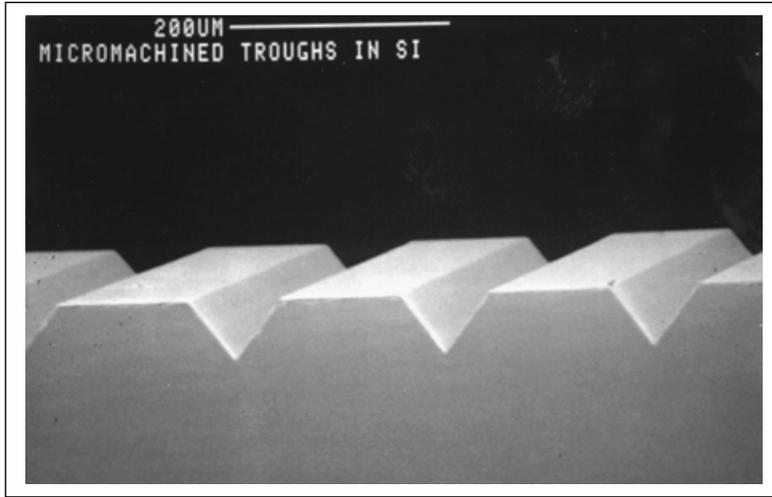

3. Silicon doped with boron is under tension as the smaller boron atoms enter the lattice substitutionally. The large local tensile stress at high boron concentration makes it energetically more favorable for the excess boron (above  $5 \times 10^{19} \text{ cm}^{-3}$ ) to enter interstitial sites. The strong B-Si bonds bind the lattice rigidly. With high enough doping the high binding energy can stop etching [Petersen, 1982]. This hypothesis is similar to item 1, except that no oxide formation is invoked.

In what follows we review the results of some typical anisotropic etching experiments.

#### 16.5.1.4 Anisotropically Etched Structures

##### Examples

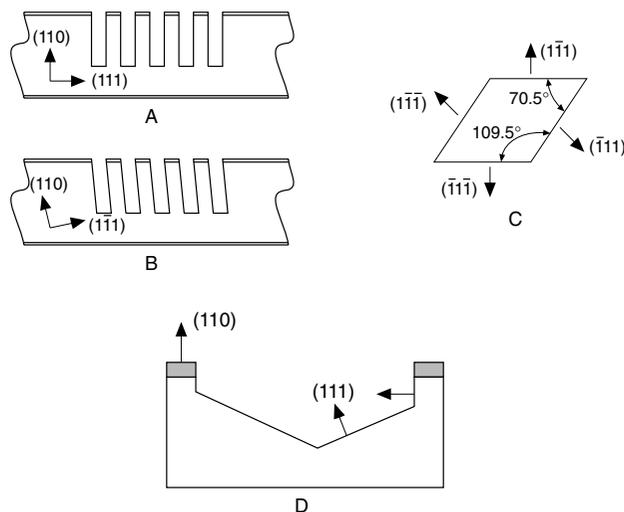

In Figure 16.30 we compare a wet isotropic etch (a) with examples of anisotropic etches (b to e). In the anisotropic etching examples, a square (b and c) and a rectangular pattern (d) are defined in an oxide mask with sides aligned along the  $\langle 110 \rangle$  directions on a  $\langle 100 \rangle$ -oriented silicon surface. The square openings are precisely aligned (within one or two degrees) with the  $\langle 110 \rangle$  directions on the (100) wafer surface to obtain pits that conform exactly to the oxide mask rather than undercutting it. Most (100) silicon wafers have a main flat parallel to a  $\langle 110 \rangle$  direction in the crystal, allowing for an easy alignment of the mask (see Figure 16.5). Etching with the square pattern results in a pit with well-defined  $\{111\}$  sidewalls (at angles of  $54.74^\circ$  to the surface) and a (100) bottom.

*Long V-shaped grooves in a (100) Si wafer.*

The dimensions of the hole at the bottom of the pit, as we saw above, are given by Eq. (16.2). The larger the square opening in the mask, the deeper the point where the  $\{111\}$  sidewalls of the pit intersect. If the oxide opening is wide enough, i.e.,  $W_m > \sqrt{2} z$  (with  $z = 600 \mu\text{m}$  for a typical 6-in. wafer, this means  $W_m > 849 \mu\text{m}$ ), the  $\{111\}$  planes do not intersect within the wafer (see also earlier in this chapter). The etched pit in this particular case extends all the way through the wafer, creating a small square opening on the bottom surface. As shown in Figure 16.30 (b to d), no under-etching of the etch mask is observed due to the perfect alignment of the concave oxide mask opening with the  $\langle 110 \rangle$  direction. In Figure 16.30a, an undercutting isotropic etch (acidic) is shown. Misalignment in the case of an anisotropic etch still results in pyramidal pits, but the mask will also be severely undercut. A rectangular pattern aligned along the  $\langle 110 \rangle$  directions on a  $\langle 100 \rangle$  wafer leads to *long V-shaped grooves* (see Figure 16.30d) or an open slit, depending on the width of the opening in the oxide mask.

Using a properly aligned mask on a  $\langle 110 \rangle$  wafer, holes with four vertical walls ( $\{111\}$  planes) result (see Figure 16.30e and Figure 16.31A and C). Figure 16.31B shows that a slight mask misorientation

**FIGURE 16.31** Anisotropic etching of  $\langle 110 \rangle$  wafers. (A) Closely spaced grooves on correctly oriented (110) surface. (B) Closely spaced grooves on misoriented  $\langle 110 \rangle$  wafer. (C) Orientations of the  $\{111\}$  planes looking down on a (110) wafer. (D) Shallow slanted (111) planes eventually form the bottom of the etched cavity.

leads to all skewed sidewalls. A U-groove based on a rectangular mask with the long sides along the  $\langle 111 \rangle$  directions and anisotropically etched in (110) silicon has a complex shape delineated by six  $\{111\}$  planes, four vertical and two slanted (see [Figure 16.31D](#)). Before emergence of  $\{111\}$  planes, the U-groove is defined by four vertical (111) planes and a horizontal (110) bottom. Self-stopping occurs when the tilted end planes intersect at the bottom of the groove. It is easy to etch long, narrow U-grooves very deeply into a  $\langle 110 \rangle$  silicon wafer. However, it is impossible to etch a short, narrow U-groove deeply into a slice of silicon [Kendall, 1979], because the narrow dimension of the groove is quickly limited by slow-etching  $\{111\}$  planes that subtend an angle of  $35^\circ$  to the surface and cause etch termination. At a groove of length  $L = 1$  mm on the top surface, etching will stop when it reaches a depth of 0.289 mm, i.e.,  $D_{\max} = L/2 \sqrt{3}$ . For very long grooves, the tilted end planes are too far apart to intersect in practical cases, making the end effects negligible compared to the remaining U-shaped part of the groove.

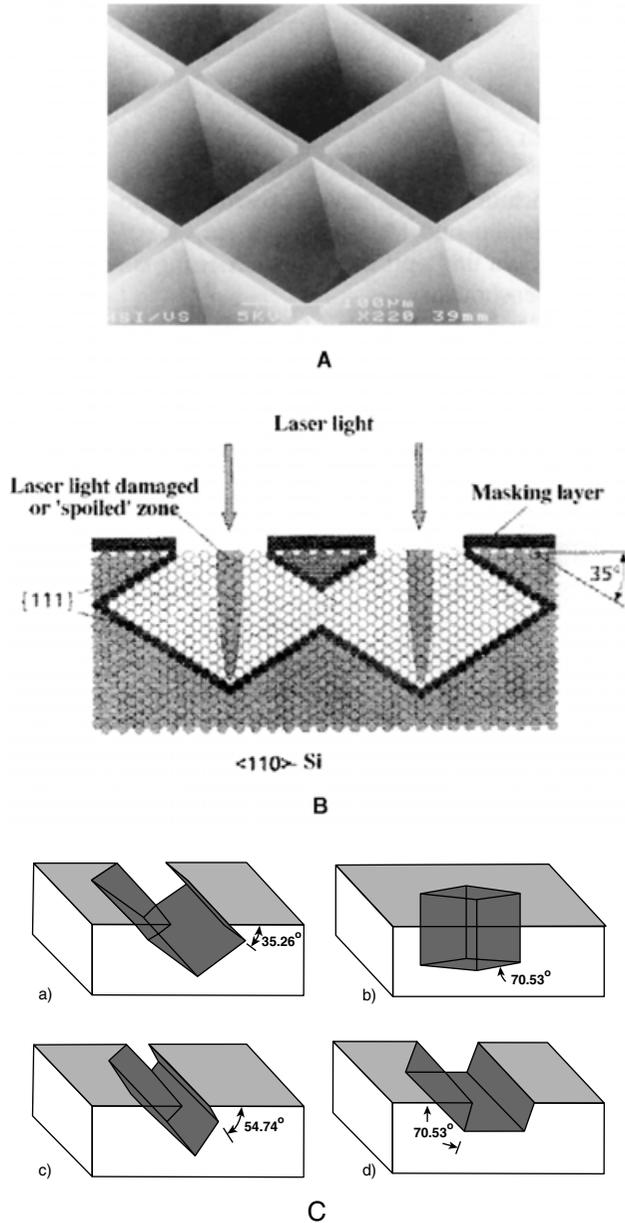

A laser can be used to melt or 'spoil' the shallow (111) surfaces, making it possible to etch deep vertical-walled holes through a (110) wafer as shown in [Figure 16.32A](#) [Schumacher et al., 1994; Barth et al., 1985; Seidel and Csepregi, 1988]. The technique is illustrated in [Figure 16.32B](#). The absorbed energy of a Nd:YAG laser beam causes a local melting or evaporation zone enabling etchants to etch the shallow (111) planes in the line-of-sight of the laser. Etching proceeds until 'unspoiled' (111) planes are encountered. Some interesting resulting possibilities, including partially closed microchannels, are shown in [Figure 16.32C](#) [Schumacher et al., 1994; Alavi et al., 1991]. Note that with this method it is possible to use  $\langle 111 \rangle$  wafers for micromachining. The light of the Nd:YAG laser is very well suited for this micromachining technique due to the 1.17-eV photon energy, just exceeding the band gap energy of Si. Details on this laser machining process can be found, for example, in Alavi et al. (1991; 1992).

Especially when machining surface structures by undercutting, the orientation of the wafer is of extreme importance. Consider, for example, the formation of a bridge in [Figure 16.33A](#) [Barth et al., 1985]. When using a (100) surface, a suspension bridge cannot form across the etched V-groove; two independent truncated V-grooves flanking a mesa structure result instead. To form a suspended bridge it must be oriented away from the  $\langle 110 \rangle$  direction. This in contrast with a (110) wafer where a microbridge crossing a V-groove with a  $90^\circ$  angle will be undercut. Convex corners will be undercut by etchant, allowing formation of cantilevers as shown in [Figure 16.33B](#). The diving board shown forms by undercutting starting at the convex corners.

To create vertical (100) faces, as shown in [Figure 16.10](#), in general only KOH works (not EDP or TMAHW) and it has to happen in high-selectivity conditions (low temperature, low concentration: 25 wt% KOH,  $60^\circ\text{C}$ ). Interestingly, high concentration KOH (45 wt%) at higher temperatures ( $80^\circ\text{C}$ ) produces a smooth sidewall, controllable and repeatable at an angle of  $80^\circ$ . EDP produces  $45^\circ$  angled planes and TMAHW usually makes a  $30^\circ$  angle [Palik et al., 1985].

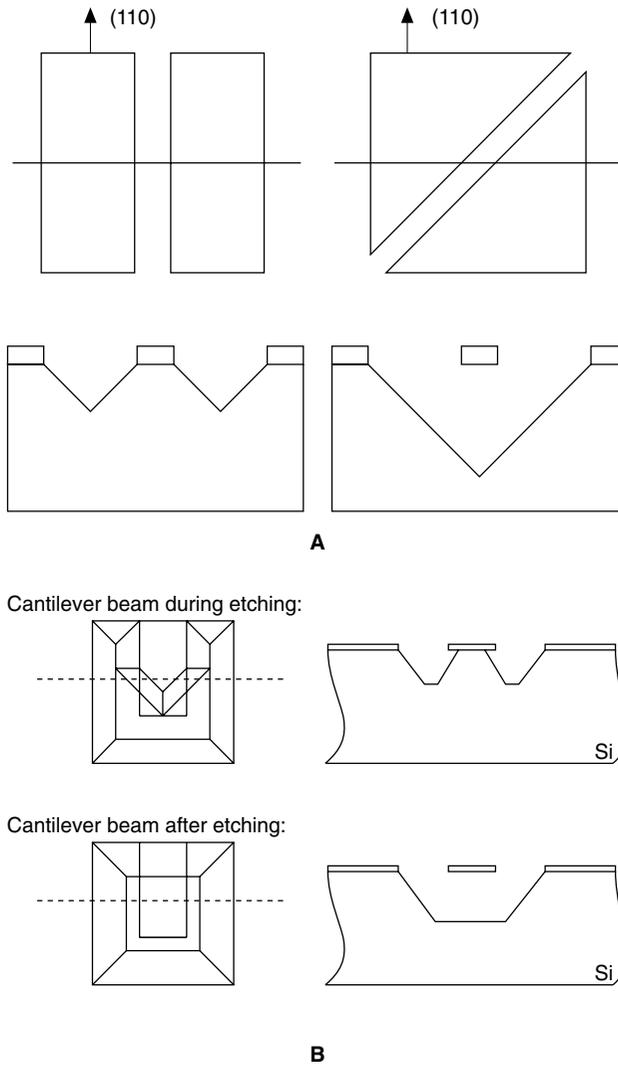

### **Alignment Patterns**

When alignment of a pattern is critical, pre-etch alignment targets become useful to delineate the planes of interest since the wafer flats often are aligned to  $\pm 1^\circ$  only. In order to find the proper alignment for the mask, a test pattern of closely spaced lines can be etched (see [Figure 16.34](#)). The groove with the best vertical walls determines the proper final mask orientation. Along this line, Ciarlo (1987) made a set of lines 3 mm long and  $8 \mu\text{m}$  wide, fanning out like spokes in a wagon wheel at angles  $0.1^\circ$  apart. This target was printed near the perimeter of the wafer and then etched  $100 \mu\text{m}$  into the surface. Again, by evaluating the undercut in this target the correct crystal direction could be determined. Alignment with better than  $0.05^\circ$  accuracy was accomplished this way. Similarly, to obtain detailed experimental data on crystal orientation dependence of etch rates, Seidel et al. (1990) used a wagon-wheel or star-shaped mask (e.g., made from CVD- $\text{Si}_3\text{N}_4$ ;  $\text{SiH}_4$  and  $\text{NH}_3$  at  $900^\circ\text{C}$ ), consisting of radially divergent segments with an angular separation of one degree. Yet finer  $0.1^\circ$  patterns were made around the principal crystal directions. The etch pattern emerging on a  $\langle 100 \rangle$  oriented wafer covered with such a mask is shown in [Figure 16.35A](#). The blossom-like figure is due to the total underetching of the passivation layer in the vicinity of the center of the wagon wheel,

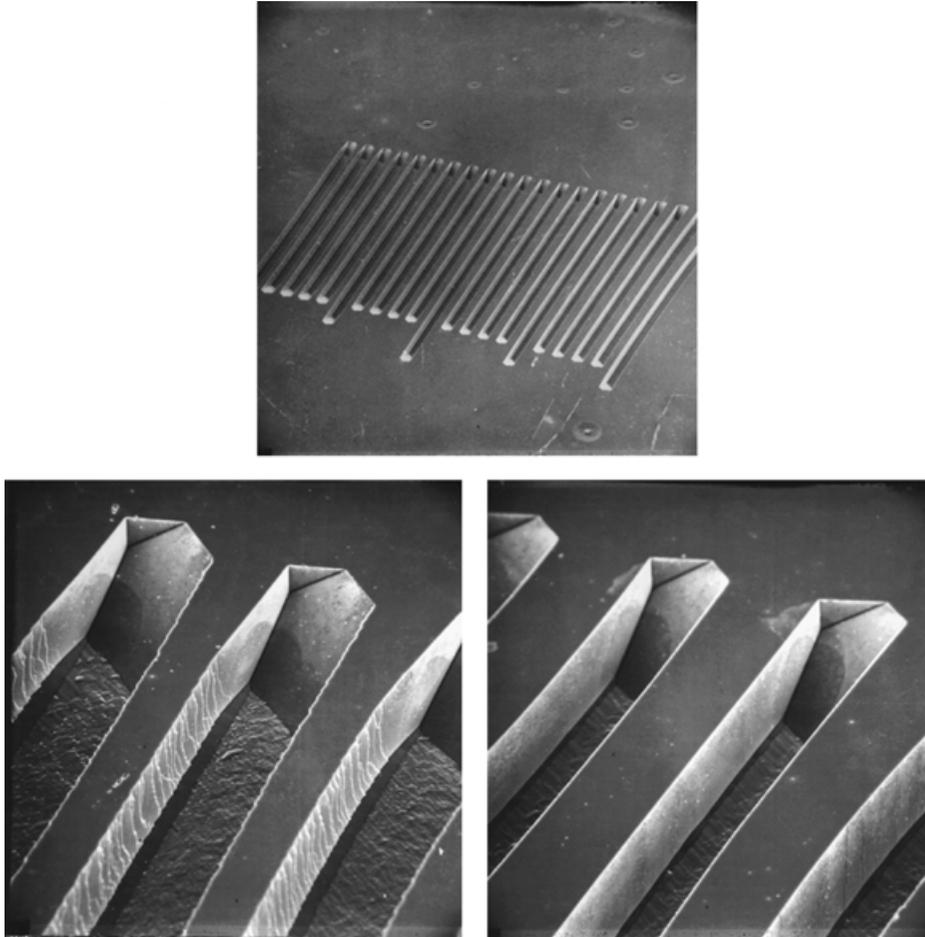

**FIGURE 16.32** Laser/KOH machining. (A) Holes through a (110) Si wafer created by laser spoiling and subsequent KOH etching. The two sets of (111) planes making an angle of  $70^\circ$  are the vertical walls of the hole. The (111) planes making a  $35^\circ$  angle with the surface tend to limit the depth of the hole but laser spoiling enables one to etch all the way through the wafer (see also B [c]). (B) After laser spoiling, the line-of-sight (111) planes are spoiled and etching proceeds until unspoiled (111) planes are reached. (C) Some of the possible features rendered by laser spoiling. (From Schumacher, A. et al., *Technische Rundschau*, 86, 20–23, 1994. With permission.)

leaving an area of bare exposed Si. The radial extension of the bare Si area depends on the crystal orientation of the individual segments, leading to a different amount of total underetching. The observation of these blossom-like patterns was used for qualitative guidance of etching rates only. In order to establish quantitative numbers for the lateral etch rates, the width,  $w$ , of the overhanging passivation layer was measured with an optical line-width measurement system (see Figure 16.35B).

**FIGURE 16.33** How to make (A) a suspension bridge from a (100) Si wafer and (B) a diving board from a (110) Si wafer [Barth et al., 1985].

Laser beam reflection was used to identify the crystal planes and ellipsometry was used to monitor the etching rate of the mask itself. Lateral etch rates determined in this way on  $\langle 100 \rangle$ - and  $\langle 110 \rangle$ -oriented wafers at  $95^\circ\text{C}$  in EDP (470 ml water, 11 ED, 176 g pyrocatechol) and at  $78^\circ\text{C}$  in a 50% KOH solution are shown in Figure 16.36. Etch rates shown are normal to the actual crystal surface and are conveniently described in a polar plot in which the distance from the origin to the polar plot surface (or curve in two dimensions) indicates the etch rate for that particular direction. Note the deep minima at the  $\{111\}$  planes. It can also be seen that in KOH the peak etch rates are more pronounced. A further difference is that with EDP the minimum at  $\{111\}$  planes is steeper than with KOH. For both EDP and KOH, the etch rate depends linearly on misalignment. All the above observations have important consequences for the interpretation of anisotropy of an etch (see below). The difference between KOH and EDP etching behavior around the  $\{111\}$  minima has the direct practical consequence that it is more important for etching in EDP to align the crystallographic direction more precisely than in KOH [Elwenspoek et al., 1994].

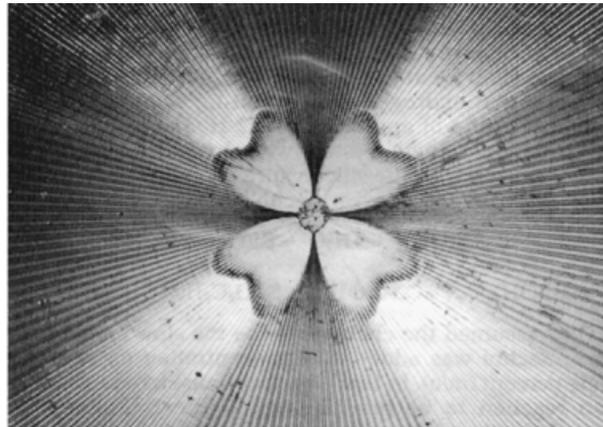

**FIGURE 16.34** Test pattern of U-grooves in a  $\langle 110 \rangle$  wafer to help in the alignment of the mask; final alignment is done with the groove that exhibits the most perfect long perpendicular walls.

When determining etch rates without using underetching masks but by using vertical etching of beveled silicon samples, results are quite different than when working with masked silicon [Herr and Baltes, 1991]. The etch rates on open areas of beveled structures are much larger than in underetching experiments with masked silicon, and different crystal planes develop. Herr et al. conclude that crevice effects may play an important role in anisotropic etching. Elwenspoek et al.'s model [Elwenspoek, 1993; Elwenspoek et al. 1994], analyzed below, is the only model which predicts such a crevice effect. He explains why, when etchants are in a small restricted crevice area and are not refreshed fast enough, etching rates slow down and increase anisotropy.

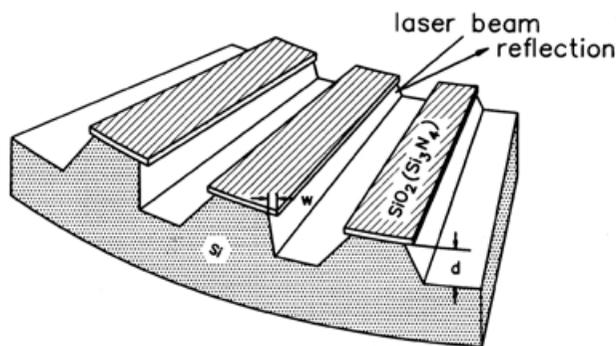

## 16.5.2 Chemical Etching Models

### 16.5.2.1 Introduction

Lots of conflicting data exist in the literature on the anisotropic etch rates of the different Si planes, especially for the higher index planes. This is not too surprising, given the multiple parameters influencing individual results: temperature, stirring, size of etching feature (i.e., crevice effect), KOH concentration, addition of alcohols and other organics, surface defects, complexing agents, surfactants, pH, cation influence etc. More rigorous experimentation and standardization will be needed, as well as better etching models, to better understand the influence of all these parameters on etch rates.

A

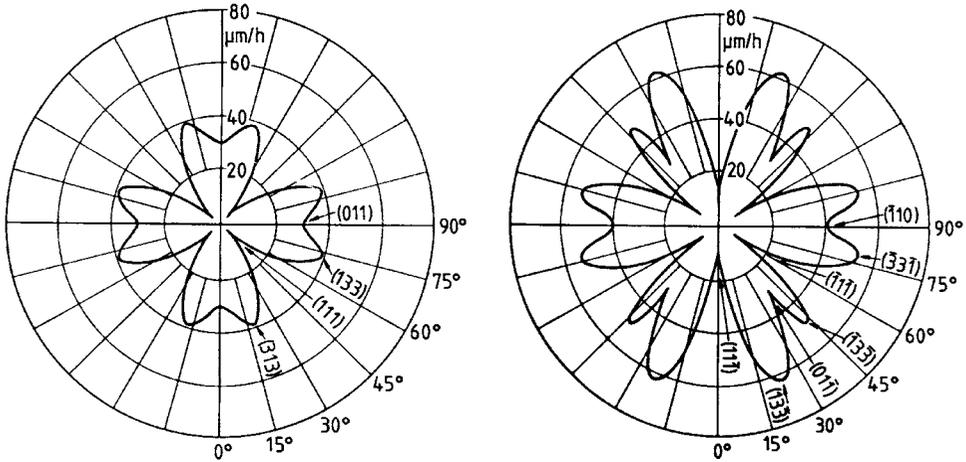

B

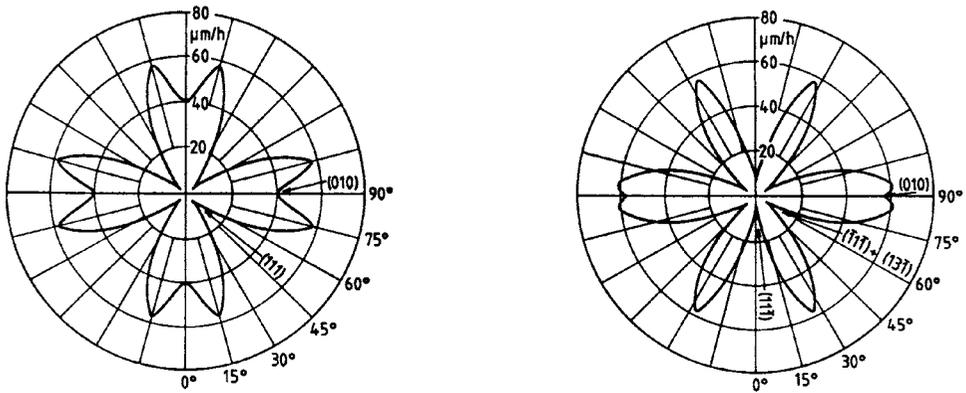

**FIGURE 16.35** (A) Etch pattern emerging on a wagon wheel-masked,  $\langle 100 \rangle$ -oriented Si wafer after etching in an EDP solution. (B) Schematic cross section of a silicon test chip covered with a wagon wheel-shaped masking pattern after etching. The measurement of 'w' is used to construct polar diagrams of lateral underetch rates as shown in Figure 16.36. (From Seidel et al., *J. Electrochem. Soc.*, 177, 3612–3626, 1990. With permission.)

Several chemical models explaining the anisotropy in etching rates for the different Si orientations have been proposed. Presently we will list all of the proposed models and compare the two most recent and most detailed models (the one by Seidel et al. [1990a; 1990b] and the one by Elwenspoek [1993] and Elwenspoek et al. [1994]). Different Si crystal properties have been correlated with the anisotropy in silicon etching.

1. It has been observed that the  $\{111\}$  Si planes present the highest density of atoms per  $\text{cm}^2$  to the etchant and that the atoms are oriented such that **three bonds are below the plane**. It is possible that these bonds become chemically shielded by surface bonded (OH) or oxygen, thereby slowing the etch rate.
2. It also has been suggested that etch rate correlates with available bond density, the surfaces with the highest bond density etching faster [Price, 1973]. The available bond densities in Si and other diamond structures follow the sequence 1:0.71:0.58 for the  $\{100\}$ ; $\{110\}$ ; $\{111\}$  surfaces. However, Kendall (1979) commented that bond density alone is an unlikely explanation because of the magnitude of etching anisotropy (e.g., a factor of 400), compared to the bond density variations of at most a factor of 2.

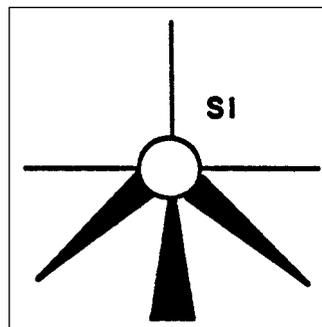

A

B

**FIGURE 16.36** Lateral underetch rates as a function of orientation for (A) EDP (470 ml water, 1 l ED, 176 g pyrocatechol) at 95°C. (B) KOH (50% solution) at 78°C. Left,  $\langle 100 \rangle$ - and right,  $\langle 110 \rangle$ -oriented Si wafers. (From Seidel, H. et al., *J. Electrochem. Soc.*, 137, 3612–3626, 1990. With permission.)

*On  $\{111\}$  planes three backbonds are below the plane.*

- Kendall (1979) explains the slow etching of  $\{111\}$  planes on the basis of their faster oxidation during etching; this does not happen on the other faces, due to greater distance of the atoms on planes other than  $(111)$ . Since they oxidize faster, these planes may be better protected against etching. The oxidation rate in particular follows the sequence  $\{111\} > \{110\} > \{100\}$ , and the etch rate often follows the

reverse sequence (see also Madou [1997, chap. 3 on Si oxidation]). In the most used KOH-H<sub>2</sub>O, however, the sequence is {110} > {100} > {111}.

4. In yet another model, it is assumed that the anisotropy is due to differences in activation energies and backbond geometries on different Si surfaces [Glembocki et al., 1985].
5. Seidel et al.'s model [Seidel et al., 1990a; 1990b] supports the previous explanation. They detail a process to explain anisotropy based on the difference in energy levels of backbond-associated surface states for different crystal orientations.
6. Finally, Elwenspoek (1993) and Elwenspoek et al. (1994) propose that it is the degree of atomic smoothness of the various surfaces that is responsible for the anisotropy of the etch rates. Basically, this group argues that the kinetics of smooth faces (the (111) plane is atomically flat) is controlled by a nucleation barrier that is absent on rough surfaces. The latter, therefore, would etch faster by orders of magnitude.

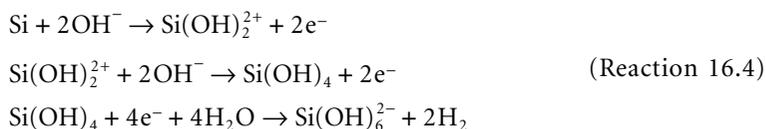

The reason why acidic media lead to isotropic etching and alkaline media to anisotropic etching was, until recently, not addressed in any of the models surveyed. In the following we will give our own model as well as Elwenspoek et al.'s to explain isotropic vs. anisotropic etching behavior.

It is our hope that the reading of this section will inspire more detailed electrochemistry work on Si electrodes. The refining of an etching model will be of invaluable help in writing more predictive Si etching software code.

### 16.5.2.2 Seidel et al.'s Model

Seidel et al.'s model is based on the fluctuating energy level model of the silicon/electrolyte interface and assumes the injection of electrons in the conduction band of Si during the etching process. Consider the situation of a piece of Si immersed in a solution without applied bias at open circuit. After immersion of the silicon crystal into the alkaline electrolyte a negative excess charge builds up on the surface due to the higher original Fermi level of the H<sub>2</sub>O/OH<sup>-</sup> redox couple as compared to the Fermi level of the solid, i.e., the work function difference is equalized. This leads to a downward bending of the energy bands on the solid surface for both p- and n-type silicon (Figure 16.37A and B). The downward bending is more pronounced for p-type than for n-type due to the initially larger difference of the Fermi levels between the solid and the electrolyte.

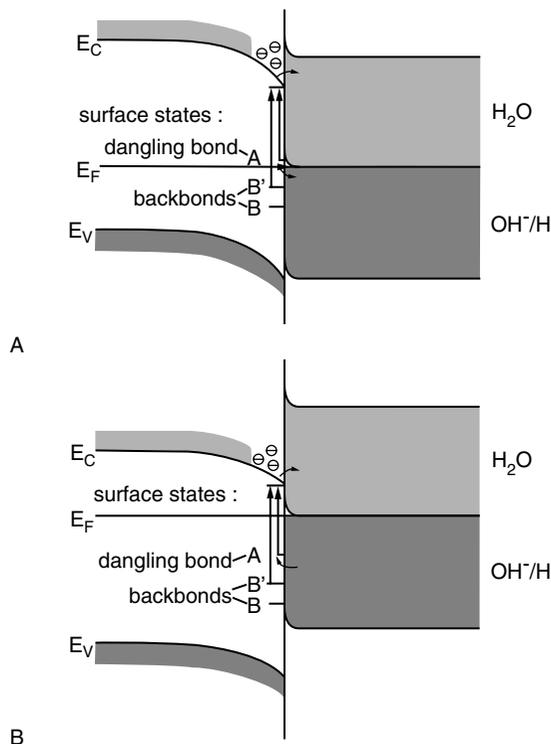

Next, hydroxyl ions cause the Si surface to oxidize, consuming water and liberating hydrogen in the process. The detailed steps, based on suggestions by Palik et al. (1985), are:

Silicate species were observed by Raman spectroscopy [Palik et al., 1983].

The overall silicon oxidation reaction consumes four electrons first injected into the conduction band, where they stay near the surface due to the downward bending of the energy bands (see Figure 16.37). Evidence for injection of four electrons rather than a mixed hole and electron mechanism was first presented by Raley et al. (1984). The authors could explain the measured etch-rate dependence on hole concentration only by assuming that the proton or water reduction reaction is rate determining and that a four-electron injection mechanism with the conduction band is involved. These injected electrons are highly 'reducing' and react with water to form hydroxide ions and hydrogen:

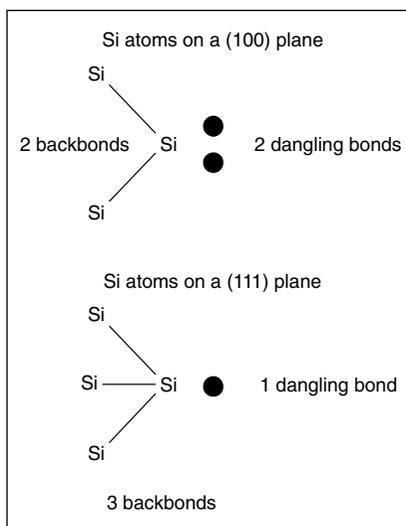

**FIGURE 16.37** Band model of the silicon/electrolyte interface for moderately doped Si (electrolyte at  $\text{pH} > 12$ ): (A) p-type Si and (B) n-type Si. We assume no applied bias and no illumination. The energy scale functions in respect to the saturated calomel electrode (SCE), an often-used reference in electrochemistry. Notice that p-type Si exhibits more band bending as its Fermi level is lower in the band gap. For simplicity, we show only one energetic position for surface states associated with dangling bonds and backbonds; in reality, there will be new surface states arising during reactions as the individual dangling bonds and backbonds are taking on different energies as new Si-OH bonds are introduced.

It is thought that the hydroxide ions in Reaction 16.6, generated directly at the silicon surface, react in the oxidation step. The hydroxide ions from the bulk of the solution may not play a major role, as they will be repelled by the negatively charged Si surface, whereas the hydroxide ions formed *in situ* do not need to overcome this repelling force. This would explain why the etch rates for an EDP solution with an  $\text{OH}^-$  concentration of 0.034 mol/l are nearly as large as those for KOH solutions with a hundred-fold higher  $\text{OH}^-$  concentration of 5 to 10 mol/l [Seidel et al., 1990]. The hydrogen formed in Reaction 16.6 can inhibit the reaction and surfactants may be added to displace the hydrogen (IBM, U.S. Patent 4,113,551, 1978). Additional support for the involvement of four water molecules (Reaction 16.5) comes from the experimentally observed correlation between the fourth power of the water concentration and the silicon etch rate for highly concentrated KOH solutions (Eq. (16.30) and Figure 16.27C). The weak dependence of the etching curve on the KOH concentration ( $\sim 1/4$  power) supports the assumption that the hydroxide ions involved in the oxidation reactions are mostly generated from water. A strong influence of water on the silicon etch rate was also observed for EDP solutions. In molar water concentrations of up to 60%, a large increase of the etch rate occurs [Finne and Klein, 1967]. The driving force for the overall Reaction 16.4 is given by the larger Si-O binding energy of 193 kcal/mol as compared to a Si-Si binding energy of only 78 kcal/mol. The role of cations,  $\text{K}^+$ ,  $\text{Na}^+$ ,  $\text{Li}^+$ , and even complicated cations such as  $\text{NH}_2(\text{CH}_2)_2\text{NH}_3^+$  can probably be neglected [Seidel et al., 1990].

The four electrons in Reaction 16.5 are injected into the conduction band in two steps. In the case of {100} planes there are two **dangling bonds** per surface atom for the first two of the four hydroxide

***Dangling bonds.***

ions to react with, injecting two electrons into the conduction band in the process. As a consequence of the strong electronegativity of the oxygen atoms, the two bonded hydroxide groups on the silicon atom reduce the strength of the two **silicon backbonds**. With two new hydroxide ions approaching, two more electrons (now stemming from the Si-Si backbonds) are injected into the conduction band and the silicon-hydroxide complex reacts with the two additional hydroxide ions. Seidel et al. (1990) claim that the step of activating the second two electrons from the backbonds into the conduction band is the rate-limiting step, with an associated thermal activation energy of about 0.6 eV for {100} planes. The electrons in the backbonds are associated with surface states within the bandgap (see Figure 16.37). The energy level of these surface states is assumed to be varying for different surface orientations, being lowest for {111} planes. The thermal activation of the backbonds corresponds to an excitation of the electrons out of these surface states into the conduction band. Since the energy for the backbond surface state level is the lowest within the bandgap for {111} planes, these planes will be hardest to etch. The {111} planes have only one dangling bond for a first hydroxide ion to react with. The second rate-limiting step involves breaking three lower energy backbonds. The lower energy of the backbond surface states for {111} Si atoms can be understood from the simple argument that their energy level is raised less by the electronegativity of a single binding hydroxide ion, compared to two in the case of the silicon atoms in {100} planes. The high etch rate generally observed on {110} surfaces is similarly explained by a high energy level of the backbond-associated surface states for these planes. Elwenspoek (1993) and Elwenspoek et al. (1994) do not accept this ‘two vs. three backbonds’ argument. They point out that the silicon atoms in the {110} planes also have three backbonds, and activation energy in these crystallographic directions should be comparable to that of {111} planes in contrast to experimental evidence. Seidel et al. would probably counter-argue here that the backbonds and the energy levels of the associated surface states is not necessarily the same for {111} and {110} planes, as that energy will also be influenced by the effect of the orientation of these bonds. Another argument in favor of the high etching rates of {110} planes is the easier penetrability of {110} surfaces for water molecules along channels in that plane.

The final step in the anisotropic etching is the removal of the reaction product  $\text{Si(OH)}_4$  by diffusion. If the production of  $\text{Si(OH)}_4$  is too fast, for solutions with a high water concentration, the  $\text{Si(OH)}_4$  leads to the formation of a  $\text{SiO}_2$ -like complex before  $\text{Si(OH)}_4$  can diffuse away. This might be observed experimentally as a white residue on the wafer surface [Wu et al., 1985]. The high pH values in anisotropic etching are required to obtain adequate solubility of the  $\text{Si(OH)}_4$  reaction product and to remove the

native oxide from the silicon surface. From silicate chemistry it is known that for pH values above 12 the  $\text{Si}(\text{OH})_4$  complex will undergo the following reaction by the detachment of two protons:

Pyrocatechol in an ethylenediamine etchant acts as complexing agent for reaction products such as  $\text{Si}(\text{OH})_4$ , converting these products into more complex anions:

There is evidence by Abu-Zeid et al. (1985) of diffusion control contribution to the etch rate in EDP, probably because the hydroxide ion must diffuse through the layer of complex silicon reaction products (see Reaction 16.9). The same authors also found that the etch rate depends on the effective Si area being exposed and on its geometry (crevice effect). That is why the silicon wafer is placed in a holder and the solution is vigorously agitated in order to minimize the diffusion layer thickness. For KOH solutions, no effect of stirring on etching rate was noticed. Stirring here is mainly used to decrease the surface roughness, probably through removal of hydrogen bubbles.

The influence of alcohol on the KOH etching rate in Eq. (16.30) mainly is due to a change in the relative water concentration and its concomitant pH change; it does not participate in the reaction (this was confirmed by Raman studies by Palik et al. [1983]). The reversal of etch rates for {110} and {100} planes through alcohol addition to KOH/water etchants can be understood by assuming that the alcohol covers the silicon surface [Palik et al., 1983], thus canceling the 'channeling advantage' of the {110} planes. In the case of EDP, alcohol has no effect, as the water concentration can be freely adjusted without significantly influencing the pH value due to the incomplete dissociation of EDP.

For the etching of  $\text{SiO}_2$  shown in Figure 16.28, Seidel et al. propose the following reaction:

At KOH concentrations up to 35% a linear correlation occurs between etch rate and KOH concentration. The  $\text{SiO}_2$  etch rate in KOH solutions exceeds those in EDP by close to three orders of magnitude. For higher concentrations, the etch rate decreases with the square of the water concentration, indicating that water plays a role in this reaction. Seidel et al. speculate that at high pH values the silicon electrode is highly negatively charged (the point of zero charge of  $\text{SiO}_2$  is 2.8), repelling the hydroxide ions while water takes over as reaction partner. An additional reason for the decrease is that the hydroxide concentration does not continue to increase with increasing KOH concentration for very concentrated solutions. The decrease of the Si/ $\text{SiO}_2$  etch rate ratio with increasing temperature and pH value of the solution follows out of the larger activation energy of the  $\text{SiO}_2$  etch rate (0.85 eV) and its linear correlation with the hydroxide concentration, whereas the silicon etch rate mainly depends on the water concentration.

The effect of water concentration and pH value on the etching process in the Seidel et al. model is summarized in Table 16.10 [Seidel, 1990]. For aqueous KOH solutions within a concentration range from 10 to 60% the following empirical formula for the calculation of the silicon etch rate  $R$  proved to be in close agreement with the experimental data:

$$R = k_0 [\text{H}_2\text{O}]^4 [\text{KOH}]^{\frac{1}{4}} e^{-\frac{E_a}{kT}} \quad (16.31)$$

The values for the fitting parameters were  $E_a = 0.595$  eV and  $k_0 = 2480$   $\mu\text{m/hr}$   $(\text{mol/l})^{-4.25}$ ; for a (100) wafer  $E_a = 0.6$  and  $k_0 = 4500$   $\mu\text{m/hr}$   $(\text{mol/l})^{-4.25}$ . For the  $\text{SiO}_2$  etch, an activation energy of 0.85 eV was used.

**TABLE 16.10** Effect of Water Concentration and pH Value on the Characteristics of Silicon Etching [Seidel, 1990]

	-H <sub>2</sub> O+	-pH+
SiO <sub>2</sub> etch rate	No effect	- ↔ +
Si etch rate	- ↔ +	Little effect
Solubility	No effect	- ↔ +
Si/SiO <sub>2</sub> ratio	- ↔ +	+ ↔ -
Diffusion effects	- ↔ +	+ ↔ -
Residue formation	- ↔ +	+ ↔ -
p <sup>+</sup> etch stop	- ↔ +	+ ↔ -
p, n etch stop	- ↔ +	+ ↔ -

In the section on etch stop techniques, we will see that the Seidel et al. model also nicely explains why all alkaline etchants exhibit a strong reduction in etch rate at high boron dopant concentration of the silicon; at high doping levels the conduction band electrons for the rate-determining reduction step are not confined to the surface anymore and the reaction basically stops.

The key points of the Seidel et al. model can be summarized as follows (see also Table 16.10) [Seidel et al., 1990]:

1. The rate-limiting step is the water reduction.
2. Hydroxide ions required for oxidation of the silicon are generated through reduction of water at the silicon surface. The hydroxide ions in the bulk do not contribute to the etching, since they are repelled from the negatively charged surface. This implies that the silicon etch rate will depend on the molar concentration of water and that cations will have little effect on the silicon etch rate.
3. The dissolution of silicon dioxide is assumed to be purely chemical with hydroxide ions. The SiO<sub>2</sub> etch rate depends on the pH of the bulk electrolyte.
4. For boron concentrations in excess of  $3 \times 10^{19} \text{ cm}^{-3}$ , the silicon becomes degenerate, and the electrons are no longer confined to the surface. This prevents the formation of the hydroxide ions at the surface and thus causes the etching to stop.
5. Anodic biases will prevent the confinement of electrons near the surface as well and lead to etch stop as in the case of a p<sup>+</sup> material.

Points 4 and 5 will become more clear when we discuss the workings of etch-stop techniques. This model applies well for lower index planes (i.e., {nnn} with  $n < 2$ ) where high etch rates always correspond to low activation energies. But, for higher index planes (i.e., {n11} and {1nn} with  $n = 2,3,4$ ), Herr and Baltes (1991) found no correlation between activation energies and etch rates. For higher index planes, we must rely mainly on empirical data.

The Si etching reactions suggested by Seidel et al. are only the latest; in earlier proposed schemes, according to Gandhi (1968) and Kern (1978), the silicon oxidation reaction steps suggested were injection of holes into the Si (raising the oxidation state of Si), hydroxylation of the oxidized Si species, complexation of the silicon reaction products and dissolution of the reaction products in the etchant solution. In this reaction scheme, etching solutions must provide a source of holes as well as hydroxide ions and they must contain a complexing agent with soluble reacted Si species in the etchant solution, e.g., pyrocatechol forming the soluble  $\text{Si}(\text{C}_6\text{H}_4\text{O}_2)_3^{2-}$  species. This older model still seems to be guiding the current thinking of many micromachinists, although Seidel et al.'s energy level based model of the silicon/electrolyte interface proves more satisfying.

### 16.5.2.3 Elwenspoek et al. Model

Elwenspoek (1993) and Elwenspoek et al. (1994) introduced an alternative model for anisotropic etching of Si, a model built on theories derived from crystal growth. According to these authors, the Seidel et al.

model does not clearly explain the fast etching of {110} planes. Those planes, having three backbonds like the {111} planes, should etch equally slowly. The activation energy of the anisotropic etch rate depends on the etching system used; for example, etching in KOH is faster than in EDP, even when the pH of the solution is the same. Seidel et al. attribute this dependence to diffusion that plays a greater role in EDP than in KOH solutions. But Elwenspoek et al. point out that, at least for slow etching, the etch rate should not be diffusion controlled but governed by surface reactions. With surface reactions, diffusion should have a minor effect, analogous to growth at low pressure in an LPCVD reactor [Madou, 1997, chap. 3]. Another comment focuses on the lack of understanding why certain etchants etch isotropically and others etch anisotropically.

Elwenspoek et al. note the parallels in the process of etching and growing of crystals; slowly growing crystal planes also etch slowly! A key to understanding both processes, growing or dissolution (etching), pertains to the concept of the energy associated with the creation of a critical nucleus on a single crystalline smooth surface, i.e., the free energy associated with the creation of an island (growth) or a cavity (etching). Etching or growing of a material starts at active kink sites on steps. Kink sites are atoms with as many bonds to the crystal as to the liquid. Kinetics depend critically on the number of such kink sites. This aspect remained neglected in the discussion of etch rates of single crystals up to now.

The free energy change,  $\Delta G$ , involved in creating an island or digging a cavity (of circular shape in an isotropic material) of radius  $r$  on or in an atomically smooth surface, is given by:

$$\Delta G = -N\Delta\mu + 2\pi r\gamma \quad (16.32)$$

where  $N$  is the number of atoms forming the island or the number of atoms removed from the cavity,  $\Delta\mu$  is the chemical potential difference between silicon atoms in the solid state and in the solution, and  $\gamma$  is the step free energy. The step free energy in Eq. (16.32) will be different at different crystallographic surfaces. This can easily be understood from the following example. A perfectly flat {111} surface in the Si diamond lattice has no kink positions (three backbonds, one dangling bond per atom), while on the {001} face every atom has two backbonds and two dangling bonds, i.e., every position is a kink position. Consequently, creating an adatom-cavity pair on {111} surfaces costs energy: three bonds must be broken and only one is reformed. In the case of {001} faces, the picture is quite different. Creating an adatom-cavity pair now costs no energy because one has to break two bonds in order to remove an atom from the {001} face, but one gets them back by placing the atom back on the surface. The binding energy  $\Delta E$  of an atom in a crystal slice with orientation (hkl) divided by  $kT$  (Boltzmann constant times absolute temperature) is known as the  $\alpha$  factor of Jackson of that crystal face [Jackson, 1966], or:

$$\alpha = \frac{\Delta E}{kT} \quad (16.33)$$

At sufficiently low temperature, where entropy effects can be ignored,  $kT\alpha$  is proportional to the step free energy  $\gamma$  and the number of adatom-cavity pairs is proportional to  $\exp(-\alpha)$ . This number is very small on the {111} silicon faces at low temperature, but 1 on the {001} silicon faces at any temperature. The consequence for {111} and {001} planes is that, at sufficiently low temperatures, the first are atomically smooth and the latter are atomically rough.  $N$  in Eq. (16.32) can be further written out as:

$$N = \pi r^2 h \rho \quad (16.34)$$

where  $h$  is the height of the step,  $r$  is the diameter of the hole or island and  $\rho$  is the density (atoms per  $\text{cm}^3$ ) of the solid material. The result is

$$\Delta G = -\pi r^2 h \rho \Delta\mu + 2\pi r\gamma \quad (16.35)$$

where  $\Delta\mu$  is counted positive and  $\gamma$  is positive in any case. In [Figure 16.38](#) we show a plot of  $\Delta G$  vs.  $r$ . Eq. (16.35) exhibits a maximum at:

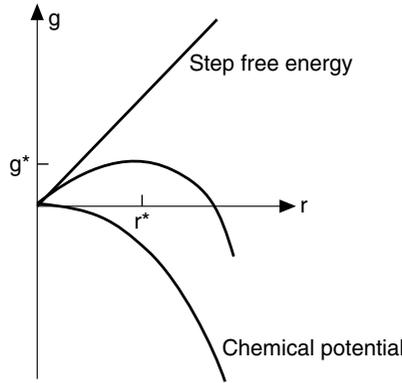

FIGURE 16.38 A plot of  $\Delta G$  vs.  $r$  based on Eq. (16.35) exhibits a maximum.

$$r^* = \frac{\gamma}{h\rho\Delta\mu} \quad (16.36)$$

At  $r^*$  the free energy is

$$\Delta G^* = \Delta G(r^*) = \frac{\pi\gamma^2}{h\rho\Delta\mu} \quad (16.37)$$

Consequently, an island or an etch cavity of critical size exist on a smooth face. If by chance a cavity is dug into a crystal plane smaller than  $r^*$ , it will be filled rather than allowed to grow and an island that is too small will dissolve rather than continue to grow, since that is the easy way to decrease the free energy. With  $r = r^*$ , islands or cavities do not have any course of action, but in case of  $r > r^*$  the islands or cavities can grow until the whole layer is filled or removed. In light of the above nucleation barrier theory, to remove atoms directly from flat crystal faces such as the  $\{111\}$  Si faces seems very difficult, since the created cavities increase the free energy of the system and filling of adjacent atoms is more probable than removal; in other words, a nucleation barrier has to be overcome. The growth and etch rates,  $R$ , of flat faces are proportional to:

$$R \sim \exp\left(-\frac{\Delta G^*}{kT}\right) \quad (16.38)$$

Since  $\Delta G^*$  is proportional to  $\gamma^2$ , the activation energy is different for different crystallographic faces and both the etch rate and the activation energy are anisotropic. If  $\Delta G^*/kT$  is large, the etch rate will be very small, as is the case for large step free energies and for small undersaturation (i.e., the 'chemical drive' or  $\Delta\mu$  is small) (see Eq. (16.37)). Both  $\Delta\mu$  and  $\gamma$  depend on the temperature and type of etchant and these parameters might provide clues to understanding the variation of etch rate, degree of anisotropy, temperature dependence etc., giving this model more bandwidth than the Seidel et al.'s model. According to Elwenspoek et al., the chemical reaction energy barrier and the transport in the liquid are isotropic and the most prominent anisotropy effect is due to the step free energy (absent on rough surfaces) rather than the surface free energy. The surface free energy and the step free energies are related, though, when comparing flat faces, those having a large surface free energy have a small step free energy, and vice versa. The most important difference in these two parameters is that the step-free energy is zero for a rough surface, whereas the surface energy remains finite.

Flat faces grow and etch with a rate proportional to  $\Delta G^*$  which predicts that faces with a large free energy to form a step will grow and etch much slower than faces with smaller free energy. Elementary

analysis indicates that the only smooth face of the diamond lattice is the (111) plane. There may be other flat faces, but with lower activation energies, due to reconstruction and/or adsorption, prominent candidates in this category are {100} and {110} planes. On the other hand, a rough crystal face grows and etches with a rate directly proportional to  $\Delta\mu$ . The temperature at which  $\gamma$  vanishes and a face transitions from smooth to rough is called the roughening transition temperature  $T_R$  [Elwenspoek and van der Weerden, 1987; Bennema, 1984]. Above  $T_R$ , the crystal is rough on the microscopic scale. Because the step free energy is equal to zero, new Si units may be added or removed freely to the surface without changing the number of steps. Rough crystal faces grow and dissolve with a rate proportional to  $\Delta\mu$  and therefore proceed faster than flat surfaces. Imperfect crystals, e.g., surfaces with screw dislocations, etch even faster with  $R$  proportional to  $\Delta\mu^2$ .

For the state of a surface slightly above or below the roughening temperature,  $T_R$ , thermal equilibrium conditions apply. Etching, in most practical cases, is far from equilibrium and kinetic roughening might occur. Kinetic roughening [Bennema, 1984] occurs if the super- or undersaturation of the solution is so large that the thermally created islands or cavities are the size of the critical nucleus. One can show that if the super- or undersaturation is larger than  $\Delta\mu_c$ , given by:

$$\Delta\mu_c = \frac{\pi f_0 \gamma^2}{kT} \quad (16.39)$$

( $f_0$  being the area one atom occupies in a given crystal plane), the growth and etch mechanism changes from a nucleation barrier-controlled mechanism to a direct growth/etch mechanism. The growth rate and etch rate again become proportional to the chemical potential difference. It can thus be expected that if the undersaturation becomes high enough, even the {111} faces could etch isotropically, as they indeed do in acidic etchants. If the undersaturation becomes so large that  $\Delta G^* \ll kT$ , the nucleation barrier breaks down. Each single-atom cavity acts as a nucleus made in vast numbers by thermal fluctuations. The face in question etches with a rate comparable to the etch rate of a rough surface. This situation is called kinetic roughening. If all faces are kinetically rough, the etch rate becomes isotropic.

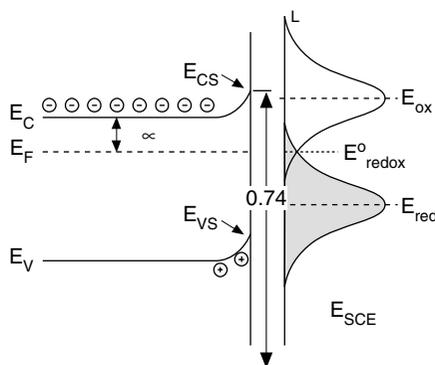

Isotropic etching requires conditions of kinetic roughening, because the etch rate is no longer dominated by a nucleation barrier but by transport processes in solution and the chemical reaction. To test this aspect of the model, Elwenspoek et al. show that there is a transition from isotropic to anisotropic etching if the undersaturation becomes too small. This can occur if one etches with an acidic etchant very long or if one etches through very small holes in a mask (crevice effect). In both cases, anisotropic behavior becomes evident as aging or limited transport of the solution causes the undersaturation to become very small. No proof is available to indicate that acidic etchants are much more undersaturated than the alkaline etchants. Still, the above explains some phenomena that the Seidel et al.'s model fails to address. Another nice confirmation of the Elwenspoek et al. model is in the effect of misalignment on etch rate. A misalignment of the mask close to smooth faces implies steps; there is no need for nucleation in order to etch. Since the density of steps is proportional to the angle of misalignment, the etch rate should be proportional to the misalignment angle, provided the distance between steps is not too large. Nucleation of new cavities becomes very probable. This has indeed been observed for the etch rate close to the  $\langle 111 \rangle$  directions [Seidel et al., 1990].

Where the Elwenspoek et al.'s model becomes a bit murky is in the classification of which surfaces are smooth and which ones are rough. Elementary analysis classifies only the {111} planes as smooth at low temperatures. At this stage the model does not explain anything more than other models; every model has an explanation for the slower {111} etch rate. But these authors invoke the possibility of surface reconstruction and/or adsorption of surface species which, by decreasing the surface-free energy, could make faces such as {001} and {110} flat as well but with lower activation energies. They also take heart in the fact that CVD experiments often end up showing flat {110}, {100}, {331} and, strongest of all, {111} planes. Especially where the influence of the etchant is concerned a lot more convincing thermodynamic data to estimate  $\Delta\mu$  and  $\gamma$  are needed.

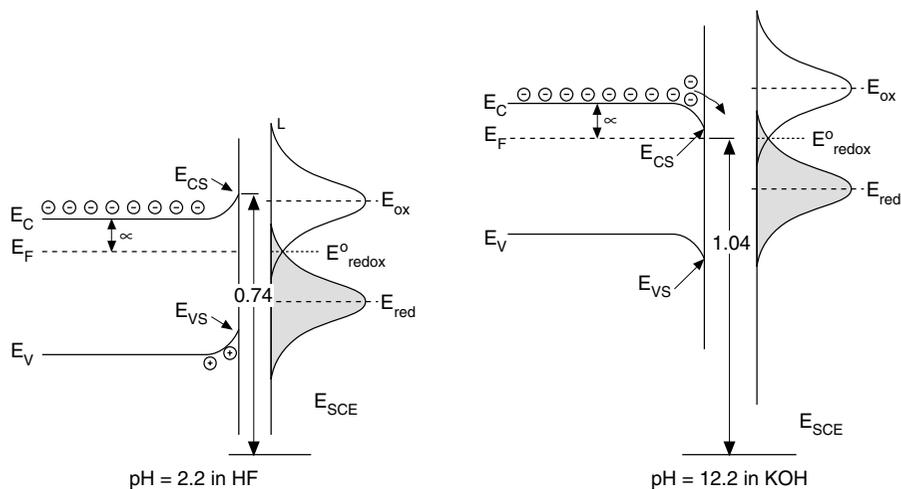

### 16.5.2.4 Isotropic vs. Anisotropic Etching of Silicon

In contrast to alkaline etching, with an acidic etchant such as HF, holes are needed for etching Si. An n-type Si electrode immersed in HF in the dark will not etch due to lack of holes. The same electrode in an alkaline medium etches readily. A p-type electrode in an HF solution, where holes are available under the proper bias, will etch even in the dark. For HF etchants one might assume that the Ghandi and Kern model [Kern, 1978; Jackson, 1966], relying on the injection of holes, applies. In terms of the band model, this must mean that the silicon/electrolyte interface in acidic solutions exhibits quite different energetics from the alkaline case. It is not directly obvious why the energetics of the silicon/electrolyte interface would be pH dependent. To the contrary, since the flatband potential of most oxide semiconductors as well as most oxide-covered semiconductors (such as Si) and the Fermi level of the  $\text{H}_2\text{O}/\text{OH}^-$  redox couple in an aqueous solution are both expected to change by 59 mV for each pH unit change [Madou and Morrison, 1989], one would expect the energetics of the interface to be pH independent. Since the electronegativity in a Si-F bond is higher than for a Si-OH bond, one might even expect the backbond surface states to be raised higher in an HF medium, making an electron injection mechanism even more likely than in alkaline media. To clarify this contradiction we will analyze the band model of a Si electrode in an acidic medium in more detail. The band model shown in Figure 16.39 was constructed on the basis of a set of impedance measurements on an n-type Si electrode in a set of aqueous solutions at different pH values. From the impedance measurements Mott-Schottky plots were constructed to determine the pH dependency of the flat-band potential. From that, the position of the conduction band and valence band edges ( $E_{cs}$  and  $E_{vs}$ , respectively) of the Si electrode in an acidic medium at a fixed pH of 2.2 (the point of zero charge) was calculated at 0.74 eV vs. SCE (saturated calomel electrode as reference) for  $E_{cs}$ , and  $-0.36$  eV vs. SCE for  $E_{vs}$  [Madou et al., 1980; 1981].

We have assumed in Figure 16.39 that the bands are bent upwards at open circuit (see below for justification), so that holes in the valence band are driven to the interface where they can react with Si atoms or with competing reducing agents from the electrolyte. Since we want to etch Si, we are only interested in the reactions where Si itself is consumed. Reactions of holes with reducing agents are of great importance in photoelectrochemical solar cells [Madou et al., 1981]. For n-type Si, holes can be (1) injected by oxidants from the solution (e.g., by adding nitric acid to the HF solution), (2) supplied at the electrolyte/semiconductor interface by shining light on a properly biased n-Si wafer, or (3) created by impact ionization, i.e., Zener breakdown, of a sufficiently high reverse biased n-Si electrode [Levy-Clement et al., 1992]. With a p-Si wafer, a small forward bias supplies all the holes needed for the oxidation of the lattice even without light, as the conduction happens via a hole mechanism. An important

**FIGURE 16.39** Band diagram for n-type Si in pH = 2.2 (no bias or illumination). Reference is the saturated calomel electrode (SCE). In Figure 16.37 no energy values were given; here we provide actual positions of the conduction band edge,  $E_{cs} = 0.74$  eV vs. SCE, and the valence band edge,  $E_{vs} = 0.74$  eV  $-1.1$  eV =  $-0.36$  eV vs. SCE (1.1 eV is the band gap of Si). These values were determined by means of Mott-Schottky plots [Madou et al., 1981]. The separation between the Fermi energy and the bottom of the conduction band is indicated by  $\mu$ .

**FIGURE 16.40** Band model comparison of the Si/electrolyte interface at low and high pH. Increasing the pH by 10 units shifts the redox-levels up by 600 mV, whereas the Si bands only move up by 300 mV. This leads to a different band-bending and a different reaction mechanism, i.e., electron injection in the alkaline media (anisotropic) and hole injection in acidic media (isotropic).

finding, explaining the different reaction paths in acidic and alkaline media comes from plotting the flat band potential as a function of pH. It was found that the band diagram of Si shifts with less than 59 mV per pH unit. Actually the shift is only about 30 mV per pH unit [Madou et al., 1981]. As shown in Figure 16.40, with increasing pH, the energy levels of the solution rise faster than the energy levels in the semiconductor. As a consequence it is more likely that electron injection takes place in alkaline media as the filled levels associated with the  $\text{OH}^-$  are closer to the conduction band, whereas in acidic media the filled levels of the redox system overlap better with the valence band, favoring a hole reaction. A lower position of the redox couple with respect to the conduction band edge,  $E_{CS}$ , in acidic media explains the upward bending of the bands as drawn in Figure 16.39. With isotropic etching in acidic media, the reaction starts with a hole in the valence band, equivalent to a broken Si-Si bond. In this case, the relative position of backbond related surface states in different crystal orientations are of no consequence and all planes etch at the same rate. A study of the interfacial energetics helps to understand why isotropic etching occurs in acidic media and anisotropic etching in alkaline media.

A few words of caution on our explanation for the reactivity difference between acidic and alkaline media are in order. Little is known about the width of the bell-shaped curves describing the redox levels in solution [Madou and Morrison, 1989]. Not knowing the surface concentrations of the reactive redox species involved in the etching reactions further hinders a better understanding of the surface energetics as the bell-shaped curves for oxidant and reductant will only be the same height (as they were drawn in Figures 16.39 and 16.40) if the concentration of oxidant and reductant are the same. Clearly, the above picture is oversimplified; several authors have found that the dissolution of Si in HF might involve both the conduction and valence band, a claim confirmed by photocurrent multiplication experiments [Matsumura and Morrison, 1983; Lewerenz et al., 1988]. These photomultiplication experiments showed that one or two holes generated by light in the Si valence band were sufficient to dislodge one Si [Brantley, 1973] unit, meaning that the rest of the charges were injected into the conduction band. Our contention here is only that the low pH dependence of the flat-band potential of a silicon electrode makes a conduction band mechanism more favorable with alkaline type etchants and a hole mechanism more favorable in acidic media.

Continued attempts at modeling the etch rates of all Si planes are under way. For example, Hesketh et al. (1993) attempted to model the etch rates of the different planes developing on silicon spheres in

etching experiments with KOH and CsOH by calculating the surface free energy. The number of surface bonds per centimeter square on a Si plane is indicative of the surface free energy, which can be estimated by counting the bond density and multiplying by the bond energy. Using the unit cell dimension “a” of Si of 5.431 Å, and a silicon-to-silicon bond energy of 42.2 kcal/mol, the surface free energy,  $\Delta G$ , can be related to,  $N_B$ , the bond density, by the following expression:

$$\Delta G = \frac{N_B}{2} \times 2.94 \times 10^{-19} \frac{J}{m^2} \quad (16.40)$$

Although Hesketh et al. could not explain the etching differences observed between CsOH and KOH (these authors identified a cation effect on the etch rate!), a plot of the calculated surface free energy vs. orientation yielded minima for all low index planes such as {100}, {110} and {111}, as well as for the high index {522} planes. Fewer bonds per unit area on the low index planes produce a lower surface energy and lower etching rate. When Hesketh et al. added the in-plane bond density to the surface bond density, producing a total bond density, a correlation with the hierarchy of etch rates in CsOH and KOH was found, i.e., {311}, {522} > {100} > {111}. The surfaces with the higher bond density etched faster, suggesting that the etch rate might be a function of the number of electrons available at the surface. Hesketh et al. imply that their result falls in line with the Seidel et al.’s model, although it is unclear how the total bond density relates to surface state energies of backbonds. Moreover, Hesketh’s model does not take into account the angles of the bonds, and in Elwenspoek’s view, the surface free energy actually does not determine the anisotropy.

More research could focus on the modeling of Si etch rates. The semiconductor electrochemistry of corroding Si electrodes will be a major tool in further developments. Interested readers may consult Sundaram and Chang (1993) in an article on Si etching in hydrazine and Palik et al. (1985) on the etch-stop mechanism in heavily doped silicon; both explain in some detail the silicon/electrolyte energetics. A more generic treatise on semiconductor electrochemistry can be found in Morrison (1980).

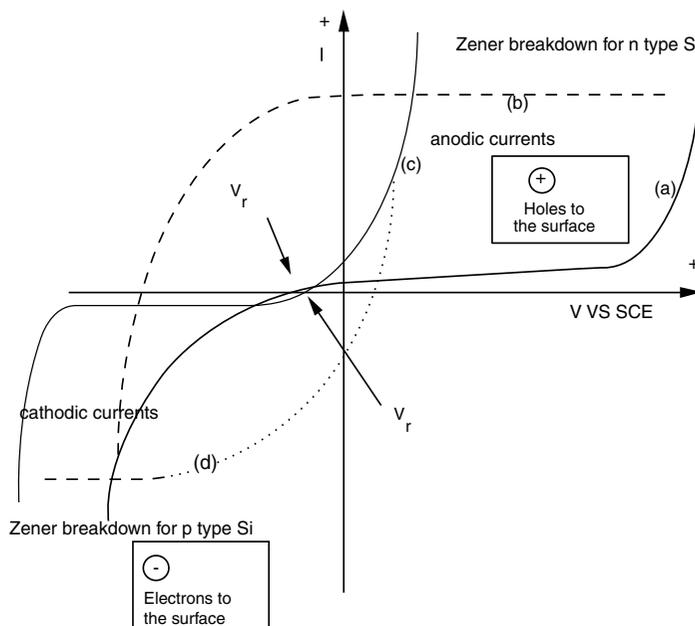

## 16.6 Etching With Bias and/or Illumination of the Semiconductor

The isotropic and anisotropic etchants discussed so far require neither a bias nor illumination of the semiconductor. The etching in such cases proceeds at open circuit and the semiconductor is shielded from light. In a cyclic voltammogram, as shown in Figure 16.41, the operational potential is the rest potential,  $V_r$ , where anodic and cathodic currents are equal in magnitude and opposite in sign, resulting in the absence of flow of current in an external circuit. This does not mean that macroscopic changes do not occur at the electrode surface, since the anodic and cathodic currents may be part of different chemical reactions. Consider isotropic etching of Si in an HF/HNO<sub>3</sub> etchant at open circuit where the local anodic reaction is associated with corrosion of the semiconductor:

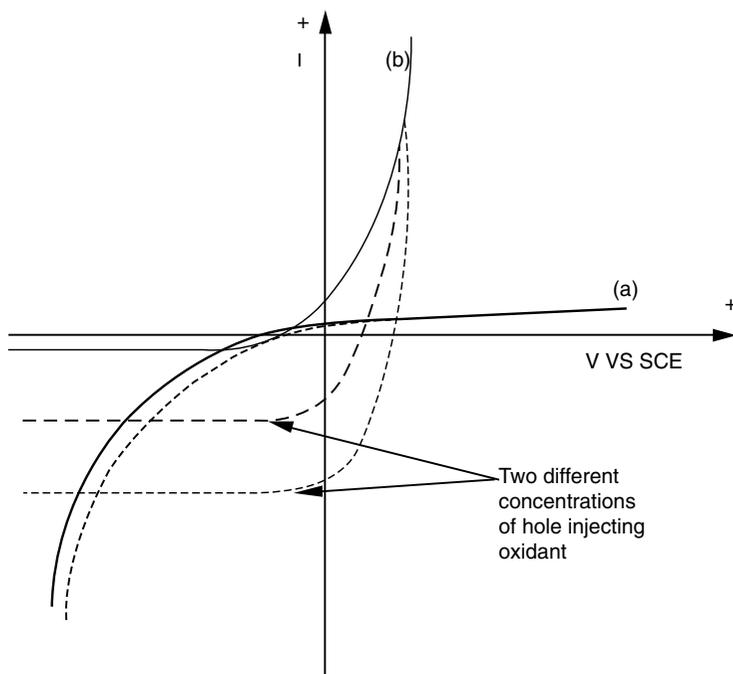

(the involvement of holes ‘h<sup>+</sup>’ in the acidic reaction was discussed in the preceding section), while the local cathodic reaction could be associated with reduction of HNO<sub>3</sub>:

**FIGURE 16.41** Basic cyclic voltammograms ( $I$  vs.  $V$ ) for n- and p-type Si in an HF solution, in the absence of a hole injecting oxidant: (a) n-type Si without illumination; (b) n-type Si under illumination; (c) p-type Si without illumination; (d) p-type Si under illumination. If the reactions on the dark Si electrode determining the rest potential  $V_r$  for n- and p-type are the same, then  $V_r$  is expected to be the same as well. For the clarity of the figure we have chosen the  $V_r$ s different here; in practice,  $V_r$  for n- and p-type Si in HF are found to be identical.

We will now explore Si etching while illuminating and/or applying a bias to the silicon sample. To simplify the situation, we will first consider the case of an oxidant-free solution so that all the holes must come from within the semiconductor. Anodic dissolution of n-Si in an HF containing solution requires a supply of holes to the surface. For an n-type wafer under reverse bias, very few holes will show at the surface unless the high reverse (anodic) bias is sufficient to induce impact ionization or Zener breakdown (see [Figure 16.41a](#)). Alternatively, the interface can be illuminated, creating holes in the space charge region which the field pushes towards the semiconductor/electrolyte interface ([Figure 16.41b](#)). In the forward direction, electrons from the Si conduction band (majority carriers) reduce oxidizing species in the solution (e.g., reduction of protons to hydrogen). A p-type Si sample exhibits high anodic currents even without illumination at small anodic (forward) bias ([Figure 16.41c](#)). Here the current is carried by holes. A p-type electrode illuminated under reverse bias gives rise to a cathodic photocurrent ([Figure 16.41d](#)). At relatively low light intensities, the photocurrent plateaus for both n- and p-types ([Figures 16.41b](#) and [16.41d](#), respectively) depend linearly on light intensity. The photocurrent is cathodic for p-type Si (species are reduced by photoproduced electrons at the surface, e.g., hydrogen formation) and anodic for n-type Si (species are oxidized by photoproduced holes at the surface; either the lattice itself is consumed or reducing compounds in solution are). In [Figure 16.42](#) we show the cyclic voltammograms of n-type and p-type Si in the presence of a hole-injecting oxidant. The most obvious effect is on the dark p-type Si electrode. The injection of holes in the valence band increases the cathodic dark current dramatically. The current level measured in this manner for varying oxidant concentration or different oxidants could be used to estimate the efficiency of different isotropic Si etchants; a pointer to the fact that semiconductor electrochemistry has been underutilized as a tool to study Si etching. When n-type Si is consumed under illumination, we experience photocorrosion (see [Figure 16.41b](#)). This photocorrosion phenomenon has been a major barrier to the long-term viability of photoelectrochemical cells [Madou et al., 1980]. In what follows, photocorrosion is put to use for electropolishing and formation of microporous and macroporous layers [Levy-Clement et al., 1992].

**FIGURE 16.42** Basic cyclic voltammograms for n- and p-type Si in an HF solution and in the presence of a hole injecting oxidant, e.g.,  $\text{HNO}_3$ : (a) n-type Si in the dark; (b) p-type Si in the dark. An increase of the cathodic dark current on the p-type electrodes is most obvious. The current level is proportional to the oxidant concentration.

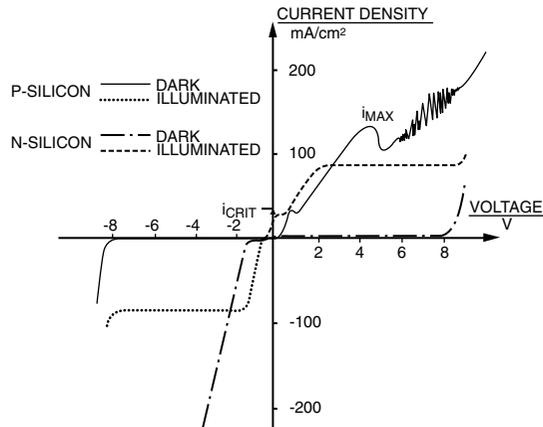

## 16.6.1 Electropolishing and Microporous Silicon

### 16.6.1.1 Electropolishing

Photoelectrochemical etching (PEC-etching) involves photocorrosion in an electrolyte in which the semiconductor is generally chemically stable in the dark, i.e., no hole-injecting oxidants are present, as in the case of an HF solution (see Figure 16.41). For carrying out the experiments a set-up as shown in Figure 16.25 may be used with a provision to illuminate the semiconductor electrode. At high light intensities the anodic curves for n- and p-type Si are the same, except for a potential shift of a few hundred mV (see Figure 16.43). Because of this equivalence, several of the etching processes described apply for both forward biased p-type and n-type Si under illumination. The anodic curves in Figure 16.43 present two peaks, characterized by  $i_{\text{CRIT}}$  and  $i_{\text{MAX}}$ . At the first peak,  $i_{\text{CRIT}}$ , partial dissolution of Si in reactions such as:

leads to the formation of porous Si while hydrogen formation occurs simultaneously. The porous Si typically forms when using low current densities in a highly concentrated HF solution—in other words, by limiting the oxidation of silicon due to a hole and  $\text{OH}^-$  deficiency. Above  $i_{\text{CRIT}}$ , the transition from the charge-supply-limited to the mass-transport-limited case, the porous film delaminates and bright electropolishing occurs at potentials positive of  $i_{\text{MAX}}$ . With dissolution of chemical reactants in the electrolyte rate limiting, HF is depleted at the electrode surface and a charge of holes builds up at the interface. Hills on the surface dissolve faster than depressions because the current density is higher on high spots. As a result, the surface becomes smoother, i.e., electropolishing takes place [Lehmann, 1993].

**FIGURE 16.43** Cyclic voltammograms identifying porous Si formation regime and electropolishing regime. (From Levy-Clement, C. et al., *Electrochimica Acta*, 37, 877–888, 1992. With permission.)

Electropolishing in this regime can be used to smooth silicon surfaces or to thin epitaxially grown silicon layers. The peak and oscillations in Figure 16.43 are explained as follows: at current densities exceeding  $i_{MAX}$  an oxide grows first on top of the silicon, leading to a decrease of the anodic photocurrent (explaining the  $i_{MAX}$  peak), until a steady state is reached in which dissolution of the oxide by HF through formation of a fluoride complex in solution ( $\text{SiF}_6^{2-}$ ) equals the oxide growth rate. The oscillations observed in the anodic curve in Figure 16.43 can be explained by a nonlinear correlation between formation and dissolution of the oxide [Levy-Clement et al., 1992].

### 16.6.1.2 Porous Silicon

#### Introduction

The formation of porous Si was first discovered by Uhlir in 1956 [Uhlir, 1956]. His discovery is leading to all types of interesting new devices from quantum structures, permeable membranes, photoluminescent and electroluminescent devices to a basis for making thick  $\text{SiO}_2$  and  $\text{Si}_3\text{N}_4$  films [Bomchil et al., 1986; Smith and Collins, 1990]. Two types of pores exist: micropores and macropores. Their sizes can differ by three orders of magnitude and the underlying formation mechanism is quite different. Some important features of porous Si, as detailed later, are

- Pore sizes in a diameter range from 20 Å to 10 μm.
- Pores that follow crystallographic orientation [Chuang and Smith, 1988].
- Very high aspect ratio (~250) pores in Si maintained over several millimeters' distance [Lehmann, 1993].
- Porous Si is highly reactive, oxidizes and etches at very high rate.
- Porosity varies with the current density.

These important attributes contribute to the essential role porous Si plays in both micromachining [Barret et al., 1992] and the fashioning of quantum structures [Canham, 1990].

#### Microporous Silicon

Whether one is in the regime of electropolishing or porous silicon formation depends on both the anodic current density and the HF concentration. The surface morphology produced by the Si dissolution process critically depends on whether mass transport or hole supply is the rate-limiting step. Porous silicon formation is favored for high HF concentrations and low currents (weak light intensities for n-type Si), where the charge supply is limiting, while etching is favored for low HF concentration and high currents

(strong light intensity for n-type Si), where mass transport is limiting. For current densities below  $i_{\text{MAX}}$  (Figure 16.43) holes are depleted at the surface and HF accumulates at the electrode/electrolyte interface. As a result, a dense network of fine holes forms [Unagami, 1980; Watanabe et al., 1975]. The formation of a porous silicon layer (PSL) in this regime has been explained as a self-adjusting electrochemical reaction due to hole depletion by a quantum confinement in the microporous structure [Lehmann and Gosele, 1991]. The structure of the pores in PSL can best be observed by transmission electron microscopy (TEM) and its thickness can be monitored with an IR microscope. The structure of the porous layer primarily depends on the doping level of the wafer and on the illumination during etching. The pore sizes decrease when etching occurs under illumination [Levy-Clement et al., 1992]. The pores formed in p-type Si show much smaller diameters than n-type ones for the same formation conditions. It is believed that the porous silicon layer (PSL) consists of silicon hydrides and oxides. The pore diameter typically ranges from 40 to 200 Å [Lehmann, 1996; Yamana et al., 1990; Arita and Sunohara, 1977]. This very reactive porous material etches or oxidizes rapidly. Heat treatment in an oxidizing atmosphere (1100°C in oxygen for 30 minutes is sufficient to make a 4- $\mu\text{m}$  thick film) leads to oxidized porous silicon (OPS). The oxidation occurs throughout the whole porous volume and several micrometers-thick  $\text{SiO}_2$  layers can be obtained in times that correspond to the growth of a few hundred nanometers on regular Si surfaces. Porous silicon is low density and remains single crystalline, providing a suitable substrate for epitaxial Si film growth. These properties have been used to obtain dielectric isolation in ICs and to make silicon-on-insulator wafers [Watanabe et al., 1975].

Porous Si can also be formed chemically through Reactions 16.11 and 16.13. In this case the difference between chemical polishing and porous Si formation conditions is more subtle. In the chemical polishing case, all reacting surface sites switch constantly from being local anode (Reaction 16.11) to being local cathode (Reaction 16.13), resulting in nonpreferential etching. If surface sites do not switch fast between being local anode and cathode, charges have time to migrate over the surface. In this case, the original local cathode site remains a cathode for a longer time, and the corresponding local anode site, somewhere else on the surface, also remains an anode in order to keep the overall reaction neutral. A preferential etching results at the localized anode sites, making the surface rough and causing a porous silicon to form [Jung et al., 1993]. Any inhomogeneity, e.g., some oxide or a kink site at the surface might increase such preferential etching [Jung et al., 1993]. Unlike PSLs fabricated by electrochemical means, the chemically etched porous Si film thickness is self limiting.

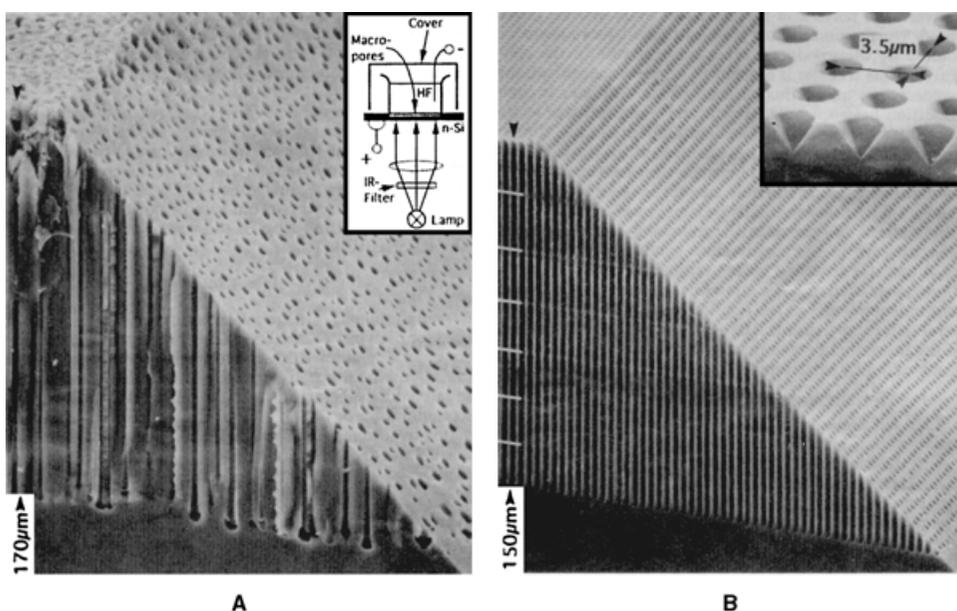

Besides its use for dielectric isolation and the fabrication of SOI wafers, porous silicon has been introduced in a wide variety of other applications: Luggin capillaries for electrochemical reference electrodes, high surface area gas sensors, humidity sensors, sacrificial layers in silicon micromachining, etc. Recently PSL was shown to exhibit photoluminescent and electroluminescent behavior; light-emitting porous silicon (LEPOS) was demonstrated. Visible light emission from regular Si is very weak due to its indirect bandgap. Pumping porous Si with a green light laser (argon) caused it to emit a red glow. If a LEPOS device could be integrated monolithically with other structures on silicon, a big step in micro-optics, photon data transmission, and processing would be achieved. To explain the blue shift of the absorption edge of LEPOS of about 0.5 eV compared to bulk silicon [Lehmann and Gosele, 1991] and room temperature photoluminescence [Canham, 1990], Searson et al. (1993) have proposed an energy-level diagram for porous silicon where the valence band is lowered with respect to bulk silicon to give a band-gap of about 1.8 eV. Not only may PSL formation, as seen above, be explained invoking quantum structures, but its remarkable optical properties may also be explained this way. Canham believes that the thin Si filaments may act as quantum wires. Significant quantum effects require structural sizes below 5 nm (see Madou [1997, chap. 7]) and the porous Si definitely can have structures of that size. By treatment of the porous Si with  $\text{NH}_3$  at high temperatures, it is possible to make thick  $\text{Si}_3\text{N}_4$  films. Even at 13  $\mu\text{m}$ , these films show little evidence of stress in contrast to stoichiometric LPCVD nitride films [Smith and Collins, 1990].

Porous Si might represent a simple way of making the quantum structures of the future. Pore size of PSL can be influenced by both light intensity and current density. The quantum aspect adds significantly to the sudden big interest taken in porous Si.

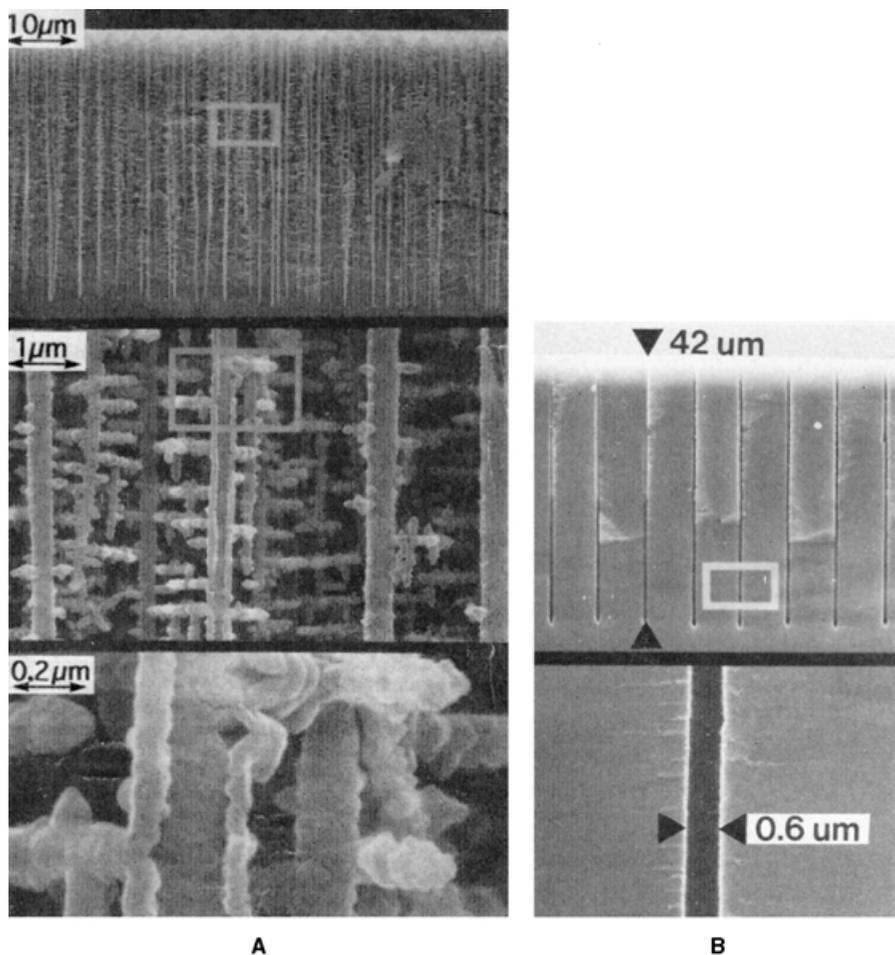

### Macroporous Silicon

In addition to micropores, well-defined macropores can also be made in Si by photo and/or bias etching in HF solutions. Macropores have sizes as large as 10  $\mu\text{m}$ , visible with a scanning electron microscope (SEM) rather than TEM. The two types of pores often coexist, with micropores covering the walls of macropores. Sizes can differ by three orders of magnitude. This is not a matter of a broad fractal type distribution of pores, but the formation mechanism is quite different.

Electrochemical etching of macropores or macroholes has been reported for n-type silicon in 2.5 to 5% HF under high voltage ( $>10\text{ V}$ ), low current density ( $10\text{ mAcm}^{-2}$ ), under illumination, and in the dark [Levy-Clement et al., 1992]. In the latter case, Zener breakdown in silicon (electric field strength in excess of  $3 \times 10^5\text{ V/cm}$ ) causes the hole formation. The macropores are formed only with lightly doped n-silicon at much higher anodic potentials than those used for micropore formation [Zhang, 1991]. By using a pore initiation pattern the macropores actually can be localized at any desired location. This dramatic effect is illustrated by comparing Figures 16.44A and B [Lehmann, 1993; 1996]. Pores orthogonal to the surface with depths up to a whole wafer thickness can be made and aspect ratios as large as 250 become possible. The formation mechanism in this case cannot be explained on the basis of depletion of holes due to quantum confinement in the fine porous structures, given that these macropores exhibit sizes well beyond 5 nm. As with microporous Si, the surface morphology produced by the dissolution process depends critically on whether mass transport or charge supply is the rate-limiting step. For pore

**FIGURE 16.44** Macroporous Si; formation of random and localized macropores or macroholes. (A) Random: surface, cross section and a  $45^\circ$  bevel of an n-type sample ( $10^{15}/\text{cm}^3$  phosphorus-doped) showing a random pattern of macropores. Pore initiation was enhanced by applying 10-V bias in the first minute of anodization followed by 149 min at 3 V. The current density was kept constant at  $10\text{ mA/cm}^2$  by adjusting the backside illumination. A 6% aqueous solution of HF was used as an electrolyte. The set-up used for anodization is sketched in the upper right corner. (B) Localized: surface, cross section and a  $45^\circ$  bevel of an n-type sample ( $10^{15}/\text{cm}^3$  phosphorus-doped) showing a predetermined pattern of macropores (3 V, 350 min, 2.5% HF). Pore growth was induced by a regular pattern of pits produced by standard lithography and subsequent alkaline etching (inset upper right). To measure the depth dependence of the growth rate, the current density was kept periodically at  $5\text{ mA/cm}^2$  for 45 min and then reduced to  $3.3\text{ mA/cm}^2$  for 5 min. This reduction resulted in a periodic decrease of the pore diameter, as marked by white labels in the figure. (From Lehmann, V., *J. Electrochem. Soc.*, 140, 2836–2843, 1993. With permission.)

**FIGURE 16.45** Comparison of macropores made with breakdown holes (A) and macropores made with light created holes (B). (A) An oxide replica of pores etched under weak backside illumination visualizes the branching of pores produced by generation of charge carriers due to electrical breakdown (5 V, 3% HF, room temperature,  $10^{15}/\text{cm}^3$  phosphorus-doped). (From Lehmann, V., *J. Electrochem. Soc.*, 140, 2836–2844, 1993. With permission.) (B) Single pore associated with KOH pit. (From Lehmann, V. and H. Foll, *J. Electrochem. Soc.*, 137, 653–659, 1990. With permission.)

formation one must work again in a charge depletion mode. Macropore formation, as micropore formation, is a self-adjusting electrochemical mechanism. In this case, the limitation is due to the depletion of the holes in the pore walls in n-Si wafers causing them to passivate. Holes keep on being collected by the pore tip where they promote dissolution. No passivating layer is involved to protect the pore wall. The only decisive differences between pore tips and pore walls are their geometry and their location. Holes generated by light or Zener breakdown are collected at pore tips. Every depression or pit in the surface initiates pore growth because the electrical field at a curved pore bottom is much larger than that of a flat surface due to the effect of the radius of curvature. The latter leads to higher current and enhances local etching [Zhang, 1991]. Zener breakdown and illumination of n-Si lead to different types of pore geometry [Lehmann, 1993; Theunissen, 1972; Lehmann and Foll, 1990]. Branched pores with sharp tips form if holes are generated by breakdown (see [Figure 16.45A](#)) [Lehmann, 1993]. Unbranched pores with larger tip radii result from holes created by illumination (see [Figure 16.45B](#)) [Lehmann and Foll, 1990]. The latter difference can be understood as follows: the electric field strength is a function of bias, doping

density and geometry. High doping level density or sharp pore tips will lower the required bias for breakdown, so macropores will tend to follow pores with the sharpest tips. Since every tip causes a new breakdown and hole generation, the position of the original pore tip becomes independent of the other pores, branching of the pores is possible, and fir-tree type pores can be observed. With illumination the pore radius may be larger as the breakdown field strength is not necessary to generate charge carriers, so the pores remain unbranched.

The Si anisotropy common with alkaline etchants surprisingly shows up here with an isotropic etchant such as HF. For example, with breakdown-supplied holes,  $\langle 100 \rangle$ -directed macroholes with  $\langle 110 \rangle$  branches form (see also Figure 16.45A) [Lehmann, 1993], leading to a complex network of caverns beneath the silicon surface. Pyramidal pore tips [Lehmann, 1993] also were observed when the current density was limited by the bias ( $i < i_{\text{CRIT}}$ ). Isotropic pore pits form when the current is larger than the critical current density, i.e., isotropy in HF etching can be changed into anisotropy when the supply of holes is limited. We refer here to the Elwenspoek et al. model (see above) which predicts that in confined spaces etching will tend to be more anisotropic, even when using a normally isotropic etchant such as HF. It was also determined that macrohole formation depends on the wavelength of the light used. No hole formation occurs below about 800 nm. Depending on the wavelength, the shape of the hole can be manipulated as well [Lehmann and Foll, 1990]. For wavelengths above 867 nm, the depth profile of the holes changed from conical to cylindrical. The latter was interpreted in terms of the influence of the local minority carrier generation rate. Carriers generated deep in the bulk would promote the hole growth at the tips, whereas near-surface generation would lead to lateral growth.

Cahill et al. (1993) reported in 1993 the creation of 1- to 5- $\mu\text{m}$ -size pores with pore spacings (center-to-center) from 200 to 1000  $\mu\text{m}$ . Until this finding, the pores typically formed were spaced in the range of 4 to 30  $\mu\text{m}$  center-to-center, while being 0.6 to 10  $\mu\text{m}$  in diameter. Making highly isolated pores presents quite another challenge. In the previous work, the relative close spacing of the pores allowed the authors to conclude that the regions between the pores were almost totally depleted and that practically all carriers were collected by the pore tips. In such a case, neither the pore side walls nor the wafer surface etched as all holes were swept to the pore tips. Since the surface was not attacked by pore-forming holes, the quality of the pore initiation mask lost its relevance. In Cahill et al.'s case, on the other hand, a long-lived mask (>20 hours) needed to be developed to help prevent pore formation everywhere except at initiation pits. The mask eventually used is shown in Figure 16.46; it shows a SiC layer sandwiched between two layers of silicon nitride. The silicon nitride directly atop the silicon served to insulate the silicon carbide from the underlying substrate. As the silicon carbide proves very resistant to HF, loss of thickness did not show during the procedure. The top nitride served to protect the carbide during anisotropic pit formation. By lowering the bias to less than two volts with respect to a saturated calomel electrode (SCE) side-branching was avoided.

It seems very likely that this macropore formation phenomenon could extend to all types of n-type semiconductors. Some evidence with InP and GaAs supports this statement [Lehmann, 1993].

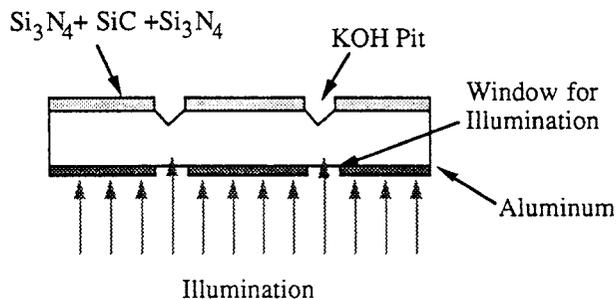

FIGURE 16.46 Long-lived macropore initiation mask.

## 16.7 Etch-Stop Techniques

---

### 16.7.1 Introduction

In many cases it is desirable to stop etching in silicon when a certain cavity depth or a certain membrane thickness is reached. Nonuniformity of etched devices due to nonuniformity of the silicon wafer thickness can be quite high. Taper of double-polished wafers, for example, can be as high as 40  $\mu\text{m}$  [Lambrechts and Sansen, 1992]! Even with the best wafer quality the wafer taper is still around 2  $\mu\text{m}$ . The taper and variation in etch depth lead to intolerable thickness variations for many applications. Etch-rate control typically requires monitoring and stabilization of:

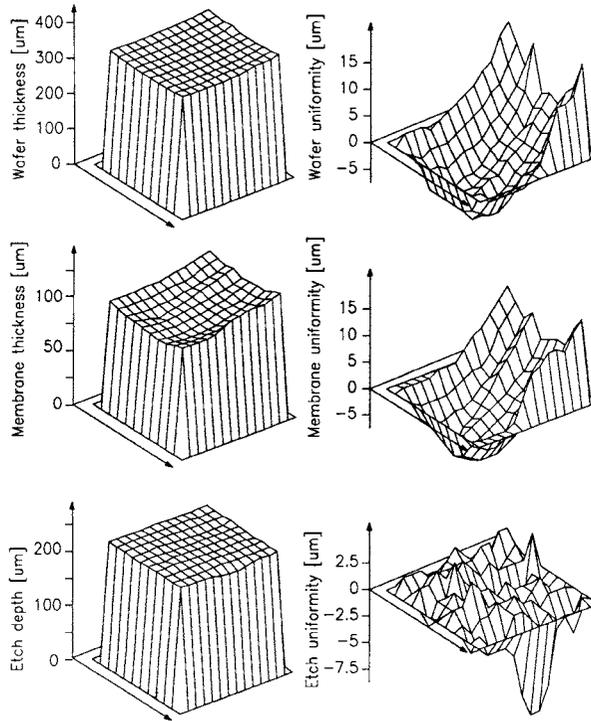

- Etchant composition
- Etchant aging
  - Stabilization with  $\text{N}_2$  sparging (especially with EDP and hydrazine)
  - Taking account of the total amount of material etched (loading effects)
- Etchant temperature
- Diffusion effects (constant stirring is required, especially for EDP)
  - Stirring also leads to a smoother surface through bubble removal
  - Trenching (also pillowing) and roughness decrease with increased stirring rate
- Light may affect the etch rate (especially with n-type Si)
- Surface preparation of the sample can have a big effect on etch rate (the native oxide retards etch start; a dip in dilute HF is recommended)

With good temperature, etchant concentration, and stirring control the variation in etch depth typically is 1% (see [Figure 16.47](#)) [Lambrechts and Sansen, 1992]. A good pretreatment of the surface to be etched is a standard RCA clean combined with a 5% HF dip to remove the native oxide immediately prior to etching in KOH.

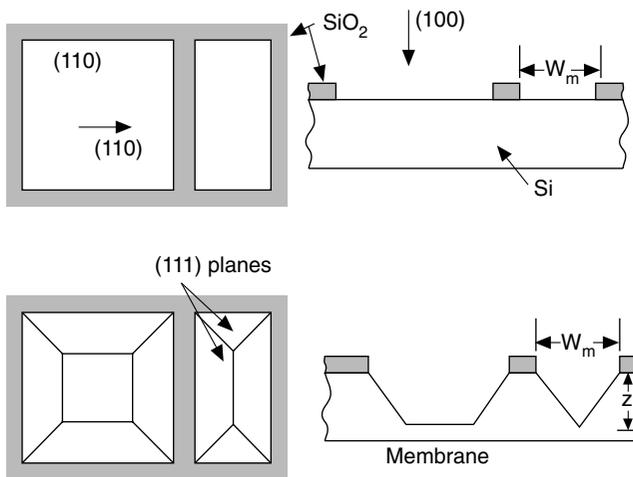

In the early days of micromachining, one of the following techniques was used to etch a Si structure anisotropically to a predetermined thickness. In the simplest mode the etch time was monitored ([Table 16.9](#) lists some etch rates for different etchants) or a bit more complex; the infrared transmittance was followed. For thin membranes the etch stop cannot be determined by a constant etch time method with sufficient precision. The spread in etch rates becomes critical if one etches membranes down to thicknesses of less than 20  $\mu\text{m}$ ; it is almost impossible to etch structures down to less than 10  $\mu\text{m}$  with a timing technique. In the V-groove technique, V-grooves with precise openings (see Eq. (16.2)) were used such that the V-groove stopped etching at the exact moment a desired membrane thickness was reached (see [Figure 16.48](#)) [Samaun et al., 1973]. One can also design wider mask openings on the wafer's edge so that the wafer is etched through at those sites at the moment the membrane has reached the appropriate thickness. Although Nunn and Angell (1975) claimed that an accuracy of about 1  $\mu\text{m}$  could be obtained using the V-groove method, none of the mentioned techniques are found to be production worthy. Nowadays the above methods are almost completely replaced by etch-stop techniques based on a change in etch rate dependant on doping level or chemical nature of a stopping layer. High resolution silicon micromachining relies on the availability of effective etch-stop layers. It is actually the existence of impurity-based etch stops in silicon that has allowed micromachining to become a high-yield production process.

### 16.7.2 Boron Etch Stop

The most widely used etch-stop technique is based on the fact that anisotropic etchants, especially EDP, do not attack boron-doped (p+) Si layers heavily. This effect was first noticed by Greenwood (1969). He assumed that the presence of a p-n junction was responsible.

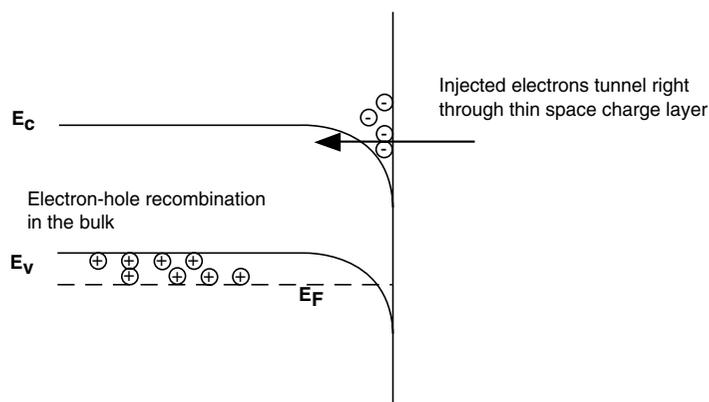

**FIGURE 16.47** A map of the wafer thickness, the membrane thickness and the etch depth. (From Lambrechts, S.W. and W. Sansen, *Biosensors: Microelectrochemical Devices*, Institute of Physics Publishing, 1992. With permission.)

**FIGURE 16.48** V-groove technique to monitor the thickness of a membrane. At the precise moment the V-groove is developed, the membrane has reached the desired thickness.

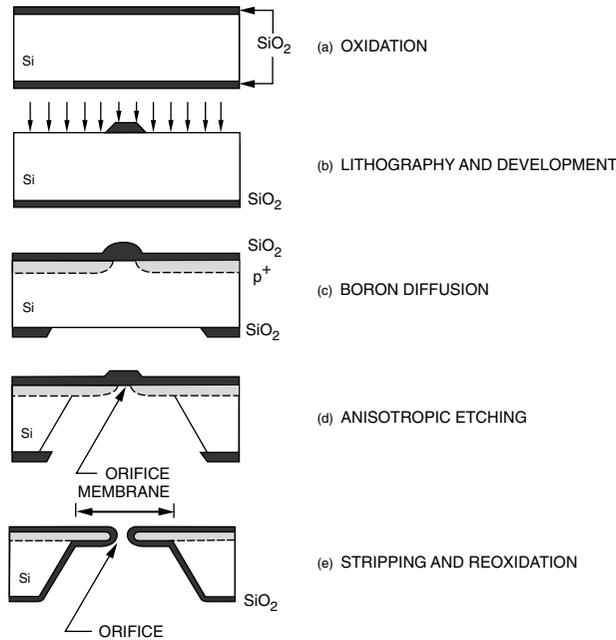

Bogh (1971) found that at an impurity concentration of about  $7 \times 10^{19}/\text{cm}^3$  resulted in the etch rate of Si in EDP dropping sharply (see also Table 16.9), but without any requirement for a p-n junction. For KOH-based solutions, Price (1973) found a significant reduction in etch rate for boron concentrations above  $5 \times 10^{18} \text{ cm}^{-3}$ . The model by Seidel et al., discussed above, provides an elegant explanation for the etch stop at high boron concentrations. At moderate dopant concentration, we saw that the electrons

**FIGURE 16.49** Si/electrolyte interface energetics at high doping level explaining etch-stop behavior.

injected into the conduction band stay localized near the semiconductor surface due to the downward bending of the bands (Figure 16.37). The electrons there have a small probability of recombining with holes deeper into the crystal even for p-type Si. This situation changes when the doping level in the silicon increases further. At a high dopant concentration, silicon degenerates and starts to behave like a metal. For a degenerate p-type semiconductor, the space charge thickness shrinks and the Fermi level drops into the valence band as indicated in Figure 16.49. The injected electrons shoot (tunnel) right through the thin surface charge layer into deeper regions of the crystal where they recombine with holes from the valence band. Consequently, these electrons are not available for the subsequent reaction with water molecules (Reaction 16.5), the reduction of which is necessary for providing new hydroxide ions in close proximity to the negatively charged silicon surface. These hydroxide ions are required for the dissolution of the silicon as  $\text{Si}(\text{OH})_4$ . The remaining etch rate observed within the etch stop region is then determined by the number of electrons still available in the conduction band at the silicon surface. This number is assumed to be inversely proportional to the number of holes and thus the boron concentration. Experiments show that the decrease in etch rate is nearly independent of the crystallographic orientation and the etch rate is proportional to the inverse fourth power of the boron concentration in all alkaline etchants.

From the above it follows that a simple boron diffusion or implantation, introduced from the front of the wafer, can be used to create beams and diaphragms by etching from the back. The boron etch-stop technique is illustrated in Figure 16.50 for the fabrication of a micromembrane nozzle [Brodie and Muray, 1982]. The  $\text{SiO}_2$  mesa in Figure 16.50b leads to the desired boron  $p^+$  profile. The anisotropic etch from the back clears the lightly doped p-Si (Figure 16.50d). Layers of  $p^+$  silicon having a thickness of 1 to 20  $\mu\text{m}$  can be formed with this process. The boron etch stop constitutes a very good etch stop; it is not very critical when the operator takes the wafer out of the etchant. One important practical note is that the boron etch stop may become badly degraded in EDP solutions that were allowed to react with atmospheric oxygen. Since boron atoms are smaller than silicon, a highly doped, freely suspended membrane or diaphragm will be stretched; the boron-doped silicon is typically in tensile stress and the microstructures are flat and do not buckle. While doping with boron decreases the lattice constant, doping with germanium increases the lattice constant. A membrane doped with B and Ge still etches much slower than undoped silicon, and the stress in the layer is reduced. A stress-free, dislocation-free and slow etching layer ( $\pm 10$  nm/min) is obtained at doping levels of  $10^{20}$   $\text{cm}^{-3}$  boron and  $10^{21}$   $\text{cm}^{-3}$  germanium [Seidel et al., 1990; Heuberger, 1989]. One disadvantage with this etch-stop technique is that the extremely high boron concentrations are not compatible with standard CMOS or bipolar techniques, so they can only be used for microstructures without integrated electronics. Another limitation of this process is the fixed number and angles of (111) planes one can accommodate. The etch stop is less effective in KOH compared to EDP. Besides boron, other impurities have been tried for use in an etch stop in anisotropic

**FIGURE 16.50** Illustration of the boron etch stop in the fabrication of a membrane nozzle. (From Brodie, I. and J. J. Muray, *The Physics of Microfabrication*, Plenum Press, New York, 1982. With permission.)

etchants. Doping Si with germanium has hardly any influence on the etch rate of either the KOH or EDP solutions. At a doping level as high as  $5 \times 10^{21} \text{ cm}^{-3}$  the etch rate is barely reduced by a factor of two [Seidel et al., 1990].

By burying the highly doped boron layer under an epitaxial layer of lighter doped Si the problem of incompatibility with active circuitry can be avoided. A  $\pm 1\%$  thickness uniformity is possible with modern epilayer deposition equipment (see, for example, *Semiconductor International*, July 1993, pp. 80–83). A widely used method of automatically measuring the epi thickness is with infrared (IR) instruments, especially Fourier transform infrared (FTIR) [Rehrig, 1990]; see also Epitaxy later in this chapter and in Madou (1997, chap. 5).

### 16.7.3 Electrochemical Etch-Stop Technique

For the fabrication of piezoresistive pressure sensors, the doping concentration of the piezo resistor must be kept smaller than  $1 \times 10^{19} \text{ cm}^{-3}$  because the piezoresistive coefficients drop considerably above this value and reverse breakdown becomes an issue. Moreover, high boron levels compromise the quality of the crystal by introducing slip planes and tensile stress and prevent the incorporation of integrated electronics. As a result, a boron stop often cannot be used to produce well-controlled thin membranes unless, as suggested above, the highly doped boron layer is buried underneath a lighter doped Si epi layer. Alternatively, a second etch-stop method, an electrochemical technique, can be used. In this case, a lightly doped p-n junction is used as an etch stop by applying a bias between the wafer and a counter electrode in the etchant. This technique was first proposed by Waggener (1970). Other early work on electrochemical etch-stops with anisotropic etchants such as KOH and EDP was performed by Palik et al. (1982), Jackson et al. (1981), Faust and Palik (1983) and Kim and Wise (1983). In electrochemical anisotropic etching a p-n junction is made, for example, by the epitaxial growth of an n-type layer (phosphorus-doped,  $10^{15} \text{ cm}^{-3}$ ) on a p-type substrate (boron-doped,  $30 \Omega\text{cm}$ ). This p-n junction forms a large diode over the whole wafer. The wafer is usually mounted on an inert substrate, such as a sapphire plate, with an acid-resistant wax and is partly or wholly immersed in the solution. An ohmic contact to the n-type epilayer is connected to one pole of a voltage source and the other pole of the voltage source is connected

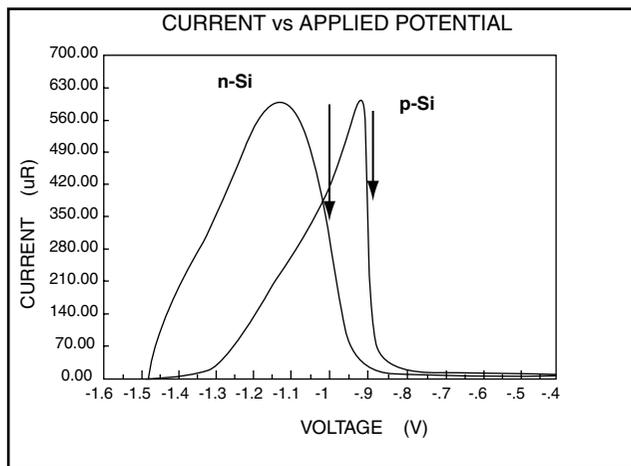

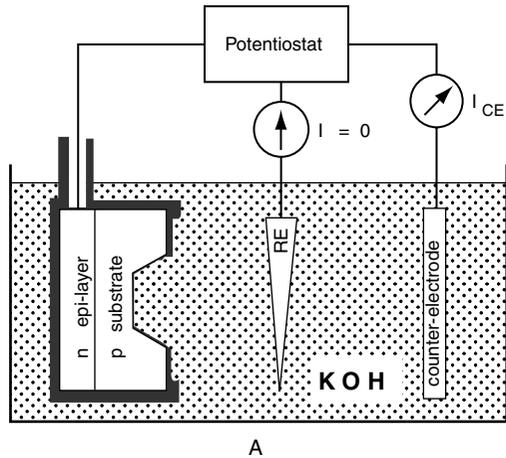

FIGURE 16.51 Electrochemical etch stop. (A) Electrochemical etching set-up with potentiostatic control (three-electrode system). Potentiostatic control, mainly used in research studies, enables better control of the potential as it is referenced now to a reference electrode such as a saturated calomel electrode (SCE). In industrial settings, electrochemical etching is often carried out in a simpler two-electrode system, i.e., a Pt counter electrode and Si working electrode [Kloeck et al., 1989]. (B) Cyclic voltammograms of n- and p-type silicon in an alkaline solution at 60°C. Flade potentials are indicated with an arrow.

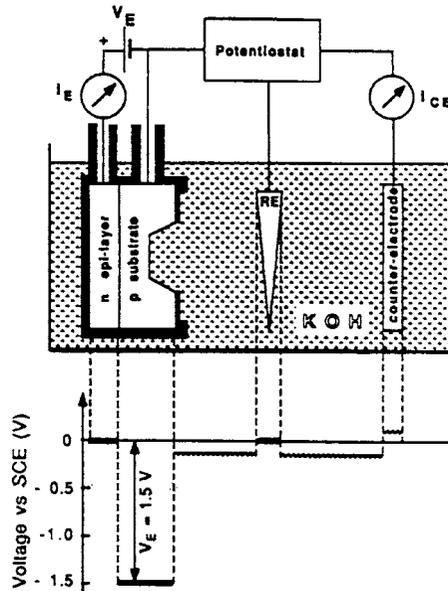

via a current meter to a counterelectrode in the etching solution (see Figure 16.51A). In this arrangement the p-type substrate can be selectively etched away and the etching stops at the p-n junction, leaving a membrane with a thickness solely defined by the thickness of the epilayer. The incorporation of a third electrode (a reference electrode) in the three-terminal method depicted in Figure 16.51A allows for a more precise determination of the silicon potential with respect to the solution than a two-terminal set-up as we illustrated in Figure 16.25.

At the Flade potential in Figure 16.51B, the oxide growth rate equals the oxide etch rate; a further increase of the potential results in a steep fall of the current due to complete passivation of the silicon surface. At potentials positive of the Flade potential, all etching stops. At potentials below the Flade potential, the current increases as the potential becomes more positive. This can be explained by the formation of an oxide which etches faster than it forms, i.e., the silicon is etched away. Whereas electrochemists like to talk about the Flade potential, physicists like to discuss matters in terms of the flat-band

potential. The flat-band potential is that applied potential at which there are no more fields within the semiconductor, i.e., the energy band diagram is flat throughout the semiconductor. The passivating SiO<sub>2</sub> layer is assumed to start growing as soon as the negative surface charge on the silicon electrode is cancelled by the externally applied positive bias, a bias corresponding to the flat band potential. At these potentials, the formation of Si(OH)<sub>x</sub> complexes does not lead to further dissolution of silicon, because two neighboring Si-OH HO-Si groups will react by splitting of water, leading to the formation of Si-O-Si bonds. As can be learned from Figure 16.51B, the value of the Flade potential depends on the dopant type. Consequently, if a wafer with both n and p regions exposed to the electrolyte is held at a certain potential in the passive range for n-type and the active range for p-type, the p-regions are etched away, whereas the n-regions are retained. In the case of the diode shown in Figure 16.51A, where at the start of the experiment only p-type Si is exposed to the electrolyte, one starts by applying a positive bias to the n-type epilayer ( $V_n$ ). This reverse biases the diode, and only a reverse bias current can flow. The potential of the p-type layer in this regime is negative of the flat-band potential and active dissolution takes place. At the moment that the p-n junction is reached, a large anodic current can flow and the applied positive potential passivates the n-type epilayer. Etching continues on the areas where the wafer is thicker until the membrane is reached there, too. The thickness of the silicon membrane is thereby solely defined by the thickness of the epilayer; neither the etch uniformity nor the wafer taper will influence the result. A uniformity of better than 1% can be obtained on a 10- $\mu\text{m}$ -thick membrane. The current vs. time curve can be used to monitor the etching process; at first, the current is relatively low, i.e., limited by the reverse bias current of the diode, then as the p-n junction is reached a larger anodic current can flow until all the p-type material is consumed and the current falls again to give a plateau. The plateau indicates we have reached the current associated with a passivated n-type Si electrode. The etch procedure can be stopped at the moment that the current plateau has been reached, and since the etch stop is thus basically one of anodic passivation one sometimes terms it an anodic oxidation etch stop. Registering an I vs. V curve as in Figure 16.51B will establish an upper limit on the applied voltage,  $V_n$  [McNeil et al., 1990] and such curves are used for *in situ* monitoring and controlling of the etch stop. A crude endpoint monitoring can be accomplished by the visual observation of cessation of hydrogen bubble formation accompanying Si etching. Palik et al. presented a detailed characterization of Si membranes made by electrochemical etch stop [Palik et al., 1988].

Hirata et al. (1988), using the same anodic oxidation etch stop in a hydrazine-water solution at  $90 \pm 5^\circ\text{C}$  and a simple two-terminal electrochemical cell, obtained a pressure sensitivity variation of less than 20% from wafer to wafer (pressure sensitivity is inversely proportional to the square of membrane thickness). A great advantage of this etch-stop technique is that it works with Si with low doping levels of the order of  $10^{16} \text{ cm}^{-3}$ . Due to the low doping levels, it is possible to fabricate structures with a very low, or controllable, intrinsic stress. Moreover, active electronics and piezo membranes can be built into the Si without problems. A disadvantage is that the back of the wafer with the aluminum contact has to be sealed hermetically from the etchant solution which requires complex fixturing and manual wafer handling. The fabrication of a suitable etch holder is no trivial matter. The holder must (1) protect the epi-contact from the etchant, (2) provide a low-resistance ohmic contact to the epi and (3) must not introduce stress into wafers during etching [Peeters, 1994; Elwenspoek et al., 1994]. Stress introduced by etch holders easily leads to diaphragm or wafer fracture and etchant seepage through to the epi-side.

Using a four-electrode electrochemical cell, controlling the potentials of both the epitaxial layer and the silicon wafer, as shown in Figure 16.52, can further improve the thickness control of the resulting membrane by directly controlling the p/n bias voltage. The potential required to passivate n-type Si can be measured using the three-electrode system in Figure 16.51A, but this system does not take into account the diode leakage. If the reverse leakage is too large, the potential of the n-Si,  $V_n$ , will approach the potential of the p-Si,  $V_p$ . If there is a large amount of reverse diode leakage, the p-region may passivate prior to reaching the n-region and etching will cease. In the four-electrode configuration, the reverse leakage current is measured separately via a p-region contact, and the counter-electrode current may be monitored for end-point detection. The four-electrode approach allows etch stopping on lower

**FIGURE 16.52** Four-electrode electrochemical etch-stop configuration. Voltage distribution with respect to the SCE reference electrode (RE) for the four-electrode case. The fourth electrode enables an external potential to be applied between the epitaxial layer and the substrate, thus maintaining the substrate at etching potentials. (From Kloeck et al., *IEEE Trans. Electron. Dev.*, 36, 663–669, 1989. With permission.)

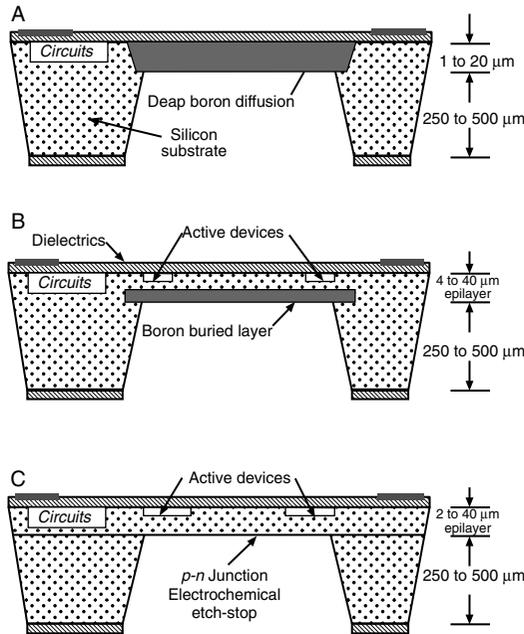

quality epis (larger leakage current) and should also enable etch stopping of p-epi on n-substrates. Kloeck et al. (1989) demonstrated that using such an electrochemical etch-stop technique and with current monitoring, the sensitivity of pressure sensors fabricated on the same wafer could be controlled to within 4% standard deviation. These authors used a 40% KOH solution at  $60 \pm 0.5^\circ\text{C}$ . Without the etch stop, the sensitivity from sensor to sensor on one wafer varied by a factor of 2.

The etching solution used in electrochemical etching can either be isotropic or anisotropic. Electrochemical etch stop in isotropic media was discussed above. In this case one uses HF/H<sub>2</sub>O mixtures to etch the highly doped regions of p<sup>+</sup>p, n<sup>+</sup>n, n<sup>+</sup>p, and p<sup>+</sup>n systems [Theunissen et al., 1970; Meek, 1971; Theunissen, 1972; Wen and Weller, 1972; van Dijk, 1972]. The rate-determining step in etching with isotropic etchants does not involve reducing water with electrons from the conduction band as it does in anisotropic etchants and the etch stop mechanism, as we learned earlier is obviously different. In isotropic media, the etch stop is simply a consequence of the fact that higher conductivity leads to higher corrosion currents and the etch slows down on lower conductivity layer. A major advantage of the KOH electrochemical etch is that it retains all of the anisotropic characteristics of KOH without needing a heavily doped p<sup>+</sup> layer to stop the etch [Saro and van Herwaarden, 1986].

In [Figure 16.53](#), we review the etch-stop techniques discussed so far: diffused boron etch stop, buried boron etch stop and electrochemical etch stop [Wise, 1985]. A comparison of the boron etch stop and the electrochemical etch stop reveals that the IC compatibility and the absence of built-in stresses, both due to the low dopant concentration, are the main assets of the electrochemical etch stop.

### 16.7.4 Photo-Assisted Electrochemical Etch Stop (for n-Type Silicon)

A variation on the electrochemical diode etch-stop technique is the photo-assisted electrochemical etch-stop method illustrated in [Figure 16.54](#) [Mlcak et al., 1993]. An n-type silicon region on a wafer may be selectively etched in an HF solution by illuminating and applying a reverse bias across a p-n junction, driving the p-layer cathodic and the n-layer anodic. Etch rates up to 10 μm/min for the n-type material and a high resolution etch stop render this an attractive potential micromachining process. Advantages

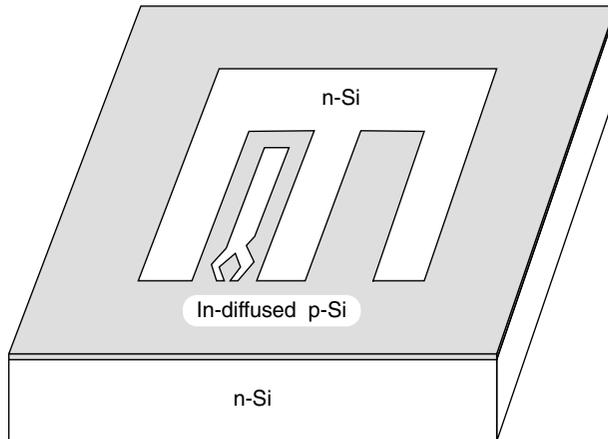

**FIGURE 16.53** Typical cross sections of bulk micromachined wafers with various methods for etch-stop formation shown. (A) Diffused boron etch stop. (B) Boron etch stop as a buried layer. (C) Electrochemical etch stop. (From Wise, K.D., in *Silicon Micromachining and Its Application to High Performance Integrated Sensors*, Fung, C.D., Ed., Elsevier, New York, 1985. With permission.)

also include the use of lightly doped n-Si, bias- and illumination intensity-controlled etch rates, *in situ* process monitoring using the cell current and the ability to spatially control etching with optical masking or laser writing. Using this method [Mlcak et al., 1993] prepared stress-free cantilever beam test samples. They diffused boron into a  $10^{15}$ - $\text{cm}^{-3}$  (100) n-Si substrate through a patterned oxide mask, leaving exposed a small n-type region which defines two p-type cantilever beams (see Figure 16.54).

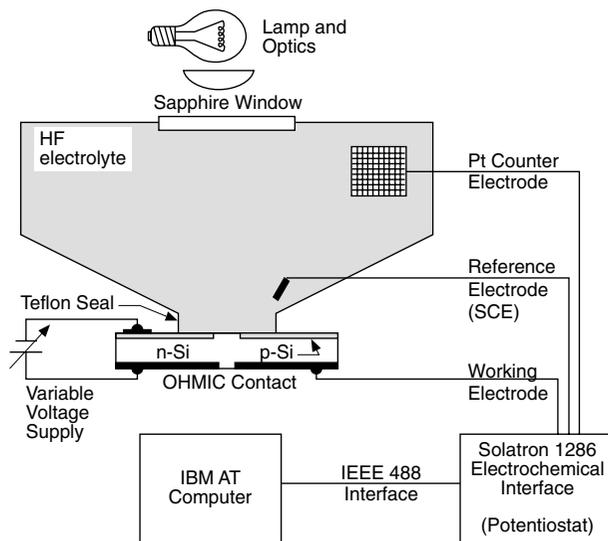

The boron diffusion resulted in a junction  $3.3\ \mu\text{m}$  underneath the surface. An ohmic contact on the backside of the wafer was used to apply a variable voltage across the p-n junction, and both p and n areas were exposed to the HF electrolyte. The exposed n-region was etched to a depth of  $150\ \mu\text{m}$  by shining light on the whole sample. The resulting n-type Si surface was at first found to be rough, as porous Si up to  $5\ \mu\text{m}$  in height forms readily in HF solutions. The Si surface could be made smoother by etching at higher bias ( $4.3\ \text{V}$  vs. SCE) and higher light intensity ( $2\ \text{W}/\text{cm}^2$ ) to a finish with features of the order of  $0.4\ \mu\text{m}$  in height. Smoothing could also be accomplished by a 5-second dip in  $\text{HNO}_3:\text{HF}:\text{H}_3\text{COOH}$  or a 30-second dip in 25 wt%,  $25^\circ\text{C}$ , KOH. Yet another way of removing unwanted porous Si is a  $1000^\circ\text{C}$  wet oxidation to make oxidized porous Si (OPS) followed by an HF etch (see next section) [Yoshida et al., 1992].

### 16.7.5 Photo-Induced Preferential Anodization, PIPA (for p-Type Silicon)

Electrochemical etching requires the application of a metal electrode to apply the bias. The application of such a metal electrode often induces contamination and constitutes at least one extra process step, and extra fixturing is needed. With photo-induced preferential anodization (PIPA) it is not necessary to deposit metal electrodes. Here one relies on the illumination of a p-n junction to bias the p-type Si anodically, and the p-Si converts automatically into porous Si while the n-type Si acts as a cathode for the reaction. The principle of photo-biasing for etching purposes was known and patented by Shockley as far back as 1963 [Shockley, 1963]. In U.S. patent 3,096,262, he writes “... light can be used in place of electrical connections ... for biasing of the sample ...” This means a small isolated area of p-type

material on an n-type body may be preferentially biased for removal of material beyond the junction by etching.” The method was reinvented by Yoshida et al. (1992) and Peeters et al. (1993a; 1993b). The latter group called the method ‘PHET’ for photovoltaic electrochemical etch-stop technique, and the former group coined the PIPA acronym.

In PIPA, etch rates of up to 5  $\mu\text{m}/\text{min}$  result in the formation of porous layers readily removed with Si etching solutions. An important advantage of the technique is that very small and isolated p-type islands can be anodized at the same time. The method also lends itself to fabricate three-dimensional structures using p-type Si as sacrificial layers [Yoshida et al., 1992]. A disadvantage of the technology is that one cannot control the process very well, as the current cannot be measured for endpoint detection. Application of PIPA to form a microbridge is shown in Figure 16.55. First, a buried p-Si layer doped to

**FIGURE 16.55** Photo-assisted electrochemical etch stop (for n-type Si). Fabrication process for a microbridge and SEM picture of Si structure before and after PIPA. (From Yoshida et al., Photo-Induced Preferential Anodization for Fabrication of Monocrystalline Micro-mechanical Structures, presented at Micro Electromechanical Systems, Trave-munde, 1992. With permission.)

$10^{18} \text{ cm}^{-3}$  and an n-type layer doped to  $10^{15} \text{ cm}^{-3}$  are formed on an n-type substrate using epitaxy (Figure 16.55a). Then p-type is preferentially anodized in 10% HF solution under  $30 \text{ mW/cm}^2$  light intensity for 180 minutes (Figure 16.55b), forming porous Si. The porous Si is then oxidized in wet oxygen at  $1000^\circ\text{C}$  (Figure 16.55c). Finally, the sacrificial layer of oxidized porous silicon is etched and removed with an HF solution (Figure 16.55d). The resulting surfaces of the n-type silicon are very smooth. It is interesting to consider making complicated three-dimensional structures by going immediately to the electropolishing regime instead. Yoshida et al. (1992) believe that porous silicon as a sacrificial intermediate is more suitable for fabricating complicated structures. The authors are probably referring to the fact that electropolishing is much more aggressive and could not be expected to lead to the same retention of the shape of the buried, sacrificial p-layers. Peeters et al. (1993) carry out their photovoltaic etching in KOH, thus skipping the porous Si stage of Yoshida et al. They, like Yosida et al., stress the fact that in one single etch step this technique can make a variety of complex shapes that would be impossible with electrochemical etching techniques. These authors found it necessary to coat the n-Si part of the wafer with Pt to get enough photovoltaic drive for the anodic dissolution; this metallization step makes the process more akin to the photoelectrochemical etching and some of the advantage of the photo-biasing process is being lost.

### 16.7.6 Etch Stop at Thin Films-Silicon on Insulator

Yet another distinct way (the fourth) to stop etching is by employing a change in composition of material. An example is an etch stopped at a  $\text{Si}_3\text{N}_4$  diaphragm. Silicon nitride is very strong, hard and chemically inert and the stress in the film can be controlled by changing the Si/N ratio in the LPCVD deposition process. The stress turns from tensile in stoichiometric films to compressive in silicon-rich films (for details see later in this chapter). A great number of materials are not attacked by anisotropic etchants. Hence, a thin film of such a material can be used as an etch stop.

Another example is the  $\text{SiO}_2$  layer in a silicon-on-insulator structure (SOI). A buried layer of  $\text{SiO}_2$ , sandwiched between two layers of crystalline silicon, forms an excellent etch stop because of the good selectivity of many etchants of Si over  $\text{SiO}_2$ . The oxide does not exhibit the good mechanical properties of silicon nitride and is consequently used rarely as a mechanical member in a microdevice. As with the photo-induced preferential anodization (PiPA), no metal contacts are needed with an SOI etch stop, greatly simplifying the process over an electrochemical etch stop technique.

## 16.8 Problems with Wet Bulk Micromachining

### 16.8.1 Introduction

Despite the introduction of better controllable etch-stop techniques, bulk micromachining remains a difficult industrial process to control. It is also not an applicable submicron technology, because wet chemistry is not able to etch reliably on that scale. For submicron structure definition dry etching is required (dry etching is also more environmentally safe). We will look now into some of the other problems associated with bulk micromachining, such as the extensive real estate consumption and difficulties in etching at convex corners, and detail the solutions that are being worked on to avoid, control or alleviate those problems.

### 16.8.2 Extensive Real Estate Consumption

#### 16.8.2.1 Introduction

Bulk micromachining involves extensive real estate consumption. This quickly becomes a problem in making arrays of devices. Consider the diagram in Figure 16.56, illustrating two membranes created by etching through a  $\langle 100 \rangle$  wafer from the backside until an etch stop, say a  $\text{Si}_3\text{N}_4$  membrane, is reached. In creating two of these small membranes a large amount of Si real estate is wasted and the resulting device becomes quite fragile.

#### 16.8.2.2 Real Estate Gain by Etching from the Front

One solution to limiting the amount of Si to be removed is to use thinner wafers, but this solution becomes impractical below  $200\ \mu\text{m}$  as such wafers break too often during handling. A more elegant solution is to etch from the front rather than from the back. Anisotropic etchants will undercut a masking material an amount dependent on the orientation of the wafer with respect to the mask. Such an etchant will etch any  $\langle 100 \rangle$  silicon until a pyramidal pit is formed, as shown in Figure 16.57. These pits have sidewalls with a characteristic  $54.7^\circ$  angle with respect to the surface of a  $\langle 100 \rangle$  silicon wafer, since the

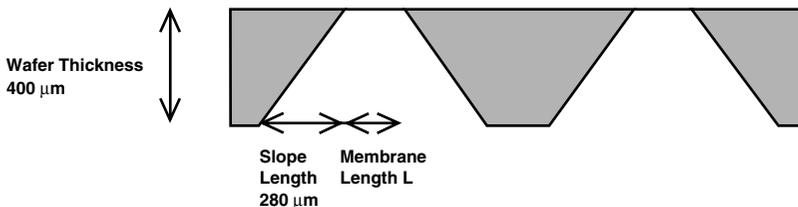

FIGURE 16.56 Two membranes formed in a  $\langle 100 \rangle$ -oriented silicon wafer.

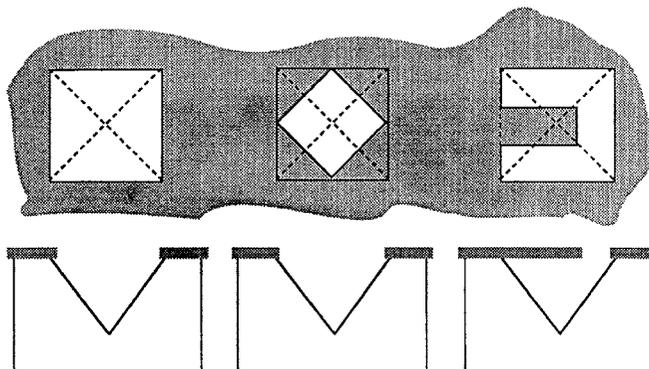

FIGURE 16.57 Three anisotropically etched pits etched from the front in a  $\langle 100 \rangle$ -oriented silicon wafer.

delineated planes are {111} planes. This etch property makes it possible to form cantilever structures by etching from the front side, as the cantilevers will be undercut and eventually will be suspended over a pyramidal pit in the silicon. Once this pyramidal pit is completed, the etch rate of the {111} planes exposed is extremely slow and practically stops. Process sequences, which depend on achieving this type of a final structure, are therefore very uniform across a wafer and very controllable. The upper drawings in Figure 16.57 represent patterned holes in a masking material: a square, a diamond and a square with a protruding tab. The drawings immediately below represent the etched pit in the silicon produced by the anisotropic etchant. Note in the first drawing that the square mask produces a four-sided pyramidal pit. In the second drawing, a similar shape oriented at 45° produces an etched pit which is oriented parallel to the pit etched in the first drawing. In the second drawing the corners of the diamond are undercut by the etchant as it produces the final etch pit. The third drawing illustrates that any protruding member is eventually undercut by the anisotropic etchant, leaving a cantilever structure suspended over the etch pit.

### 16.8.2.3 Real Estate Gain by Using Silicon Fusion-Bonded Wafers

Using silicon fusion-bonded (SFB) wafers rather than conventional wafers also makes it possible to fabricate much smaller microsensors. The process is clarified in Figure 16.58 for the fabrication of a gauge pressure sensor [Bryzek et al., 1990]. The bottom, handle wafer has a standard thickness of 525 μm and is anisotropically etched with a square cavity pattern. Next, the etched handle wafer is fusion bonded to a top sensing wafer (see SFB and surface micromachining later in this chapter, and packaging in Madou [1997, chap. 8]). The sensor wafer consists of a p-type substrate with an n-type epilayer corresponding to the required thickness of the pressure-transducing membrane. The sensing wafer is thinned all the way to the epilayer by electrochemical etching and resistors are ion implanted. The handle wafer is ground and polished to the desired thickness. For gauge measurement, the anisotropically etched cavity is truncated by the polishing operation, exposing the backside of the diaphragm. For an absolute pressure sensor the cavity is left enclosed. With the same diaphragm dimensions and the same overall thickness of the chip, an SFB device is almost 50% smaller than a conventional machined device (see Figure 16.59).

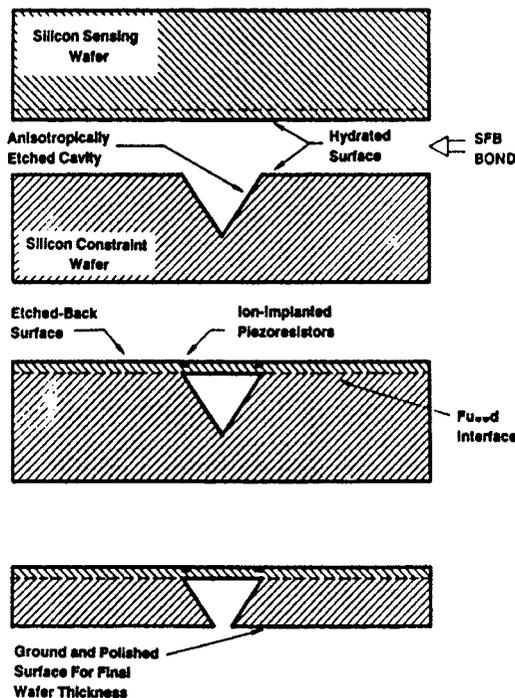

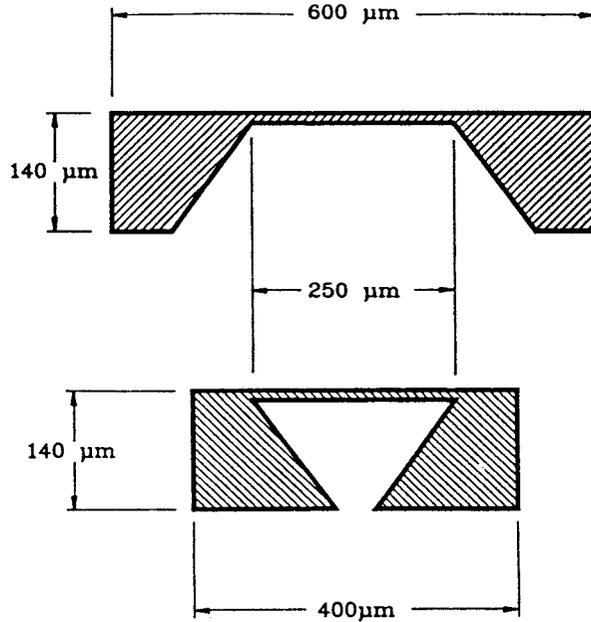

FIGURE 16.58 Fabrication process of an SFB-bonded gauge pressure sensor. (From Bryzek, J. et al., *Silicon Sensors and Microstructures*, Novasensor, Fremont, CA, 1990. With permission.)

**FIGURE 16.59** Comparison of conventional and SFB processes. The SFB process results in a chip which is at least 50% smaller than the conventional chip. (From Bryzek, J. et al., *Silicon Sensors and Microstructures*, Novasensor, Fremont, CA, 1990. With permission.)

## 16.8.3 Corner Compensation

### 16.8.3.1 Underetching

Underetching of a mask which contains no convex corners, i.e., corners turning outside in, in principle stems from mask misalignment and/or from a finite etching of the {111} planes. Peeters measured the widening of {111}-walled V-grooves in a (100) Si wafer after etching in 7 M KOH at  $80 \pm 1^\circ$  over 24 hours as  $9 \pm 0.5 \mu\text{m}$  [Peeters, 1994]. The sidewall slopes of the V-groove are a well-defined  $54.74^\circ$ , and the actual etch rate  $R_{111}$  is related to the rate of V-groove widening  $R_v$  through:

$$R_{111} = \frac{1}{2} \sin(54.74^\circ) R_v \quad \text{or} \quad R_{111} = 0.408 \cdot R_v \quad (16.41)$$

with  $R_{111}$  the etch rate in nm/min and  $R_v$  the groove widening, also in nm/min. The V-groove widening experiment then results in a  $R_{111}$  of  $2.55 \pm 0.15$  nm/min. In practice, this etch rate implies a mask underetching of only  $0.9 \mu\text{m}$  for an etch depth of  $360 \mu\text{m}$ . For a 1-mm-long V-groove and a  $1^\circ$  misalignment angle, a total underetching of  $18 \mu\text{m}$  is theoretically expected, with 95% due to misalignment and only 5% due to etching of the {111} sidewalls [Peeters, 1994]. The total underetching will almost always be determined by misalignment, rather than by etching of {111} walls.

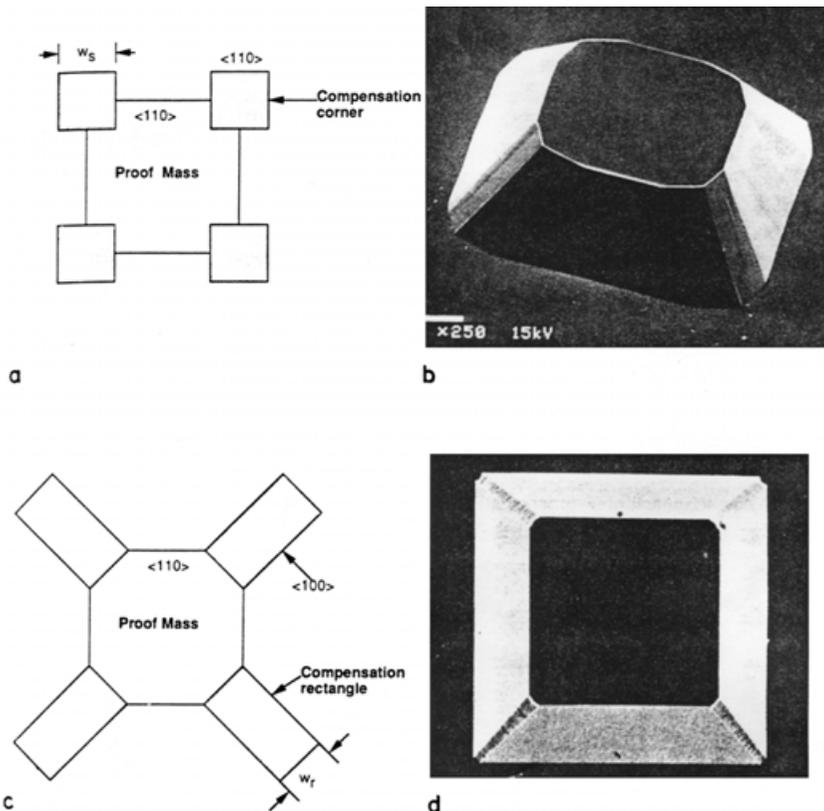

Mask underetching with masks that do include convex corners is usually much larger than the underetching just described, as the etchant tends to circumscribe the mask opening with {111} walled cavities. This is usually called undercutting rather than underetching. It is advisable to avoid mask layouts with convex corners. Often mesa-type structures are essential, though, and in that case there are two possible ways to reduce the undercutting. One is by chemical additives, reducing the undercut at the expense of a reduced anisotropy ratio, and the other is by a special mask compensating the undercut at the expense of more lost real estate.

### 16.8.3.2 Undercutting

When etching rectangular convex corners, deformation of the edges occurs due to undercutting. This is an unwanted effect, especially in the fabrication of, say, acceleration sensors, where total symmetry and perfect  $90^\circ$  convex corners on the proof mass are mandatory for good device prediction and specification. The undercutting is a function of etch time and thus directly related to the desired etch depth. An undercut ratio is defined as the ratio of undercut to etch depth ( $\delta/H$ ).

Saturating KOH solutions with isopropanol (IPA) reduces the convex corner undercutting; unfortunately, this happens at the cost of the anisotropy of the etchant. This additive also often causes the formation of pyramidal or cone-shaped hillocks [Peeters, 1994; Gravesen, 1986]. Peeters claims that these hillocks are due to carbonate contamination of the etchant and he advises etching under inert atmosphere also and stock-piling all etchant ingredient under an inert nitrogen atmosphere [Peeters, 1994].

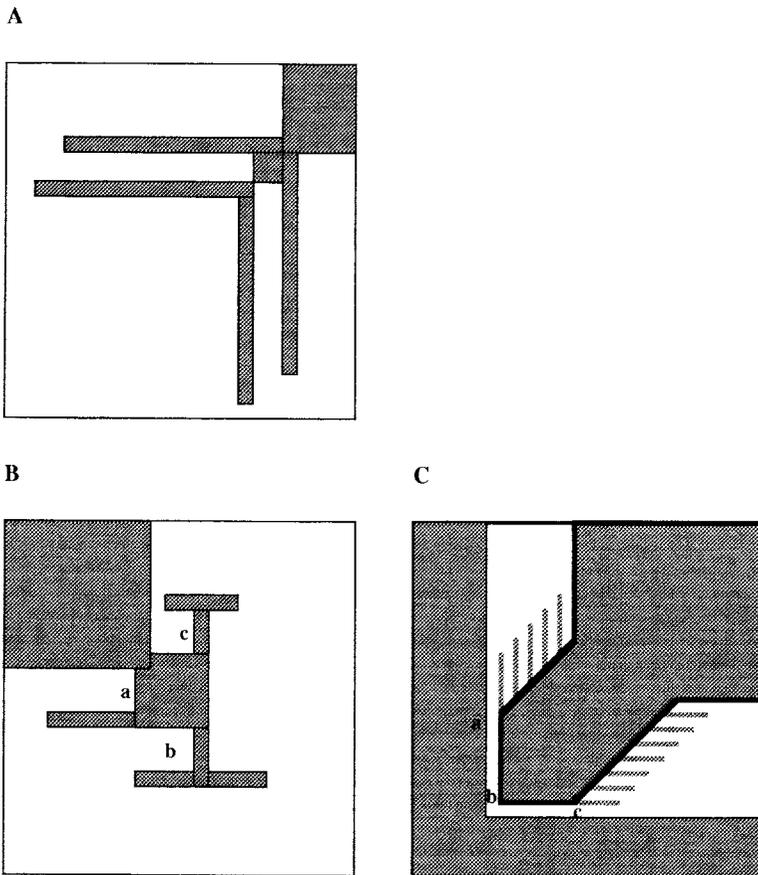

Undercutting can also be reduced or even prevented by so-called corner compensation structures which are added to the corners in the mask layout. Depending on the etching solution, different corner compensation schemes are used. Commonly used are square corner compensation (EDP or KOH) and rotated rectangle corner compensation methods (KOH). In Figure 16.60, these two compensation methods are illustrated. In the square corner compensation case, the square of  $\text{SiO}_2$  in the mask, outlining the square proof mass feature for an accelerometer, is enhanced by adding an extra  $\text{SiO}_2$  square to each corner (Figure 16.60a). Both the proof mass and the compensation squares are aligned with their sides parallel to the  $\langle 110 \rangle$  direction. In this way, two concave corners are created at the convex corner to be protected. Thus, direct undercutting is prevented. The three 'sacrificial' convex corners at the protective square

**FIGURE 16.60** Formation of a proof mass by silicon bulk micromachining. (a,b) Square corner compensation method, using EDP as the etchant. (c,d) Rotated rectangle corner compensation method, using KOH as the etchant.

are undercut laterally by the fast etching planes during the etch process. The dimension of the compensation square,  $w_s$ , for a 500- $\mu\text{m}$ -thick wafer (4 in.) is about 500  $\mu\text{m}$ . The resulting mesa structure after EDP or KOH etching is shown in Figure 16.60b. In the rotated rectangle corner compensation method shown in Figure 16.60c, a properly scaled rectangle ( $w_r$  should be twice the thickness of the wafer) is added to each of the mask corners. The four sides of the mesa square are still aligned along the  $\langle 110 \rangle$  direction, but the compensation rectangles are rotated ( $45^\circ$ ) with their longer sides along the  $\langle 100 \rangle$  directions. Using KOH as an etchant reveals the mesa shown in Figure 16.60d. A proof mass is frequently dislodged by simultaneously etching from the front and the back. Corner compensation requires significant amount of space around the corners, making the design less compact, and the method is often only applicable for simple geometries.

Different groups around the world have been using different corner compensation schemes and they all claim to have optimized spatial requirements. For an introduction to corner compensation, refer to Puers and Sansen (1990), and Sandmaier et al. (1991) for KOH etching use  $\langle 110 \rangle$ -oriented beams,  $\langle 110 \rangle$ -oriented squares and  $\langle 010 \rangle$ -oriented bands for corner compensation. They found that spatial requirements for compensation structures could be reduced dramatically by combining several of these compensation structures. The mask layouts for some of the different compensation schemes used by Sandmaier et al. are shown in Figure 16.61. To understand the choice and dimensioning of these compensation structures, as well as those in Figure 16.60, we will first look at the planes emerging at convex corners during KOH

**FIGURE 16.61** Mask layout for various convex corner compensation structures. (From Sandmaier, H. et al., Corner Compensation Techniques in Anisotropic Etching of (100) Silicon Using Aqueous KOH, presented at Transducers '91, San Francisco, CA, 1991. With permission.)

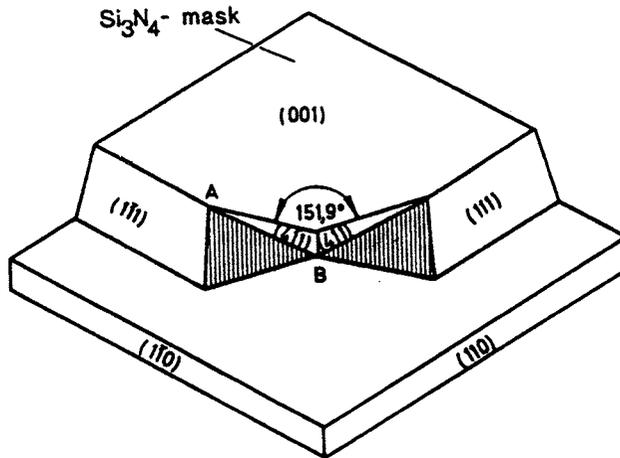

FIGURE 16.62 Planes occurring at convex corners during KOH etching. (From Mayer, G.K. et al., *J. Electrochem. Soc.*, 137, 3947–3951, 1990. With permission.)

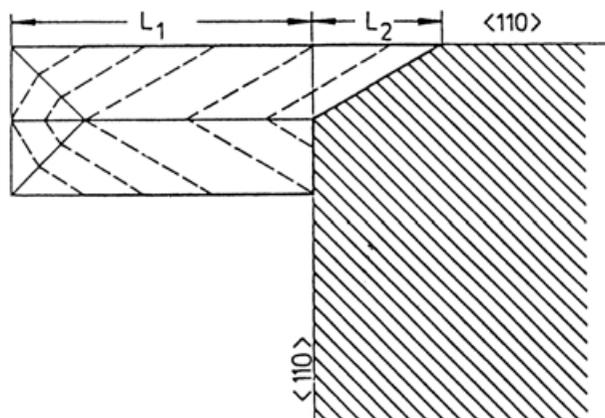

FIGURE 16.63 Dimensioning of the corner compensation structure with a <110>-oriented beam. (From Sandmaier, H. et al., *Corner Compensation Techniques in Anisotropic Etching of (100) Silicon Using Aqueous KOH*, presented at Transducers '91, San Francisco, CA, 1991. With permission.)

etching. Mayer et al. (1990) found that the undercutting of convex corners in pure KOH etch is determined exclusively by {411} planes. The {411} planes of the convex undercutting corner, as shown in Figure 16.62, are not entirely laid free, however; rugged surfaces, where only fractions of the main planes can be detected, overlap the {411} planes under a diagonal line shown as AB in this figure. The ratio of {411} to {100} etching does not depend on temperature between 60 and 100°C. The value does decline with increasing KOH concentration from about 1.6 at 15% KOH to 1.3 at above 40% where the curve flattens out [Mayer et al., 1990]. Ideally one avoids rugged surfaces and searches for well-defined planes bounding the convex corner. In Figure 16.63 it is shown how a <110> beam is added to the convex corner to be etched. The fast etching {411} planes, starting at the two convex corners, are laterally undercutting a <110>-oriented beam (broken lines in Figure 16.63). It is clear that the longer this <110>-oriented beam is, the longer the convex corner is protected from undercutting. It is essential that by the end of the etch the beam has disappeared to maintain a minimum of rugged surface at the convex edge. On the other hand, as is obvious from Figure 16.63, a complete disappearance of the beam

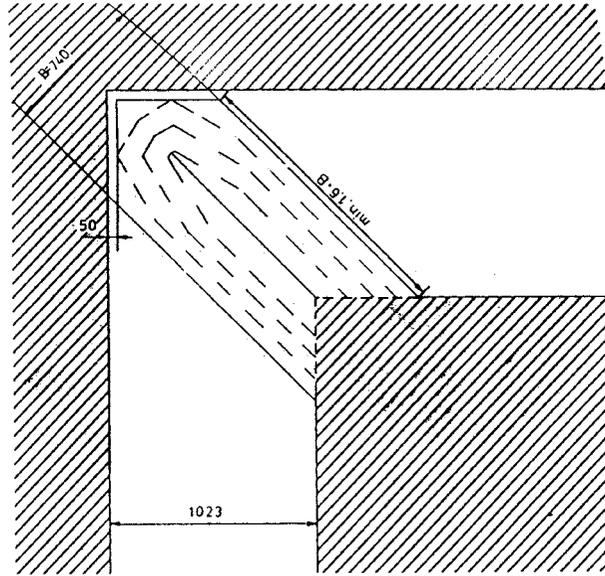

leads to a beveling at the face of the convex corner. The dimensioning of the compensating  $\langle 110 \rangle$  beam works then as follows: the length of the compensating beam is calculated primarily from the required etch depth ( $H$ ) and the etch rate ratio  $R\{411\}/R\{100\}$  ( $\approx \delta/H$ ), at the concentration of the KOH solution used:

$$L = L_1 - L_2 = 2H \frac{R\{411\}}{R\{100\}} - \frac{B_{\langle 110 \rangle}}{2 \tan(30.9^\circ)} \quad (16.42)$$

with  $H$  the etch depth;  $B_{\langle 110 \rangle}$  the width of the  $\langle 110 \rangle$ -oriented beam;  $\tan(30.9^\circ)$  the geometry factor [Mayer et al., 1990]. The factor 2 in the first term of this equation results as the etch rate of the  $\{411\}$  plane is determined normal to the plane and has to be converted to the  $\langle 110 \rangle$  direction. The second term in Eq. (16.42) takes into account that the  $\langle 110 \rangle$  beam needs to disappear completely by the time the convex corner is reached. The resulting beveling in Figure 16.63 can be reduced by further altering the compensation structures. This is done by decelerating the etch front, which largely determines the corner undercutting. One way to accomplish this is by creating more concave shapes right before the convex corner is reached. In Figure 16.61A, splitting of the compensation beam creates such concave corners, and by arranging two such double beams a more symmetrical final structure is achieved. By using these split beams, the bevelling at the corner is reduced by a factor of 1.4 to 2 and leads to bevel angles under  $45^\circ$ .

Corner compensation with  $\langle 110 \rangle$ -oriented squares (as shown in Figure 16.60A) features considerably higher spatial requirements than the  $\langle 110 \rangle$ -oriented beams. Since these squares are again undercut by  $\{411\}$  planes that are linked to the rugged surfaces described above, the squares do not easily lead to sharp  $\{111\}$ -defined corners. Dimensioning of the compensation square is done by using Eq. (16.42) again, where  $L_1$  is half the side length of the square, and for  $B_{\langle 110 \rangle}$  the side length is used. All fast-etching planes have to reach the convex corner at the same time. As before, the spatial requirements of this compensation structure can be reduced if it is combined with  $\langle 110 \rangle$ -oriented beams. Such a combination is shown in Figure 16.61B. The three convex corners of the compensation square are protected from undercutting by the added  $\langle 110 \rangle$  beams. During the first etch step, the  $\langle 110 \rangle$ -oriented side beams are undercut by the etchant. Only after the added beams have been etched does the square itself compensate the convex corner etching. The dimensioning of this combination structure is carried out in two steps. First the  $\langle 110 \rangle$ -oriented square is selected with a size that is permitted by the geometry of the device to be etched. From these dimensions, the etch depth corresponding to this size is calculated from Eq. (16.42). For the remaining etch depth the  $\langle 110 \rangle$ -oriented beams are dimensioned like any other  $\langle 110 \rangle$ -oriented beam. If the side beam on corner b is selected about 30% longer than the other two side beams, the quality of the convex corner can be further improved. In this case, the corner is formed by the etch fronts starting at the corners a and b (Figure 16.61B).

A drawback to all the above proposed compensation schemes is the impossibility, due to rugged surfaces always accompanying  $\{411\}$  planes, of obtaining a clean corner in both the top and the bottom of a convex edge. Buser and de Rooij (1988) introduced a compensation scenario where a convex corner was formed by two  $\{111\}$  planes which were well defined all the way from the mask to the etch bottom. No rugged, undefined planes show in this case. The mask layout to create such an ideal convex corner has bands that are added to convex corners in the  $\langle 100 \rangle$  direction (see Figure 16.61C and Figure 16.60c and d). These bands will be underetched by vertical  $\{100\}$  planes from both sides. With suitable dimensioning of such a band, a vertically oriented membrane results, thinning, and eventually freeing the convex edge shortly before the final intended etch depth is reached. In contrast to compensation structures undercut by  $\{411\}$  planes, posing problems with undefined rugged surfaces (see above), this compensation structure is mainly undercut by  $\{100\}$  planes. Over the temperature range of 50 to  $100^\circ\text{C}$  and KOH concentrations ranging from 25 to 50 wt%, no undefined surfaces could be detected in the case of structures undercut by  $\{100\}$  planes [Sandmaier et al., 1991]. The width of these  $\langle 010 \rangle$ -oriented compensation beams, which determines the minimum dimension of the structures to etch,

**FIGURE 16.64** Beam structure open on one side. The beam is oriented in the  $\langle 010 \rangle$  direction. Dimensions in microns.  $B$  is the width of the beam.

has to be twice the etching depth. These beams can either connect two opposite corners and protect both from undercutting simultaneously, or they can be added to the individual convex corners (open beam). With an open beam approach (see Figure 16.64) one has to be certain that the  $\{100\}$  planes reach the corner faster than the  $\{411\}$  planes. For that purpose the beams have to be wide enough to avoid complete underetching by  $\{411\}$  planes moving in from the front side, before they are completely underetched by  $\{100\}$  planes moving in from the side. For instance, in a 33% KOH etchant a ratio between beam length and width of at least 1.6 is required. To make these compensation structures smaller while at the same time maintaining  $\{100\}$  undercutting to define the final convex corner, Sandmaier et al. remarked that the shaping  $\{100\}$  planes do not need to be present at the beginning of the etching process. These authors implement delaying techniques by adding fan-like  $\langle 110 \rangle$ -oriented side beams to a main  $\langle 100 \rangle$ -oriented beam (see Figure 16.61C). As described above, these narrow beams are underetched by  $\{411\}$  planes and the rugged surfaces they entail until reaching the  $\langle 100 \rangle$ -oriented beam. Then the  $\{411\}$  planes are decelerated in the concave corners between the side beams by the vertical  $\{100\}$  planes with slower etching characteristics. The length of the  $\langle 110 \rangle$ -oriented side beams is calculated from:

$$L_{\langle 110 \rangle} = \left( H - \frac{B_{\langle 010 \rangle}}{2} \right) \frac{R_{\{411\}}}{R_{\{100\}}} \quad (16.43)$$

with  $H$  being the etching depth at the deepest position of the device.

The width of the side beams does not influence the calculation of their required length. In order to avoid the rugged surfaces at the convex corner, the width of the side beams as well as the spaces between them should be kept as small as possible. For an etching depth of  $500 \mu\text{m}$ , a beam width of  $20 \mu\text{m}$  and a space width of  $2 \mu\text{m}$  are optimal [Sandmaier et al., 1991].

Depending on the etchant, different planes are responsible for undercutting. From the above we learned that in pure KOH solutions undercutting, according to Mayer et al. (1990) and Sandmaier et al. (1991), mainly proceeds through  $\{411\}$  planes or  $\{100\}$  planes. That the  $\{411\}$  planes are the fastest undercutting

planes was confirmed by Seidel (1986); at the wafer surface, the sectional line of a (411) and a (111) plane point in the  $\langle 410 \rangle$  direction, forming an angle of  $30.96^\circ$  with the  $\langle 110 \rangle$  direction, and it was in this direction that he found a maximum in the etch rate. In KOH and EDP etchants Bean (1978) identified the fast undercutting planes as {331} planes. Puers and Sansen (1990), for alkali/alcohol/water, identified the fast underetching planes as {331} planes, as well. Mayer et al. (1990), working with pure KOH, could not confirm the occurrence of such planes. Lee indicated that in hydrazine-water the fastest underetching planes are {211} planes [Lee, 1969]. Abu-Zeid (1984) reported that the main beveling planes are {212} planes in ethylene-diamine-water solution (no added pyrocatechol). Wv and Ko (1989) found the main beveling planes at undercut corners to be {212} planes whether using KOH, hydrazine, or EPW solutions are used. In view of our earlier remarks on the sensitivity of etching rates of higher index rates on a wide variety of parameters (temperature, concentration, etching size, stirring, cation effect, alcohol addition, complexing agent, etc.) these contradictory results are not too surprising. Along the same line, Wu and Ko (1989) and Peurs et al. (1990) have suggested triangles to compensate for underetching, but Mayer et al. (1997) found them to lead to rugged surfaces at the convex corner. Combining a chemical etchant with more limited undercutting (IPA in KOH) with Sandmaier's reduced compensation structure schemes could further decrease the required size of the compensation features while retaining an acceptable anisotropy.

Corner compensation for  $\langle 110 \rangle$ -oriented Si was explored by Ciarlo [1987]. Ciarlo comments that both corner compensation and corner rounding can be minimized by etching from both surfaces so as to minimize the etch time required to achieve the desired features. This requires accurate front-to-back alignment and double-sided polished wafers.

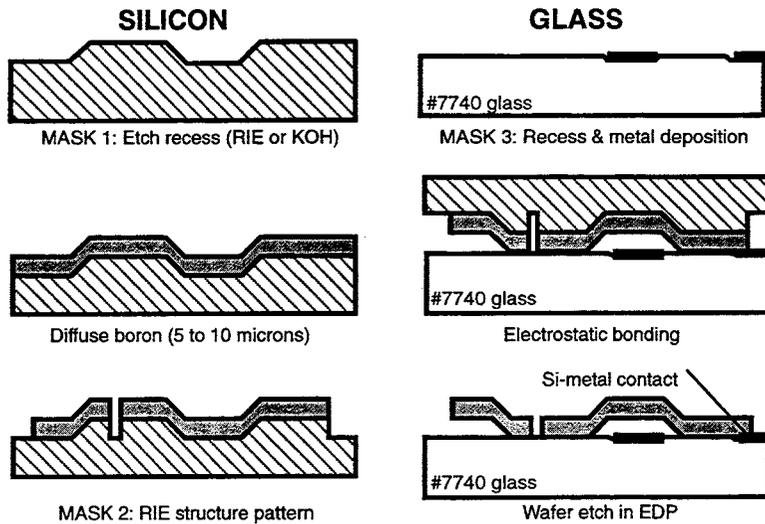

Employing corner compensation offers access to completely new applications such as rectangular solids, orbiting V-grooves, truncated pyramids with low cross-sections on the wafer surface, bellow structures for decoupling mechanical stresses between micromechanical devices and their packaging, etc. [Sandmaier et al., 1991].

## 16.9 Wet Bulk Micromachining Examples

---

### Example 1. Dissolved Wafer Process

Figure 16.65 illustrates the dissolved wafer process Cho is optimizing for the commercial production of low-cost inertial instruments [Cho, 1995]. This process, also in use by Draper Laboratory [Greiff, 1995; Weinberg et al., 1996] for the same application, involves a sandwich of a silicon sensor anodically bonded to a glass substrate. The preparation of the silicon part requires only two masks and three processing steps. A recess is KOH-etched into a p-type (100) silicon wafer (step 1 with mask 1), followed by a high-temperature boron diffusion (step 2 with no mask). In step one RIE may be used as well. Cho claims that by maintaining a high-temperature uniformity in the KOH etching bath ( $\pm 0.1^\circ\text{C}$ ), the accuracy and absolute variation of the etch across the wafer, wafer-to-wafer, and lot-to-lot, can be maintained to  $< 0.1 \mu\text{m}$  using pre-mixed, 45 wt% KOH. Cho is also using low-defect oxidation techniques (e.g., nitrogen annealing and dry oxidation) to form defect-free silicon surfaces. In the boron diffusion the key is optimizing the oxygen content. In general, the optimal flow of oxygen is on the order of 3 to 5% of the nitrogen flow, in which case the doping uniformity is on the order of  $\pm 0.2 \mu\text{m}$ . Varying the KOH etch depth and the shallow boron diffusion time, a wide variety of operating ranges and sensitivities for sensors can be obtained. Next, the silicon is patterned for a reactive ion etching (RIE) etch (step 3 with mask 2). Aspect ratios above 10 are accessible. Using some of the newest dry etching techniques depths in excess of  $500 \mu\text{m}$  at rates above  $4 \mu\text{m}/\text{min}$  (with a  $\text{SF}_6$  chemistry) are now possible [Craven and Pandhumsporn, 1995]. The glass substrate (#7740 Corning glass) preparation involves etching a recess, depositing and in a one-mask step patterning a multi-metal system of Ti/Pt/Au. The electrostatic bonding of glass to silicon takes place at  $335^\circ\text{C}$  with a potential of 1000 V applied between the two parts (electrostatic or anodic bonding is explained in detail in Madou [1997, chap. 8]). Commercial bonders have alignment accuracies on the order of  $< 1 \mu\text{m}$ . The lightly doped silicon is dissolved in an EDP solution at  $95^\circ\text{C}$ . The keys to uniform EDP etching are temperature uniformity

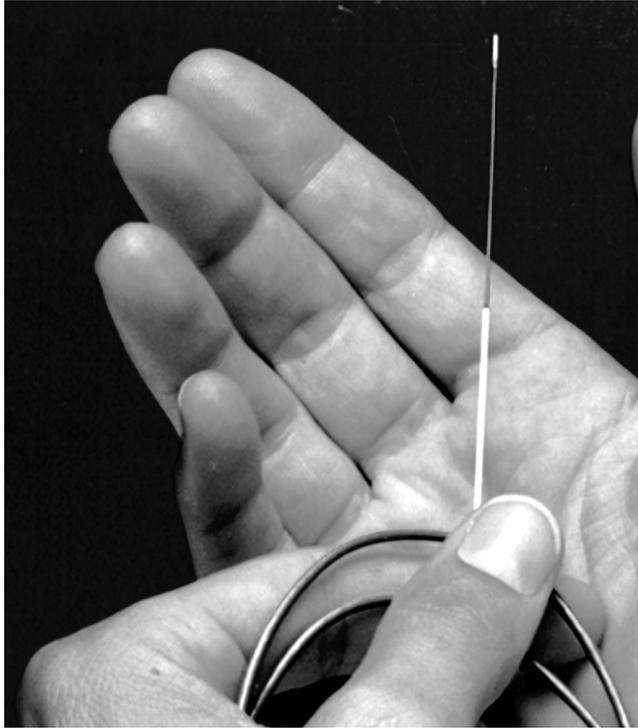

**FIGURE 16.65** Dissolved wafer process. (From Greiff, P., SOI-Based Micromechanical Process, presented at Micro-machining and Microfabrication Process Technology, Austin, TX, 1995. With permission.)

and suppression of etchant depletion through chemical aging or restricted flow (e.g., through bubbles). These effects can be minimized by techniques that optimize temperature control and reduce bubbling (e.g., proper wafer spacing, lower temperature, large bath). The structures are finally rinsed in DI water and a hot methanol bath.

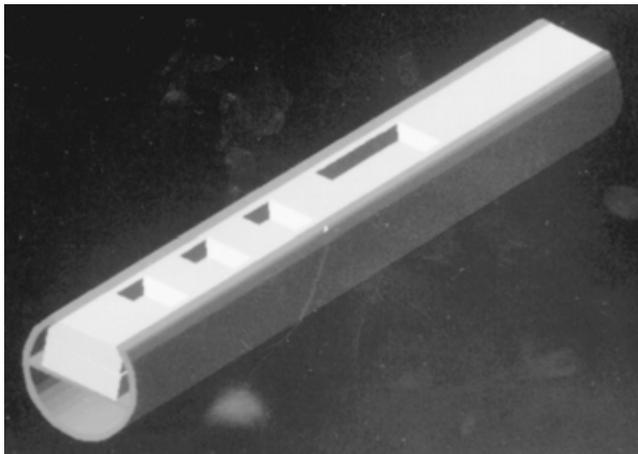

Draper Laboratory, although obtaining excellent device results with the dissolved wafer process, is now exploring an SOI process as an alternative. The latter yields an all-silicon device while preserving many of the dissolved wafer process advantages (see also “SOI Surface Micromachining” later in this chapter).

### Example 2. An Electrochemical Sensor Array Measuring pH, CO<sub>2</sub>, and O<sub>2</sub> in a Dual Lumen Catheter

This sensor array developed by the author is shown in Figure 16.66, packaged and ready for *in vivo* monitoring of blood pH, CO<sub>2</sub> and O<sub>2</sub>. The linear electrochemical array fits inside a 20-gauge catheter (750 μm in diameter) without taking up so much space as to distort the pressure signal monitored by a pressure sensor outside the catheter. A classical (macro) reference electrode, making contact with the blood through the saline drip, was used for the pH signal, while the CO<sub>2</sub> and O<sub>2</sub> had their own internal reference electrodes. The high impedance of the small electrochemical probes makes a close integration of the electronics mandatory; otherwise, the high impedance connector leads, in a typical hospital setting, act as antennas for the surrounding electronic noise. As can be seen from the computer-aided design (CAD) picture in Figure 16.67, the thickness of the sensor comes from two silicon pieces, the top piece containing electrochemical cells and the bottom piece containing the active electronics. Each wafer is 250 μm thick. The individual electrochemical cells are etched anisotropically into the top silicon wafer. The bottom piece is fabricated in a custom IC housing using standard IC processes. The process sequence to build a generic electrochemical cell in a 250-μm-thick Si wafer with one or more electrodes at the bottom of each well is illustrated in Figure 16.68. Electrochemical wells are etched from the front of the wafer and, after an oxidation step, access cavities for the metal electrodes are also etched from the back. The etching of the vias stops at the oxide-covered bottoms of the electrochemical wells (Figure 16.68A). Next, the wafers are oxidized a second time with the oxide thickness doubling everywhere except in the suspended window areas where no more Si can feed further growth (Figure 16.68B). The desired electrode metal is subsequently deposited from the back of the wafer into the access cavities and against the oxide window

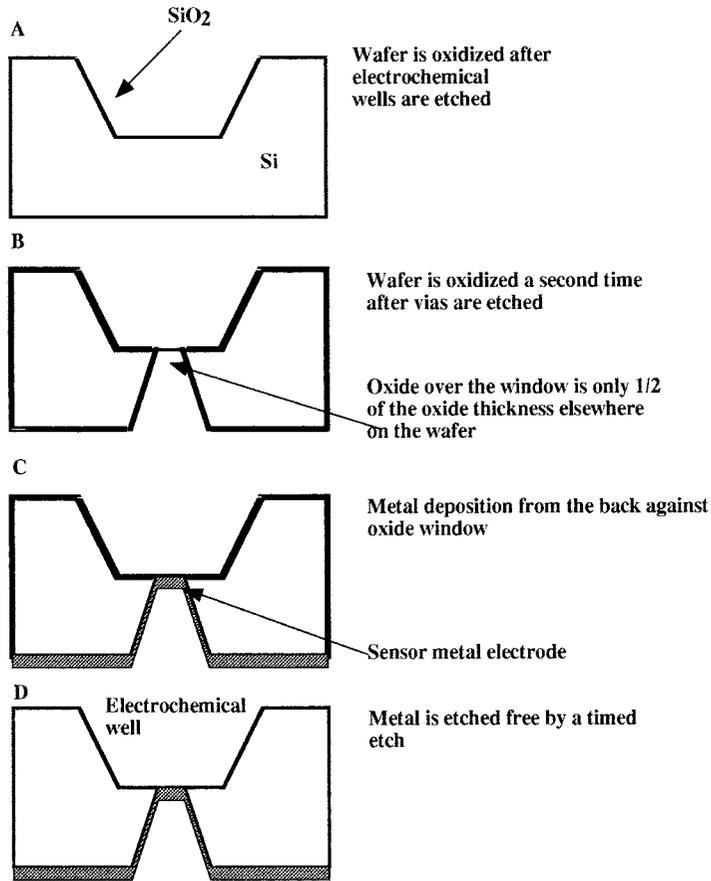

**FIGURE 16.66** An *in vivo* pH, CO<sub>2</sub> and O<sub>2</sub> sensor based on a linear array of electrochemical cells.

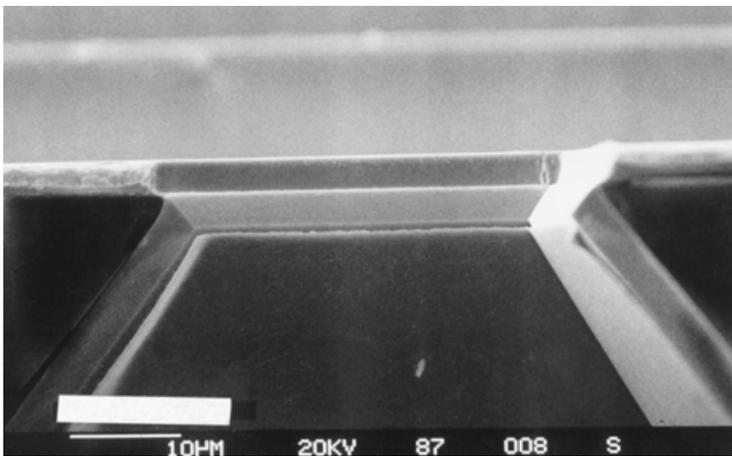

**FIGURE 16.67** CAD of the electrochemical sensor array showing two pieces of Si (each 250  $\mu\text{m}$  thick) on top of each other, mounted in a dual lumen catheter. The bottom part of the catheter is left open so pressure can be monitored and blood samples can be taken.

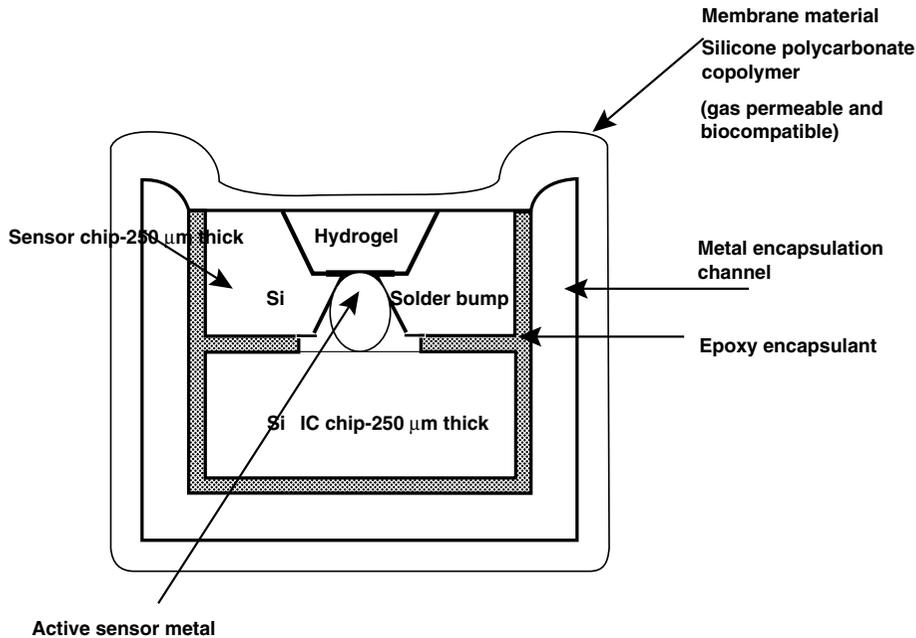

(Figure 16.68C). Finally, a timed oxide etch removes the sacrificial oxide window from above the underlying metal, while preserving the thicker oxide layer in the other areas on the chip (Figure 16.68D) [Joseph et al., 1989; Madou and Otagawa, 1989; Holland et al., 1988]. An SEM micrograph demonstrating step D in Figure 16.68 is shown in Figure 16.69. The electrodes in the electrochemical cells of the top wafer are further connected to the bottom wafer electronics by solder balls in the access vias of the top silicon wafer (see Figure 16.70). Separating the chemistry from the electronics in this way provides extra

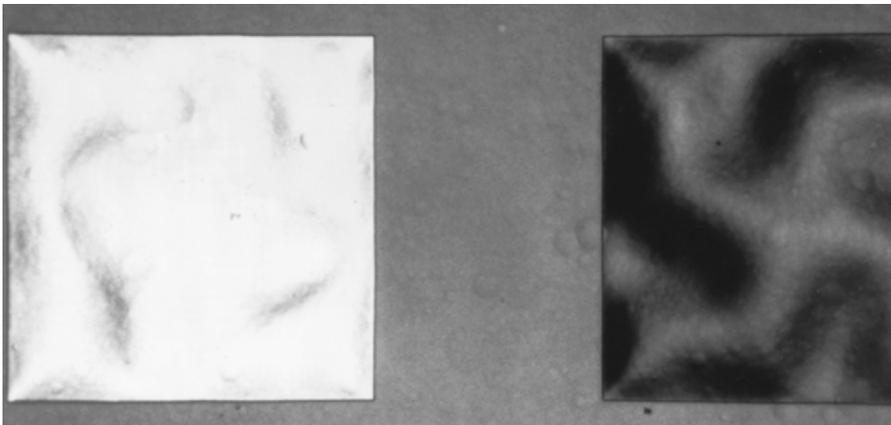

**FIGURE 16.68** Fabrication sequence for a generic electrochemical cell in Si. Depth of the electrochemical well, number of electrodes and electrode materials can be varied.

**FIGURE 16.69** SEM micrograph illustrating process step D from [Figure 16.67](#). A  $30 \times 30\text{-}\mu\text{m}$  Pt electrode is shown at the bottom of an electrochemical well. This Pt electrode is further contacted to the electronics from the back.

**FIGURE 16.70** Schematic of the bonding scheme between sensor wafer and IC. The schematic is a cut-through of the catheter.

**FIGURE 16.71** SEM micrograph of an Ag/AgCl (left) and an IrO<sub>x</sub> (right) electrode at the bottom of an anisotropically etched well in Si. This electrochemical cell forms the basis for a Severinghaus CO<sub>2</sub> sensor.

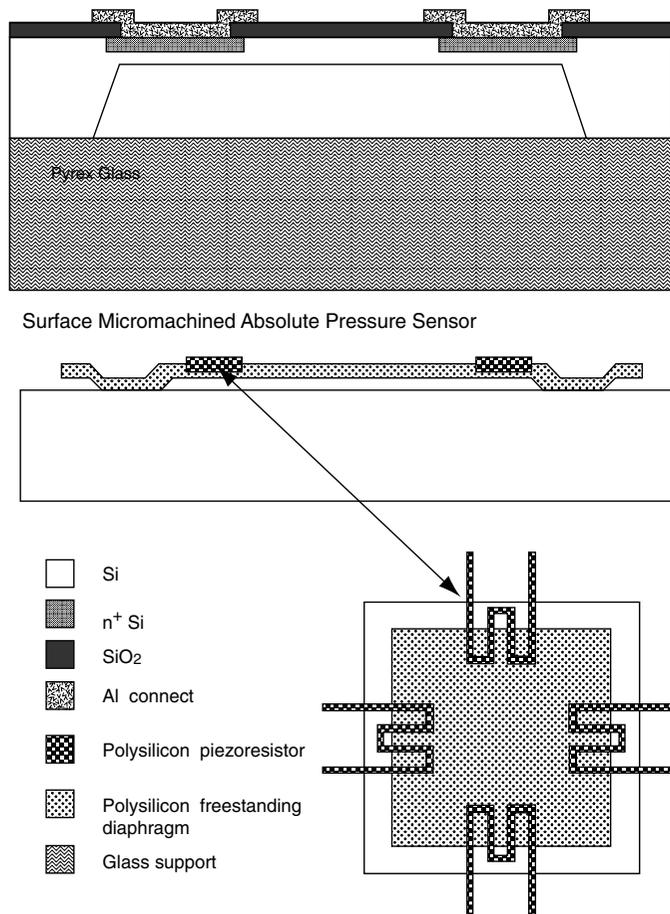

protection for the electronics from the electrolyte as well as from the electronics, and chemical sensor manufacture can proceed independently. Depending on the type of sensor element, one or more electrodes are fabricated at the bottom of the electrochemical cells. For example, shown in [Figure 16.71](#) is an almost completed (Severinghaus) CO<sub>2</sub> sensor with an Ag/AgCl electrode as the reference electrode (left in the figure) and an IrO<sub>x</sub> pH-sensitive electrode, both at the bottom of one electrochemical well. The metal electrodes are electrically isolated from each other by the SiO<sub>2</sub> passivation layer over the surface of the silicon wafer. To complete the CO<sub>2</sub> sensor, we silk-screen a hydrogel containing an electrolytic medium into the silicon sensor cavity and dip-coat the sensor into a silicone-polycarbonate rubber solution to form the gas-permeable membrane. For hydrogel inside the micromachined well, we use poly(2-hydroxyethyl)methacrylate (PHEMA) or polyvinylalcohol (PVA).

The concept of putting the sensor chemistries and the electronics on opposite sides of a substrate is a very important design feature we decided upon several years ago in view of the overwhelming problems encountered in building chemical sensors based on ISFETs or EGFETs [Madou and Morrison, 1989].

## 16.10 Surface Micromachining: Introduction

Bulk micromachining means that three-dimensional features are etched into the bulk of crystalline and noncrystalline materials. In contrast, surface micromachined features are built up, layer by layer, on the surface of a substrate (e.g., a single crystal silicon wafer). Dry etching defines the surface features in the  $x,y$  plane and wet etching releases them from the plane by undercutting. In surface micromachining, shapes in the  $x,y$  plane are unrestricted by the crystallography of the substrate. For illustration, in Figure 16.72 we compare an absolute pressure sensor based on poly-Si and made by surface micromachining with one made by bulk micromachining in single crystal Si.

The nature of the deposition processes involved determines the very flat surface micromachined features (Hal Jerman from EG&G's IC Sensors called them 2.5 D features [Jerman, 1994]). Specifically, low-pressure chemical vapor deposited (LPCVD) polycrystalline silicon (poly-Si) films generally are only a few microns high (low  $z$ ). In contrast with wet bulk micromachining only the wafer thickness limits the feature height. A low  $z$  may mean a drawback for some sensors. For example, it will be difficult to fashion a large inertial mass

**FIGURE 16.72** Comparison of bulk micromachined and surface micromachined absolute pressure sensors equipped with piezoresistive elements. (Top) Bulk micromachining in single crystal Si. (Bottom) Surface micromachining with poly-Si.

for an accelerometer from those thin poly-Si plates. Not only do many parameters in the LPCVD polysilicon process need to be controlled very precisely, subsequent high temperature annealing (say, at temperatures of about 580°C) is needed to transform the as-deposited amorphous silicon into polysilicon—the main structural material in surface micromachining. Even with the best possible process control, polysilicon has some material disadvantages over single crystal Si. For example, it generates a somewhat smaller yield strength (values between 2 and 10 times smaller have been reported) [Biebl and von Philipsborn, 1993; Greek et al., 1995] and has a lower piezoresistivity [Le Berre et al., 1996]. Moreover, since a grain diameter may constitute a significant fraction of the thickness of a mechanical member, the effective Young's modulus may exhibit significant variability from sensor to sensor [Howe, 1995]. An important positive attribute of poly-Si is that its material properties, although somewhat inferior to single crystal, are far superior compared to those of metal films, and, most of all, since they are isotropic, design is rendered dramatically simpler than with single crystal material. Dimensional uncertainties are of greater concern than material issues. Although absolute dimensional tolerances obtained with lithography techniques may be submicron, relative tolerances are poor, perhaps 1% on the length of a 100- $\mu\text{m}$ -long feature. The situation becomes critical with yet smaller feature sizes [Madou, 1997, chap. 7, Figure 7.1]. Although the relatively coarse dimensional control in the microdomain is not specific to surface micromachining, there is no crystallography to rely on for improved dimensional control as in the case of wet bulk micromachining. Moreover, since the mechanical members in surface micromachining tend to be smaller, more post-fabrication adjustment of the features is required to achieve reproducible characteristics. Finally, the wet process for releasing structural elements from a substrate tends to cause sticking of suspended structures to the substrate, so-called stiction, introducing another disadvantage associated with surface micromachining.

Some of the mentioned problems associated with surface micromachining have recently been resolved by process modifications and/or alternative designs, and the technique has rapidly gained commercial interest, mainly because it is the most IC-compatible micromachining process developed to date. Moreover, in the last 5 to 10 years, processes such as silicon on insulator (SOI) [Diem et al., 1993], hinged poly-Si [Pister, 1992], Keller's molded milli-scale polysilicon [Keller and Ferrari, 1994], thick poly-Si (10  $\mu\text{m}$  and beyond) [Lange et al., 1995], as well as LIGA<sup>1</sup> and LIGA-like processes, have further enriched the surface micromachining arsenal. Some preliminary remarks on each of these surface micromachining extensions follow.

Silicon crystalline features, anywhere between fractions of a micron to 100  $\mu\text{m}$  high, can readily be obtained by surface micromachining of the epi-silicon or fusion-bonded silicon layer of SOI wafers [Noworolski et al., 1995]. Structural elements made from these single crystalline Si layers result in more reproducible and reliable sensors. SOI machining combines the best features of surface micromachining (i.e., IC compatibility and freedom in x,y shapes) with the best features of bulk micromachining (superior single crystal Si properties). Moreover, SOI surface micromachining frequently involves fewer process steps and offers better control over the thickness of crucial building blocks. Given the poor reproducibility of mechanical properties and generally poor electronic characteristics of polysilicon films, SOI machining may surpass the poly-Si technology for fabricating high performance devices.

The fabrication of poly-Si planar structures for subsequent vertical assembly by mechanical rotation around micromachined hinges dramatically increases the plethora of designs feasible with poly-Si [Pister, 1992]. Today, erecting these poly-Si structures with the probes of an electrical probe station or, occasionally, assembly by chance in the HF etch or DI water rinse [Chu et al., 1995] represents too complicated or unreliable postrelease assembly methods for commercial acceptance.

At the University of California at Berkeley, Keller introduced a combination of surface micromachining and LIGA-like molding processes [Keller and Ferrari, 1994] in the so-called HEXSIL<sup>2</sup> process, a technology enabling the fabrication of tall three-dimensional microstructures without postrelease assembly. Using CVD processes one can generally only deposit thin films (~2 to 5  $\mu\text{m}$ ) on flat surfaces. If however, these surfaces are the opposing faces of deep narrow trenches, the growing films will merge to form solid beams. Releasing

---

<sup>1</sup>LIGA is the acronym for the German Lithographie, Galvanoformung, Abformung (see chap. 17).

<sup>2</sup>HEXSIL is the acronym for HEXagonal honeycomb polySILicon.

of such polysilicon structures and the incorporation of electroplating steps expand the surface micromachining bandwidth in terms of choice of materials and accessible feature heights. In this fashion, high aspect ratio structures normally associated with LIGA can now also be made of CVD polysilicon.

Applying classical LPCVD to obtain poly-Si deposition is a slow process. For example, a layer of 10  $\mu\text{m}$  typically requires a deposition time of 10 hours. Consequently, most micromachined structures are based on layer thicknesses in the 2- to 5- $\mu\text{m}$  range. Based on dichlorosilane ( $\text{SiH}_2\text{Cl}_2$ ) chemistry, Lange et al. (1995) developed a CVD process in a vertical epitaxy batch reactor with deposition rates as high as 0.55  $\mu\text{m}/\text{min}$  at 1000°C. The process yields acceptable deposition times for thicknesses in the 10- $\mu\text{m}$  range. The highly columnar poly-Si films were deposited on sacrificial  $\text{SiO}_2$  layers and exhibit low internal tensile stress making them suitable for surface micromachining.

Finally, thick layers of polyimide and other new UV resists also receive a lot of attention as important new extensions of surface micromachining. Due to their transparency to exposing UV light, they can be transformed into tall surface structures with LIGA-like high aspect ratios. They may be both electroplated and molded.

In this part of the chapter, we first review thin film material properties in general, focusing on significant differences with bulk properties of the same material, followed by a review of the main surface micromachining processes. Next, we clarify the recent extensions of the surface micromachining technique listed above. Because of the complexity of the many parameters influencing thin film properties, we then present a set of case studies on the most commonly used thin film materials.

In the surface micromachining examples at the end of this chapter, we first look at a lateral resonator. Resonators have found an important industrial application in accelerometers introduced by Analog Devices. The other example concerns a micromotor: an electrostatic linear motor with a slider stepping between two poly-Si rails. Micromotors may lack practical use as of yet, but, just as the ion-sensitive field effect transistor (ISFET) galvanized the chemical sensor community in trying out new chemical sensing approaches, micromotors energized the micromachining research community to fervently explore miniaturization of a wide variety of mechanical sensors and actuators. Micromotors also brought about the christening of the micromachining field into 'Microelectromechanical Systems' or MEMS.

## 16.11 Historical Note

---

The first example of a surface micromachine for an electro-mechanical application consisted of an underetched metal cantilever beam for a resonant gate transistor made by Nathanson (1967). By 1970, a first suggestion for a magnetically actuated metallic micromotor emerged [Dutta, 1970]. Because of fatigue problems metals rarely are counted on as mechanical components. The surface micromachining method as we know it today was first demonstrated by Howe and Muller in the early 1980s and relied on polysilicon as the structural material [Howe and Muller, 1982]. These pioneers and Guckel [Guckel and Burns, 1985], an early contributor to the field, produced free-standing LPCVD polysilicon structures by removing the oxide layers on which the polysilicon features were formed. Howe's first device consisted of a resonator designed to measure the change of mass upon adsorption of chemicals from the surrounding air. A gas sensor does not necessarily represent a good application of a surface micromachined electrostatic structure since humidity and dust foul the thin air gap of such an unencapsulated microstructure in a minimal amount of time. Later mechanical structures, especially hermetically sealed mechanical devices, provided proof that the IC revolution could be extended to electromechanical systems [Howe, 1995]. In these structures, the height (z-direction) typically is limited to less than 10  $\mu\text{m}$ , ergo the name surface micromachining.

The first survey of possible applications of poly-Si surface micromachining was presented by Gabriel et al. (1989). Microscale movable mechanical pin joints, springs, gears, cranks, sliders, sealed cavities and many other mechanical and optical components have been demonstrated in the laboratory [Muller, 1987; Fan et al., 1987]. In 1991, Analog Devices announced the first commercial product based on surface micromachining, namely, the ADXL-50, a 50-g accelerometer for activating air-bag deployment [Editor, 1991]. A new wave of major commercial applications for surface micromachining could be based on

Texas Instruments' Digital Micromirror Device™. This surface micromachined movable mirror is a digital light switch that precisely controls a light source for projection display and hard copy applications [Hornbeck, 1995]. The commercial acceptance of this application will likely determine the staying power of the surface micromachining option.

## 16.12 Mechanical Properties of Thin Films

---

### 16.12.1 Introduction

Thin films in surface micromachines must satisfy a large set of rigorous chemical, structural, mechanical and electrical requirements. Excellent adhesion, low residual stress, low pinhole density, good mechanical strength and chemical resistance all may be required simultaneously. For many microelectronic thin films, the material properties depend strongly on the details of the deposition process and the growth conditions. In addition, some properties may depend on post-deposition thermal processing, referred to as annealing. Furthermore, the details of thin-film nucleation and/or growth may depend on the specific substrate or on the specific surface orientation of the substrate. Although the properties of a bulk material might be well characterized, its thin-film form may have properties substantially different from those of the bulk. For example, thin films generally display smaller grain size than bulk materials. An overwhelming reason for the many differences stem from the properties of thin films, which exhibit a higher surface-to-volume ratio than large chunks of material and are strongly influenced by the surface properties.

For more details on deposition techniques in general, refer to Madou (1997, chap. 3); now we focus on the physical characteristics of the resulting thin deposits. Some terminology characterizing thin films and their deposition is introduced in [Table 16.11](#).

Since thin films were not intended for load-bearing applications, their mechanical properties have largely been ignored. The last 10 years saw the development of a strong appreciation for understanding the mechanical properties as essential for improving the reliability and life-time in thin films, even in nonstructural applications [Vinci and Braveman, 1991]. Surface micromachining contributes heavily to this understanding. One of the most influential long-term contributions of surface micromachining might well lie in the elucidation of stress mechanism in thin films.

### 16.12.2 Adhesion

One cannot stress enough the importance of adhesion of various films to one another and to the substrate in overall IC performance and reliability. As mechanical pulling forces might be involved, adhesion is even more crucial in micromachining. If films lift from the substrate under a repetitive, applied mechanical force, the device will fail. Classical adhesion tests include the scotch tape test, abrasion method, scratching, deceleration (ultrasonic and ultracentrifuge techniques), bending, pulling etc. [Campbell, 1970]. Micromachined structures, because of their sensitivity to thin-film properties, enable some innovative new ways of *in situ* adhesion measurement. [Figure 16.73](#) illustrates how a suspended membrane may be used for adhesion measurements. [Figure 16.73A](#) shows the membrane suspended but still adherent to the substrate. [Figure 16.73B](#) shows the membrane after it has been peeled from its substrate by an applied load (gas pressure). [Figure 16.73C](#) illustrates the accompanying P(ressure)-V(olume) cycle, in which the membrane is inflated, peeled and then deflated. The shaded portion of [Figure 16.73C](#) illustrates the P-V work creating the new surface, which equals the average work of adhesion for the film-substrate interface times the area peeled during the test [Senturia, 1987].

Cleanliness of a substrate is a *condition sine qua non* for good film adhesion. Roughness, providing more bonding surface area and mechanical interlocking further improve it. Adhesion also improves with increasing adsorption energy of the deposit and/or increasing number of nucleation sites in the early growth stage of the film. Sticking energies between film and substrate range from less than 10 kcal/mole in physisorption to more than 20 kcal/mole for chemisorption. The weakest form of adhesion involves van der Waals forces only (see also [Table 16.11](#)).

TABLE 16.11 Thin Film Terms Used in Characterizing Deposition

Term	Remark
Physisorbed film	Bond energy < 10 kcal/mole
Chemisorbed film	Bond energy > 20 kcal/mole
Nucleation	Adatoms forming stable clusters
Condensation	Initial formation of nuclei
Island formation	Nuclei grow in three dimensions, especially along the substrate surface
Coalescence	Nuclei contact each other and larger, rounded shapes form
Secondary nucleation	Areas between islands are filled in by secondary nucleation, resulting in a continuous film
Grain size of thin film	Generally smaller than for bulk materials and function of deposition and annealing conditions (higher T, larger grains)
Surface roughness	Lower at high temperatures except when crystallization starts; at low temperature the roughness is higher for thicker films; also oblique deposition and contamination increase roughness
Epitaxial and amorphous films	Very low surface roughness
Density	More porous deposits are less dense; density reveals a lot about the film structure
Crystallographic structure	Adatom mobility: amorphous, polycrystalline, single crystal or fiber texture, or preferred orientation

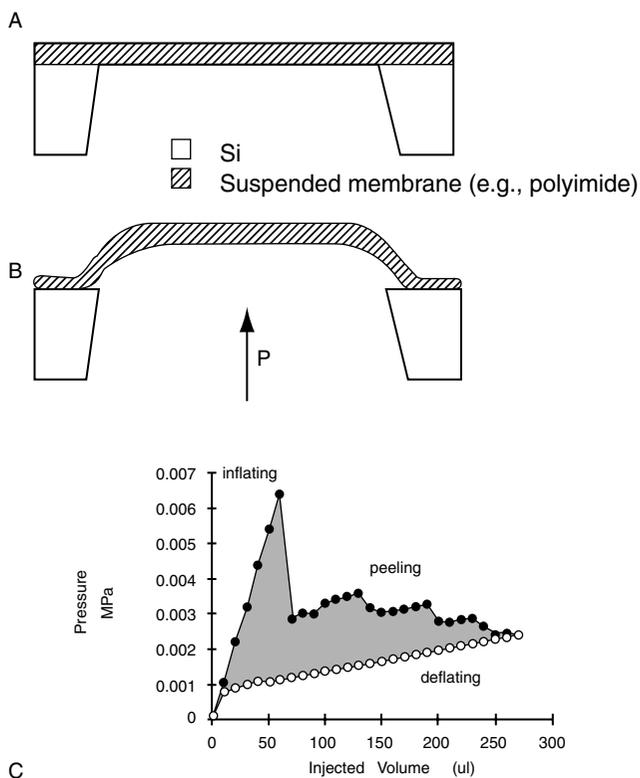

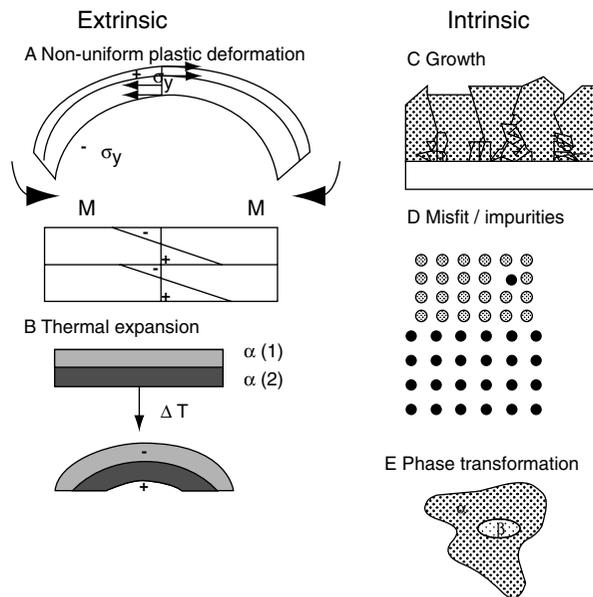

FIGURE 16.73 Micromachined structure to evaluate adhesion. (A) Suspended membrane. (B) Partially detached membrane-outward peel. (C) Pressure-volume curve during inflate-deflate cycle. (From Senturia, S., Can We Design Microrobotic Devices Without Knowing the Mechanical Properties of Materials?, presented at Micro Robots and Tekoperators Workshop, Hyannis, MA, 1987. With permission.)

It is highly advantageous to include a layer of oxide-forming elements between a metal and an oxide substrate. These adhesion layers, such as Cr, Ti, Al etc., provide good anchors for subsequent metallization. Intermediate film formation allowing a continuous transition from one lattice to the other results in the best adhesion. Adhesion also improves when formation of intermetallic metal alloys takes place.

### 16.12.3 Stress in Thin Films

#### 16.12.3.1 Stress in Thin Films—Qualitative Description

Film cracking, delamination and void formation may all be linked to film stress. Nearly all films foster a state of residual stress, due to mismatch in the thermal expansion coefficient, nonuniform plastic deformation, lattice mismatch, substitutional or interstitial impurities and growth processes. Figure 16.74 lists stress-causing factors categorized as either intrinsic or extrinsic [Krulvitch, 1994]. The intrinsic stresses (also growth stresses) develop during the film nucleation. Extrinsic stresses are imposed by unintended external factors such as temperature gradients or sensor package-induced stresses. Thermal stresses, the most common type of extrinsic stresses, are well understood and often easy to calculate (see below). They arise either in a structure with inhomogeneous thermal expansion coefficients subjected to a uniform temperature change or in a homogeneous material exposed to a thermal gradient [Krulvitch, 1994]. Intrinsic stresses in thin films often are larger than thermal stresses. They usually are a consequence of the nonequilibrium nature of the thin-film deposition process. For example, in chemical vapor deposition, depositing atoms (adatoms) may at first occupy positions other than the lowest energy configuration. With too high a deposition rate and/or too low adatom surface mobility, these first adatoms may become pinned by newly arriving adatoms, resulting in the development of intrinsic stress. Other types of intrinsic stresses illustrated in Figure 16.74 include: transformation stresses occurring when part of a material under-

**FIGURE 16.74** Examples of intrinsic and extrinsic residual stresses. (A) Nonuniform plastic deformation results in residual stresses upon unloading.  $M$  = bonding moment. (B) Thermal expansion mismatch between two materials bonded together.  $\alpha(1)$  and  $\alpha(2)$  are thermal expansion coefficients. (C) Growth stresses evolve during film deposition. (D) Misfit stresses due to mismatches in lattice parameters in an epitaxial film and stresses from substitutional or interstitial impurities. (E) Volume changes accompanying phase transformations cause residual stresses [Vinci and Braveman, 1991]. (After Krulvitch, P.A., *Micromechanical Investigations of Silicon and Ni-Ti-Cu Thin Films*, Ph.D. thesis, University of California, Berkeley, 1994.)

goes a volume change during a phase transformation, misfit stresses arising in epitaxial films due to lattice mismatch between film and substrate, and impurities either interstitial or substitutional which cause intrinsic residual stresses due to the local expansion or contraction associated with point defects. Intrinsic stress in a thin film does not suffice to result in delamination unless the film is quite thick. For example, to overcome a low adsorption energy of 0.2 eV, a relatively high stress of about  $5 \times 10^9 \text{ dyn cm}^{-2}$  ( $10^7 \text{ dyn/cm}^2 = 1 \text{ MPa}$ ) is required [Campbell, 1970]. High stress can result in buckling or cracking of films.

The stress developing in a film during the initial phases of a deposition may be compressive (i.e., the film tends to expand parallel to the surface), causing buckling and blistering or delamination in extreme cases (especially with thick films). Alternatively, thin films may be in tensile stress (i.e., the film tends to contract), which may lead to cracking if forces high enough to exceed the fracture limit of the film material are present. Subsequent rearrangement of the atoms, either during the remainder of the deposition or with additional thermal processing, can lead to further densification or expansion, decreasing remaining tensile or compressive stresses, respectively.

The mechanical response of thin-film structures is affected by the residual stress, even if the structures do not fail. For example, if the residual stress varies in the direction of film growth, the resulting built-in bending moment will warp released structures, such as cantilever beams. The presence of residual stress also alters the resonant frequency of thin-film, resonant microstructures (see Eq. (16.59) below) [Pratt et al., 1992]. Also, residual stress can lead to degradation of electrical characteristics and yield loss through defect generation, such as {311} defects [Krulvitch, 1994]. Another observation found the resistivity of stressed metallic films to be higher than that of their annealed counterparts. In a few cases residual stress has been used advantageously, such as in self-adjusting microstructures [Judy et al., 1991], and for altering the shape-set configuration in shape memory alloy films [Krulvitch, 1994].

In general, the stresses in films, by whatever means produced, are in the range of  $10^8$  to  $5 \times 10^{10} \text{ dyn/cm}^{-2}$  and can be either tensile or compressive. For normal deposition temperatures (50 to a few hundred degrees C), the stress in metal films typically ranges from  $10^8$  to  $10^{10} \text{ dyn cm}^{-2}$  and is tensile, the refractory metals at the upper end, the soft ones (Cu, Ag, Au, Al) at the lower end. At low substrate temperatures, metal films tend to exhibit tensile stress. This often decreases in a linear fashion with increasing substrate temperature, finally going through zero or even becoming compressive. The changeover to compressive stress occurs at lower temperatures for lower melting point metals. The mobility of the adatoms is key to understanding the ranking for refractory and soft metals. A metal such as aluminum has a low melting temperature and a corresponding high diffusion rate even at room temperature, thus usually it is fairly stress free. By comparison, tungsten has a relatively high melting point and a low diffusion rate and tends to accumulate more stress when sputter-deposited. With dielectric films, stresses often are compressive and have slightly lower values than commonly noted in metals.

Tensile films result, for example, when a process by-product is present during deposition and later driven off as a gas. If the deposited atoms are not sufficiently mobile to fill in the holes left by these departing byproducts, the film will contract and go in tension. Nitrides deposited by plasma CVD usually are compressive due to the presence of hydrogen atoms in the lattice. By annealing, driving the hydrogen out, the films can turn highly tensile. Annealing also has a dramatic effect on most oxides. Oxides often are porous enough to absorb or give off a large amount of water. Full of water, they are compressive; devoid of water they are tensile. Thermal  $\text{SiO}_2$  is compressive, though, even when dry. If atoms are jammed in place (such as with sputtering) the film tends to act compressively. The stress in a thin film also varies with depth. The RF power of a plasma-enhanced CVD (PECVD) deposition influences stress, e.g., a thin film may start out tensile, decrease as the power increases, and finally become compressive with further RF power increase. CVD equipment manufacturers concentrate on building stress-control capabilities into new equipment by controlling plasma frequency (see also Madou [1997, chap. 3]).

### 16.12.3.2 Stress in Thin Films on Thick Substrates—Quantitative Analysis

The total stress in a thin film typically is given by:

$$\sigma_{\text{tot}} = \sigma_{\text{th}} + \sigma_{\text{int}} + \sigma_{\text{ext}} \quad (16.44)$$

i.e., the sum of any intentional external applied stress ( $\sigma_{\text{ext}}$ ), the thermal stress ( $\sigma_{\text{th}}$ , an unintended external stress) and different intrinsic components ( $\sigma_{\text{int}}$ ). With constant stress through the film thickness, the stress components retain the form of

$$\begin{aligned}\sigma_x &= \sigma_x(x, y) \\ \sigma_y &= \sigma_y(x, y) \\ \tau_{xy} &= \tau_{xy}(x, y) \\ \tau_{xz} &= \tau_{yz} = \sigma_z = 0\end{aligned}\tag{16.45}$$

That is, the three nonvanishing stress components are functions of  $x$  and  $y$  alone. No stress occurs in the direction normal to the substrate ( $z$ ). With  $x, y$  as principal axes, the shear stress  $\tau_{xy}$  also vanishes [Chou and Pagano, 1967] and Eq. (16.45) reduces to the following strain–stress relationships:

$$\begin{aligned}\epsilon_x &= \frac{\sigma_x}{E} - \frac{\nu\sigma_y}{E} \\ \epsilon_y &= \frac{\sigma_y}{E} - \frac{\nu\sigma_x}{E} \\ \sigma_z &= 0\end{aligned}\tag{16.46}$$

In the isotropic case  $\epsilon = \epsilon_x = \epsilon_y$  so that  $\sigma_x = \sigma_y = \sigma$ , or:

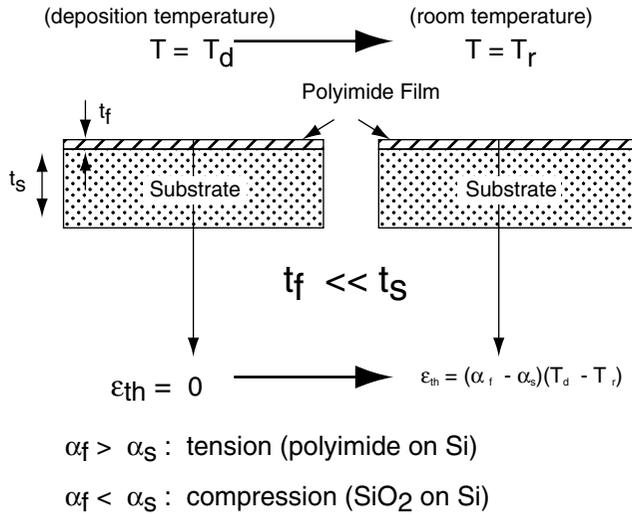

$$\sigma = \left( \frac{E}{1 - \nu} \right) \epsilon\tag{16.47}$$

where the Young's modulus of the film and the Poissons's ratio of the film act independently of orientation. The quantity  $E/(1 - \nu)$  often is called the biaxial modulus. Uniaxial testing of thin films is difficult, prompting the use of the biaxial modulus, rather than Young's uniaxial modulus. Plane stress, as described here, presents a good approximation several thicknesses away from the edge of the film (say, three thicknesses from the edge).

### **Thermal Stress**

Thermal stresses develop in thin films when high temperature deposition or annealing are involved, and usually are unavoidable due to mismatch of thermal expansion coefficients between film and substrate. The problem of a thin film under residual thermal stress can be modeled by considering a thought experiment involving a stress-free film at high temperature on a thick substrate. Imagine detaching the film from the high-temperature substrate and cooling the system to room temperature. Usually, the substrate dimensions undergo minor shrinkage in the plane while the film's dimensions may reduce significantly. In order to reapply the film to the substrate with complete coverage, the film needs stretching with a biaxial tensile load to a uniform radial strain  $\epsilon$ , followed by perfect bondage to the rigid substrate and load removal. The film stress is assumed to be the same in the stretched and free-standing film as in the film bonded to the substrate, i.e., no relaxation occurs in the bonding process. To calculate the thermal residual stress from Eq. (16.47) the elastic moduli of the film must be known, as well as the volume change associated with the residual stress, i.e., the thermal strain,  $\epsilon_{\text{th}}$ , resulting from the difference in the coefficients of thermal expansion between the film and the substrate.

Let us now consider whether, qualitatively, the above assumptions apply to the measurement of thin films on Si wafers. Such films typically measure 1  $\mu\text{m}$  thick and are deposited on 4-in. wafers nominally

**FIGURE 16.75** Thermal stress. Tension and compression are determined by the relative size of thermal expansion coefficients of film and substrate. Suppose a strain-free film at deposition temperature,  $T_d$ , is cooled to room temperature,  $T_r$ , on a substrate with a different coefficient of thermal expansion.

550  $\mu\text{m}$  thick. In this case, the substrate measures nearly three orders of magnitude thicker than the film, and, because the bending stiffness is proportional to the thickness cubed, the substrate essentially is rigid relative to the film. The earlier assumptions clearly apply.

Figure 16.75 portrays a quantitative example where a polyimide film, strain-free at the deposition temperature ( $T_d$ ) of 400°C, is cooled to room temperature  $T_r$  (25°C) on an Si substrate with a different coefficient of thermal expansion. The resulting strain is given by:

$$\epsilon_{th} = \int (\alpha_f(T) - \alpha_s(T)) dt \quad (16.48)$$

where  $\alpha_f$  and  $\alpha_s$  represent the coefficients of thermal expansion for the polyimide film and the Si substrate, respectively. The thermal strain can be of either sign, based on the relative values of  $\alpha_f$  and  $\alpha_s$ : positive is tensile, negative is compressive. Polyimide features a thermal expansion ( $\alpha_f = 70 \times 10^{-6} \text{ } ^\circ\text{C}^{-1}$ ) larger than the thermal expansion coefficient of Si ( $\alpha_s = 2.6 \times 10^{-6} \text{ } ^\circ\text{C}^{-1}$ ); hence, a tensile stress is expected. With SiO<sub>2</sub> grown or deposited on silicon at elevated temperatures, a compressive component [ $\alpha_f (0.35 \times 10^{-6} \text{ } ^\circ\text{C}^{-1}) < \alpha_s (2.6 \times 10^{-6} \text{ } ^\circ\text{C}^{-1})$ ] is expected. Assuming that the coefficients of thermal expansion are temperature independent, Eq. (16.48) simplifies to:

$$\epsilon_{th} = (\alpha_f - \alpha_s)(T_d - T_r) \quad (16.49)$$

The calculated thermal strain  $\epsilon_{th}$  for polyimide on Si then measures  $25 \times 10^{-3}$  at room temperature. The biaxial modulus ( $E/(1 - \nu)$ ), with  $E = 3 \text{ GPa}$  and  $\nu = 0.4$ , equals 5 GPa, and the residual stress  $\sigma$ , from Eq. (16.47), is 125 MPa and tensile.

### Intrinsic Stress

The intrinsic stress,  $\sigma_i$ , reflects the internal structure of a material and is less clearly understood than the thermal stress which it often dominates [Guckel et al., 1988]. Several phenomena may contribute to  $\sigma_i$ , making its analysis very complex. Intrinsic stress depends on thickness, deposition rate (locking in defects), deposition temperature, ambient pressure, method of film preparation, type of substrate used (lattice mismatch), incorporation of impurities during growth etc. Some semiquantitative descriptions of various intrinsic stress-causing factors follow:

- Doping ( $\sigma_{\text{int}} > 0$  or  $\sigma_{\text{int}} < 0$ ): When doping Si, the atomic or ionic radius of the dopant and the substitutional site determine the positive or negative intrinsic stress ( $\sigma_{\text{int}} > 0$  or tensile, and  $\sigma_{\text{int}} < 0$  or compressive). With boron-doped poly-Si, an atom small compared to Si, the film is expected to be tensile ( $\sigma_{\text{int}} > 0$ ); with phosphorous doping, an atom large compared to Si, the film is expected to be compressive ( $\sigma_{\text{int}} < 0$ ).
- Atomic peening ( $\sigma_{\text{int}} < 0$ ): Ion bombardment by sputtered atoms and working gas densifies thin films, rendering them more compressive. Magnetron sputtered films at low working pressure ( $< 1$  Pa) and low temperature often exhibit compressive stress.
- Microvoids ( $\sigma_{\text{int}} > 0$ ): Microvoids may arise when byproducts during deposition escape as gases and the lateral diffusion of atoms evolves too slowly to fill all the gaps, resulting in a tensile film.
- Gas entrapment ( $\sigma_{\text{int}} < 0$ ): As an example we can cite the hydrogen trapped in  $\text{Si}_3\text{N}_4$ . Annealing removes the hydrogen, and a nitride film, compressive at first, may become tensile if the hydrogen content is sufficiently low.
- Shrinkage of polymers during cure ( $\sigma_{\text{int}} > 0$ ): The shrinkage of polymers during curing may lead to severe tensile stress, as becomes clear in the case of polyimides. Special problems are associated with measuring the mechanical properties of polymers as they exhibit a time-dependent mechanical response (viscoelasticity), a potentially significant factor in the design of mechanical structures where polymers are subjected to sustained loads [Maseeh and Senturia, 1990].
- Grain boundaries ( $\sigma_{\text{int}} = ?$ ): Based on intuition one expects that the interatomic spacing in grain boundaries differs depending on the amount of strain, thus contributing to the intrinsic stress. But the origin of, for example, the compressive stress in polysilicon and how it relates to the grain structure and interatomic spacing are not yet completely clear (see also below on coarse and fine-grated Si).

For further reading on thin-film stress, refer to Hoffman (1975; 1976).

### 16.12.3.3 Stress-Measuring Techniques

#### *Introduction*

A stressed thin film will bend a thin substrate by a measurable degree. A tensile stress will bend and render the surface concave; a compressive stress renders the surface convex. The most common methods for measuring the stress in a thin film are based on this substrate bending principle. The deformation of a thin substrate due to stress is measured either by observing the displacement of the center of a circular disk or by using a thin cantilevered beam as a substrate and calculating the radius of curvature of the beam and hence the stress from the deflection of the free end. More sophisticated local stress measurements use analytical tools such as X-ray [Wong, 1978], acoustics, Raman spectroscopy [Nishioka et al., 1985], infrared spectroscopy [Marco et al., 1991], and electron-diffraction techniques. Local stress does not necessarily mean the same as the stress measured by substrate bending techniques, since stress is defined microscopically, while deformations are induced mostly macroscopically. The relation between macroscopic forces and displacements and internal differential deformation, therefore, must be modeled carefully. Local stress measurements may also be made using *in situ* surface micromachined structures such as strain gauges made directly out of the film of interest itself [Mehregany et al., 1987]. The deflections of thin suspended and pressurized micromachined membranes may be measured by mechanical probe [Jaccodine and Schlegel, 1966], laser [Bromley et al., 1983], or microscope [Allen et al., 1987]. Intrinsic stress influences the frequency response of microstructures (see Eq. (16.59)) which can be measured by laser [Zhang et al., 1991], spectrum analyzer [Pratt et al., 1991], or stroboscope. Whereas residual stress can be determined from wafer curvature and microstructure deflection data, material structure of the film can be studied by X-ray diffraction and transmission electron microscopy (TEM). Krulevitch, among others, attempted to link the material structure of poly-Si and its residual strain [Krulevitch, 1994]. Following, we will review stress-measuring techniques, starting with the more traditional ones and subsequently clarifying the problems and opportunities in stress measuring with surface micromachined devices.

### Disk Method

For all practical purposes only stresses in the x and y directions are of interest in determining overall thin-film stress, as a film under high stress can only expand or contract by bending the substrate and deforming it in a vertical direction. Vertical deformations will not induce stresses in a substrate because it freely moves in that direction. The latter condition enables us to obtain quite accurate stress values by measuring changes in bow or radius of curvature of a substrate. The residual stresses in thin films are large and sensitive optical or capacitive gauges may measure the associated substrate deflections.

The disk method, most commonly used, is based on a measurement of the deflection in the center of the disk substrate (say, a Si wafer) before and after processing. Since any change in wafer shape is directly attributable to the stress in the deposited film, it is relatively straightforward to calculate stress by measuring these changes. Stress in films using this method is found through the Stoney equation [Hoffman, 1976], relating film stress to substrate curvature:

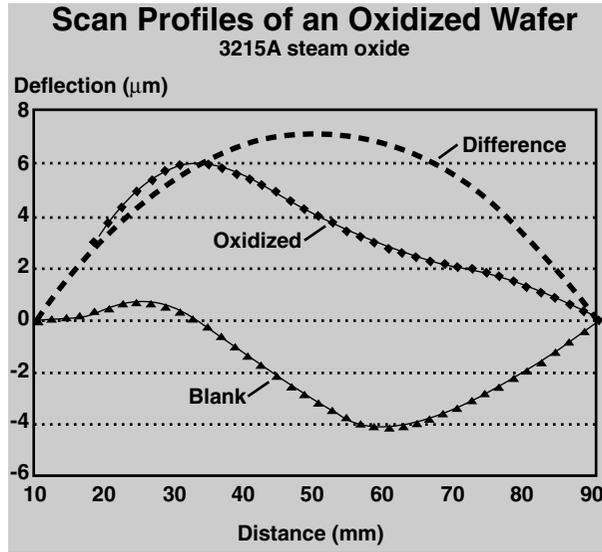

$$\sigma = \frac{1}{R} \frac{E}{6(1-\nu)} \frac{T^2}{t} \quad (16.50)$$

where  $R$  represents the measured radius of curvature of the bent substrate,  $E/(1-\nu)$  the biaxial modulus of the substrate,  $T$  the thickness of the substrate, and  $t$  the thickness of the applied film [Singer, 1992]. The underlying assumptions include:

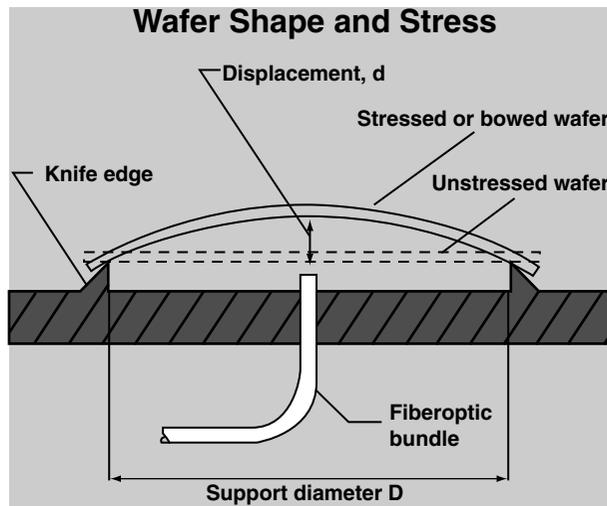

- The disc substrate is thin and has transversely isotropic elastic properties with respect to the film normal.
- The applied film thickness is much less than the substrate thickness.
- The film thickness is uniform.
- Temperature of the disk substrate/film system is uniform.
- Disc substrate/film system is mechanically free.
- Disc substrate without film has no bow.
- Stress is equi-biaxial and homogeneous over the entire substrate.
- Film stress is constant through the film thickness.

For most films on Si we assume that  $t \leq T$ ; for example,  $t/T$  measures  $\sim 10^{-3}$  for thin films on Si. The legitimacy of the uniform thickness, homogeneous, and equi-biaxial stress assumptions depend on the deposition process. Chemical vapor deposition (CVD) is such a widely used process as it produces relatively uniform films; however, sputter-deposited films can vary considerably over the substrate. In regard to the assumption of stress uniformity with film thickness, residual stress can vary considerably through the thickness of the film. Eq. (16.50) only gives an average film stress in such cases. In cases where thin films are deposited onto anisotropic single crystal substrates, the assumption of a substrate with transversely isotropic elastic properties with respect to the film normal is not always satisfied. Using single crystal silicon substrates possessing moderately anisotropic properties (Eq. (16.20)) (<100>- or <111>-oriented wafers) satisfies the transverse isotropy argument. Any curvature inherent in the substrate must be measured before film deposition and algebraically added to the final measured radius of curvature. To give an idea of the degree of curvature, 1  $\mu\text{m}$  of thermal oxide may cause a 30- $\mu\text{m}$  warp of a 4-in. silicon wafer, corresponding to a radius of curvature of 41.7 m.

Presently, five companies offer practical disk method-based instruments to measure stress on wafers: ADE Corp. (Newton, MA), GCA/Tropel (Fairport, NY), Ionic Systems (Salinas, CA), Scientific Measurements Systems, Inc. (San Jose, CA), and Tencor Instruments (Mountain View, CA) [Singer, 1992]. [Figure 16.76A](#) illustrates the sample output from Tencor's optical stress analysis system. [Figure 16.76B](#) represents the measuring principle of Ionic Systems' optical stress analyzer. None of the above tech-

niques satisfies the need for measuring stress in low modulus materials such as polyimide. For the latter applications the suspended membrane approach (see below) is more suited.

#### **Uniaxial Measurements of Mechanical Properties of Thin Films**

Many problems associated with handling thin films in stress test equipment may be bypassed by applying micromachining techniques. One simple example of problems encountered with thin films is the measurement of uniaxial tension to establish the Young's modulus. This method, effective for macroscopic samples, proves problematic for small samples. The test formula is illustrated in Figure 16.77A. The gauge length  $L$  in this figure represents the region we allow to elongate and the area  $A$  ( $=W \times H$ ) is the cross section of the specimen. A stress  $F/A$  is applied and measured with a load cell; the strain  $\delta L/L$  is measured

**FIGURE 16.77** Measuring Young's modulus. (A) With a bar-shaped structure. (B) With a dog-bone, Instron specimen. (After Senturia and Howe, 1990.)

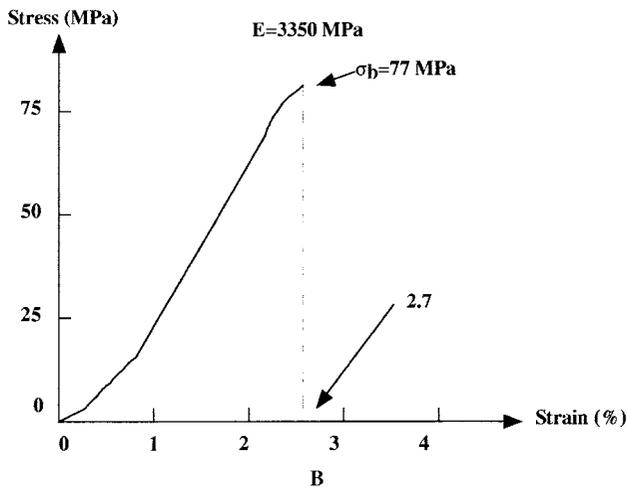

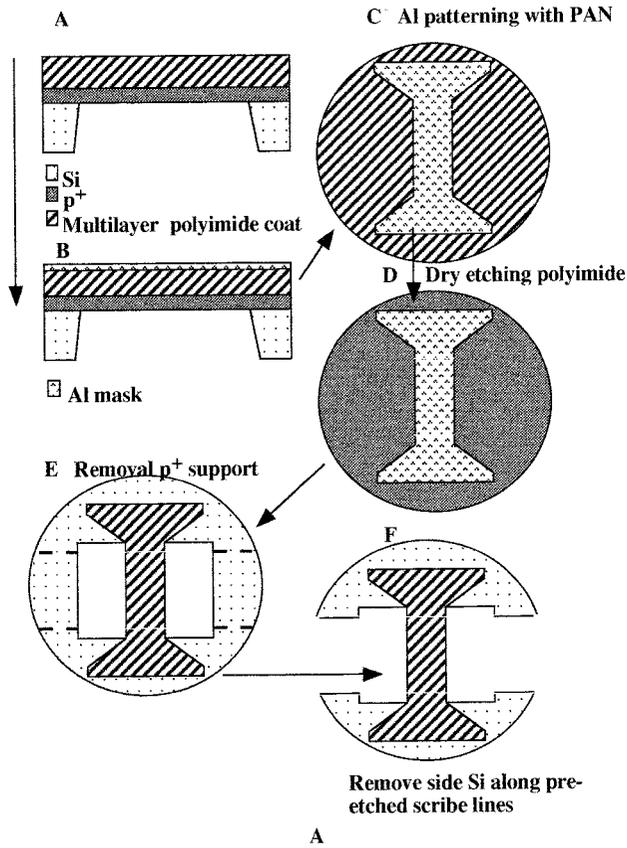

with an LVDT or another displacement transducer (a typical instrument used is the Instron 1123). The Young's modulus is then deduced from:

$$E = \left(\frac{F}{A}\right)\left(\frac{L}{\delta L}\right) \quad (16.51)$$

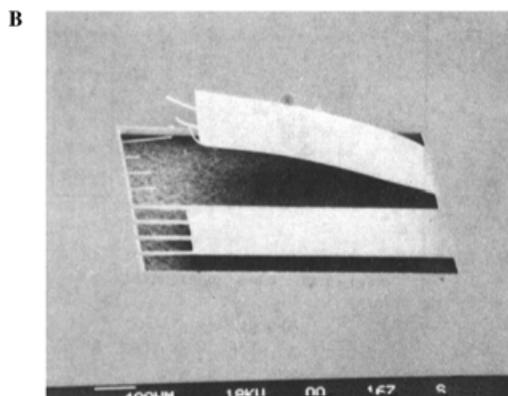

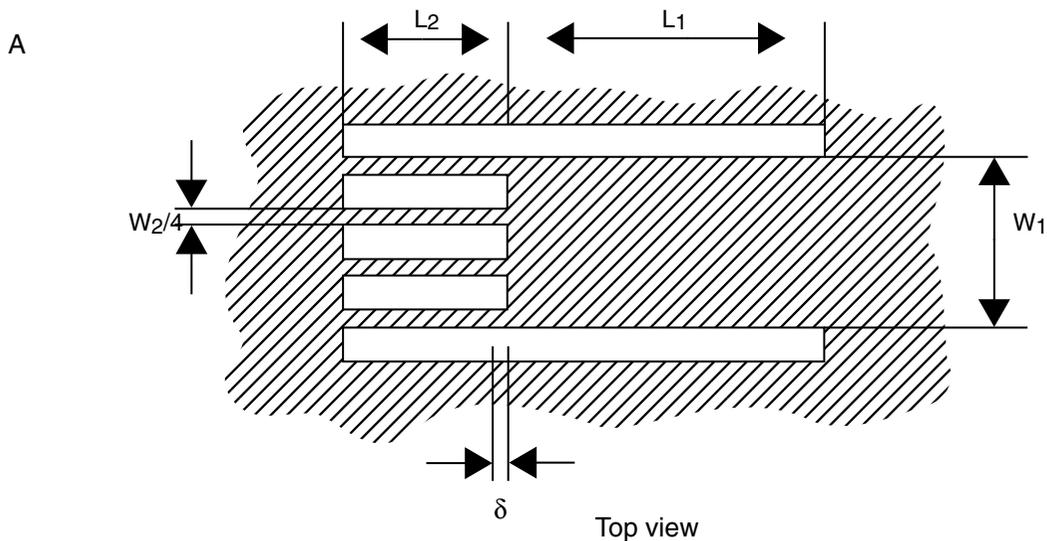

The obvious problem, for small or large samples, is how to grip onto the sample without changing  $A$ . Under elongation,  $A$  will indeed contract by  $(w + H)\delta vL$ . In general, making a dog-bone shaped structure (Instron specimen) solves that problem as shown in [Figure 16.77B](#). Still, the grips introduced in an Instron sample can produce end effects and uncertainties in determining  $L$ . Making Instron specimens in thin films is even more of a challenge since the thin film needs to be removed from the surface, possibly changing the stress state, while the removal itself may modify the film.

As in the case of adhesion, some new techniques for testing stress in thin films, based on micromachining, are being explored. These microtechniques prove more advantageous than the whole wafer disc technique in that they are able to make local measurements.

The fabrication of micro-Instron specimens of thin polyimide samples is illustrated in [Figure 16.78A](#). Polyimide is deposited on a  $p^+$  Si membrane in multiple coats. Each coat is prebaked at  $130^\circ\text{C}$  for 15 min. After reaching the desired thickness the film is cured at  $400^\circ\text{C}$  in nitrogen for 1 hr (A). The polyimide is then covered with a  $3000\text{-\AA}$  layer of evaporated aluminum (B). The aluminum layer is patterned by wet etching (in phosphoric-acetic-nitric solution referred to as PAN etch) to the Instron specimen shape (C). Dry etching transfers the pattern to the polyimide (D). After removing the Al mask by wet etching, the  $p^+$  support is removed by a wet isotropic etch (HNA) or a  $\text{SF}_6$  plasma etch (E), and finally the side silicon is removed along four pre-etched scribe lines, releasing the residual stress (F). The remaining silicon acts as supports for the grips of the Instron [Meseeh-Tehrani, 1990]. The resulting structure can

**FIGURE 16.78** Uniaxial stress measurement. (A) Fabrication process of a dog bone sample for measurement of uniaxial strain. (B) Stress vs. strain for Du Pont's 2525 polyimide. (Courtesy of Dr. F. Maseeh-Tehrani.)

**FIGURE 16.79** Ultimate strain. (A) Test structures for stress-to-modulus (strain) and ultimate stress measurements. (B) Two released structures, one of which has exceeded the ultimate strain of the film, resulting in fracture of the necks. (From Senturia, S., Can We Design Microbotic Devices without Knowing the Mechanical Properties of the Materials?, presented at Micro Robots and Teleoperators Workshop, Hyannis, MA, 1987. With permission.)

be manipulated as any macrosample without the need for removal of the film from its substrate. This technique enables the gathering of stress/strain data for a variety of commercially available polyimides [Maseeh and Senturia, 1989]. A typical measurement result for Dupont's polyimide 2525, illustrated in Figure 16.78B, gives a break stress and strain of 77 MPa ( $\sigma_b$ ) and 2.7% ( $\epsilon_b$ ), respectively, and 3350 MPa for the Young's modulus.

Figure 16.79A illustrates a micromachined test structure able to establish the strain and the ultimate stress of a thin film [Senturia, 1987]. A suspended rectangular polymer membrane is patterned into an asymmetric structure before removing the thin supporting Si. Once released, the wide suspended strip (width  $w_1$ ) pulls on the thinner necks (total width  $w_2$ ), resulting in a deflection  $\delta$  from its original mask position toward the right to its final position after release. The residual tensile stress in the film drives the deformation  $\delta$  as shown in Figure 16.79A. By varying the geometry, it is possible to create structures exhibiting small strain in the thinner sections as opposed to others that exceed the ultimate strain of the film. For structures where the strain is small enough to be modeled with linear elastic behavior, the deflection  $\delta$  can be related to the strain as follows:

$$\varepsilon = \frac{\sigma}{E} = \frac{\delta \left( \frac{W_1}{L_1} + \frac{W_2}{L_2} \right)}{W_1 - W_2} \quad (16.52)$$

where the geometries are defined as illustrated in Figure 16.79A. Figure 16.79B displays a photograph of two released structures: one with thicker necks, the other with necks so thin that they fractured upon release of the film. Based on the residual tensile strain of the film and the geometry of the structures that failed, the ultimate strain of the particular polyimide used was determined to be 4.5%.

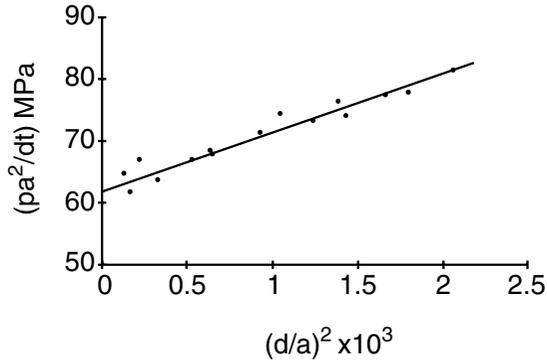

Using similar micromachined tensile test structures [Biebl and von Philipsborn, 1993] measured the fracture strength of undoped and doped polysilicon and found  $2.84 \pm 0.09$  GPa for undoped material and  $2.11 \pm 0.10$  GPa in the case of phosphorous doping,  $2.77 \pm 0.08$  GPa for boron doping and  $2.70 \pm 0.09$  GPa for arsenic doping. No statistically significant differences were observed between samples released using concentrated HF or buffered HF. However, a 17% decrease of the fracture stress was observed for a 100% increase in etching time. These data contrast with Greek et al. (1995) *in situ* tensile strength test result of 768 MPa for an undoped poly-Si film. A mean tensile strength almost ten times less than that of single crystal Si (6 GPa) [Ericson and Schweitz, 1990]. We normally expect polycrystalline films to be stronger than single crystal films (see below under Strength of Thin Films). Greek et al. (1995) explain this discrepancy for poly-Si by pointing out that their polysilicon films have a very rough surface compared to single crystal material, containing many locations of stress concentration where a fracture crack can be initiated.

#### ***Biaxial Measurements of Mechanical Properties of Thin Films: Suspended Membrane Methods***

We noted earlier that none of the disk stress-measuring techniques is suitable for measuring stress in low modulus tensile materials such as polyimides. Suspended membranes are very convenient for this purpose. The same micromachined test structure used for adhesion testing, sometimes called the blister test, as shown in Figure 16.73, can measure the tensile stress in low modulus materials. This type of test structure ensues from shaping a silicon diaphragm by conventional anisotropic etching, followed by applying the coating, and, finally, removing the supporting silicon from the back with an  $SF_6$  plasma [Senturia, 1987]. By pressurizing one side of the membrane and measuring the deflection, one can extract both the residual stress and the biaxial modulus of the membrane. Pressure to the suspended film can be applied by a gas or by a point-load applicator [Vinci and Braveman, 1991]. The load-deflection curve at moderate deflections (strains less than 5%) answers to:

$$p = C_1 \frac{\sigma t d}{a^2} + C_2 \left( \frac{E}{1 - \nu} \right) \frac{t d^3}{a^4} \quad (16.53)$$

where  $p$  represents the pressure differential across the film;  $d$ , the center deflection;  $a$ , the initial radius;  $t$ , the membrane thickness; and  $\sigma$ , the initial film stress. In the simplified Cabrera model for circular membranes the constants  $C_1$  and  $C_2$  equal 4 respectively  $8/3$ . For more rigorous solutions for both circular and rectangular membranes and references to other proposed models, refer to Maseeh-Tehrani [Maseeh-Tehrani, 1990]. The relation in Eq. (16.53) can simultaneously determine  $\sigma$  and the biaxial modulus  $E/(1 - \nu)$ ; plotting  $pa^2/dt$  vs.  $(d/a)^2$  should yield a straight line. The residual stress can be extracted from the intercept and the biaxial modulus from the slope of the least-squares-best-fit line [Senturia, 1987]. A typical result obtained via such measurements is represented in Figure 16.80. For the same Dupont polyimide 2525, measuring a Young's modulus of 3350 MPa in the uniaxial test (Figure 16.78B), the measurements give 5540 MPa for the biaxial modulus and 32 MPa for the residual stress. The residual stress-to-biaxial modulus ratio, also referred to as the residual biaxial strain, thus reaches 0.6%. The latter quantity must be compared to the ultimate strain when evaluating potential reliability problems associated with cracking of films. By loading the membranes to the elastic limit point, yield stress and strain can be determined as with the uniaxial test.

**FIGURE 16.80** Load deflection data of a polyimide membrane (Du Pont 2525). From the intercept, a residual stress of 32 MPa was calculated and from the slope, a biaxial modulus of 5540 MPa. (From Senturia, S., Can We Design Microbiotic Devices without Knowing the Mechanical Properties of the Materials?, presented at Micro Robots and Teleoperators Workshop, Hyannis, MA, 1987. With permission.)

### **Poisson Ratio for Thin Films**

The Poisson ratio for thin films presents us with more difficulties to measure than the Young's modulus as thin films tend to bend out of plane in response to in-plane shear. Maseeh and Senturia (1989) combine uniaxial and biaxial measurements to calculate the in-plane Poisson ratio of polyimides. For example, for the Dupont polyimide 2525, they determined 3350 MPa for  $E$  and 5540 MPa for the biaxial modulus ( $E/1 - \nu$ ) leading to  $0.41 \pm 0.1$  for the Poisson's ratio ( $\nu$ ). The errors on both the biaxial and uniaxial measurements need to be reduced in order to develop more confidence in the extracted value of the Poisson's ratio. At present, the precision on the Poisson's ratio is limited to about 20%.

### **Other Surface Micromachined Structures to Gauge Intrinsic Stress**

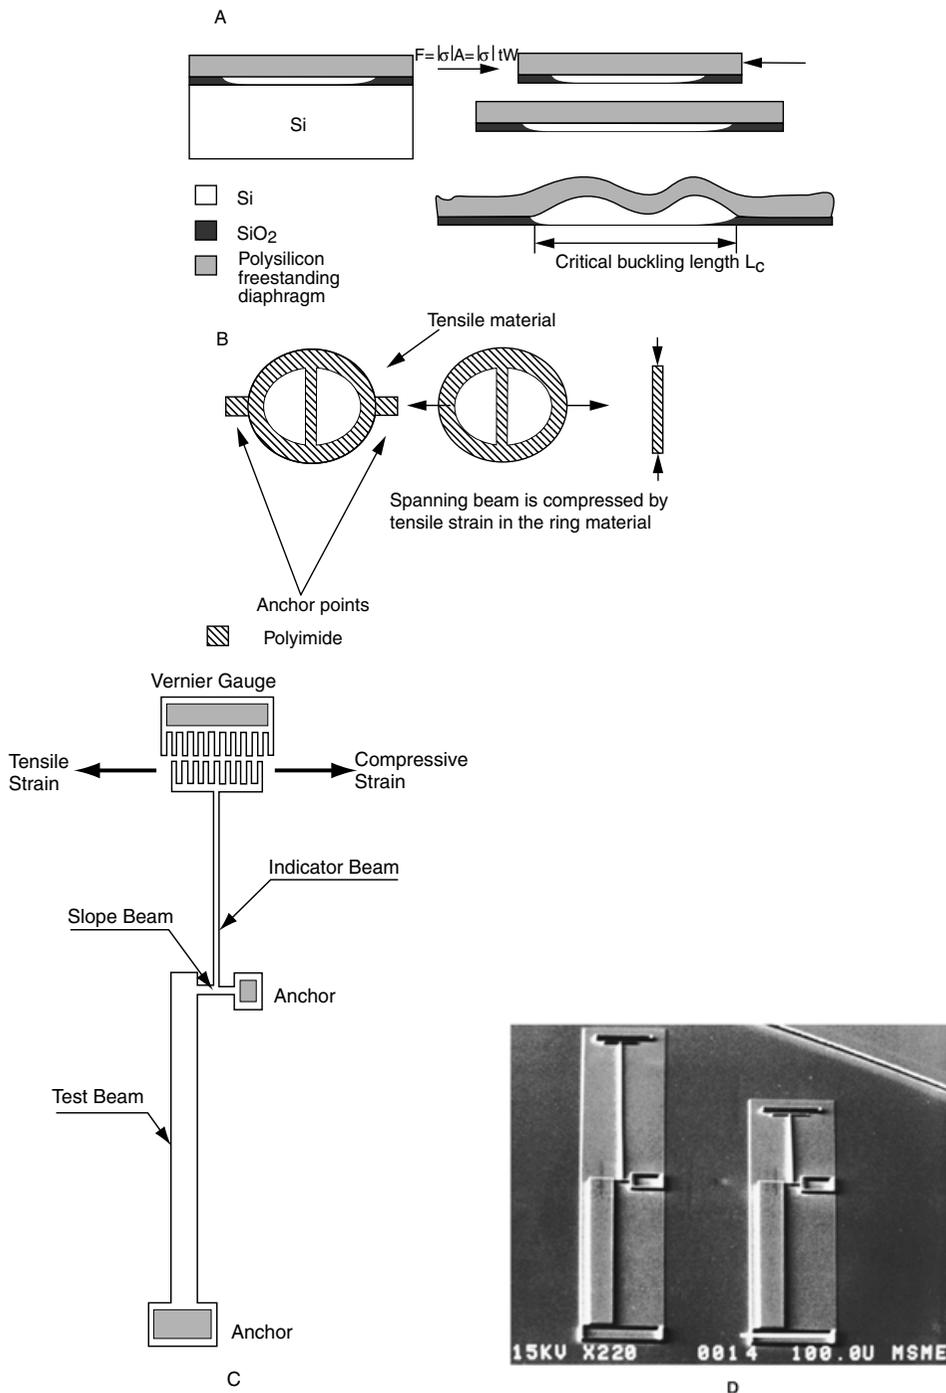

Various other surface micromachined structures have been used to measure mechanical properties of thin films. We will give a short review here, but the interested reader might want to consult the original references for more details.

**Clamped-Clamped Beams.** Several groups have used rows of clamped-clamped beams (bridges) with incrementally increasing lengths to determine the critical buckling load and hence deduce the residual compressive stress in polysilicon films (Figure 16.81A) [Sekimoto et al., 1982; Guckel et al., 1985]. The residual strain,  $\epsilon = \sigma/E$ , is obtained from the critical length,  $L_c$ , at which buckling occurs (Euler's formula for elastic instability of struts):

$$\epsilon = \frac{4\pi^2 I}{A L_c^2} \quad (16.54)$$

where  $A$  is the beam cross-sectional area and  $I$  the moment of inertia. As an example, with a maximum beam length of 500  $\mu\text{m}$  and a film thickness of 1.0  $\mu\text{m}$ , the buckling beam method can detect compressive stress as small as 0.5 MPa. This simple Euler approach does not take into considerations additional effects such as internal moments resulting from gradients in residual stress.

**Ring Crossbar Structures.** Tensile strain can be measured by a series of rings (Figure 16.81B) constrained to the substrate at two points on a diameter and spanned orthogonally by a clamped-clamped beam. After removal of the sacrificial layer, tensile strain in the ring places the spanning beam in compression; the critical buckling length of the beam can be related to the average strain [Guckel et al., 1988].

**FIGURE 16.81** Some micromachined structures used for stress measurements. (A) Clamped-clamped beams: measuring the critical buckling length of clamped-clamped beams enables measurement of residual stress. (B) Crossbar rings: tensile stress can be measured by buckling induced in the crossbar of a ring structure. (C) A schematic of a strain gauge capable of measuring tensile or compressive stress. (D) SEM microphotograph of two strain gauges. (C and D from Lin, L., *Selective Encapsulations of MEMS: Micro Channels, Needles, Resonators and Electromechanical Filters*, Ph.D. thesis, University of California, Berkeley, 1993. With permission.)

**Vernier Gauges.** Both clamped-clamped beams and ring structures need to be implemented in entire arrays of structures. They do not allow easy integration with active microstructures due to space constraints. As opposed to proof structures one might use vernier gauges to measure the displacement of structures induced by residual strain [Lin, 1993]. The idea was first explored by Kim (1991), whose device consisted of two cantilever beams fixed at two opposite points. The end movement of the beams caused by the residual strain was measured by a vernier gauge. This method only requires one structure, but the best resolution for strain measurement reported is only 0.02% for 500- $\mu\text{m}$  beams. Moreover, the vernier gauge device may indicate an erroneous strain when an out-of-plane strain gradient occurs [Lin, 1993]. Other types of direct strain measurement devices are the T- and H-shaped structures from Allen et al. (1987) and Mehregany et al. (1987). Optical measurement of the movement at the top of the T- or H-shape structures only becomes possible with very long beams (greater than 2.5 mm). They occupy large areas and their complexity requires finite element methods to analyze their output. The same is true for the strain magnification structure by Goosen et al. (1993). This structure measures strain by interconnecting two opposed beams such that the residual strain in the beams causes a third beam to rotate as a gauge needle. The rotation of the gauge needle quantifies the residual strain. A schematic of a micromachined strain gauge capable of measuring tensile or compressive residual stress, as shown in Figure 16.81C, was developed by Lin at University of California, Berkeley [Lin, 1993]. Figure 16.81D represents a scanning electron microscope (SEM) photograph of Lin's strain gauge. This gauge by far outranks the various *in situ* gauges explored. The strain gauge uses only one structure, can be fabricated *in situ* with active devices, determines tensile or compressive strain under optical microscopes, has a fine resolution of 0.001%, and resists to the out-of-plane strain gradient. When the device is released in the sacrificial etch step, the test beam (length  $L_t$ ) expands or contracts, depending on the sign of the residual stress in the film, causing the compliant slope beam (length  $L_s$ ) to deflect into an 's' shape. The indicator beam (length  $L_i$ ), attached to the deforming beam at its point of inflection, rotates through an angle  $\theta$ , and the deflection  $\delta$  is read on the vernier scale. The residual strain is calculated as [Lin, 1993]:

$$\epsilon_f = \frac{2L_s\delta}{3L_tL_iC} \quad (16.55)$$

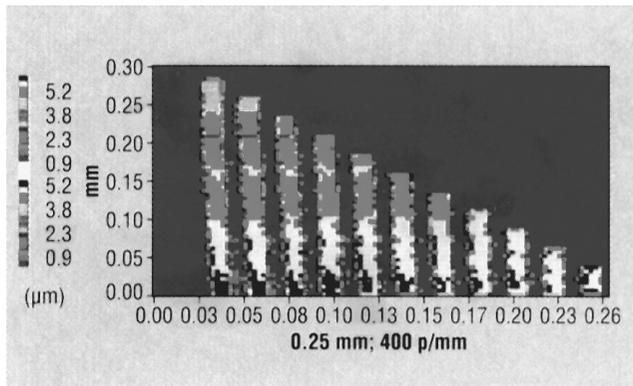

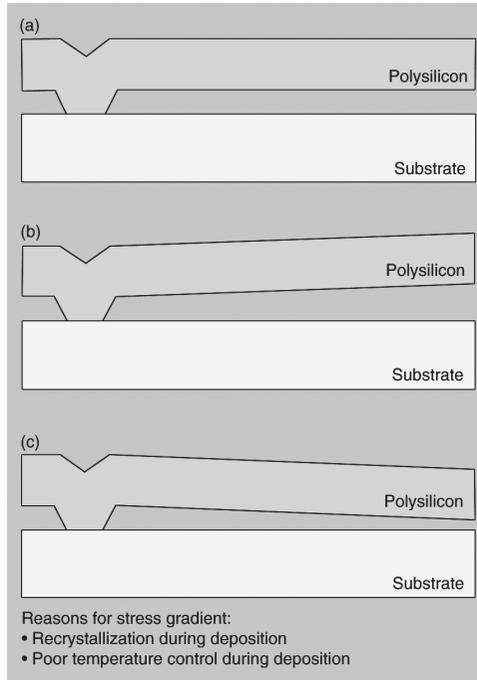

where  $C$  is a correction factor due to the presence of the indicator beam [Lin, 1993]. This equation was derived from simple beam theory relations and assumes that no out-of-plane motion occurs. The accuracy of the strain gauge is greatly improved because its output is independent of both the thickness of the deposited film and the cross section of the microstructure. Krulevitch used these devices to measure residual stress in *in situ* phosphorus-doped poly-Si films [Krulevitch, 1994], while Lin tested LPCVD silicon-rich silicon nitride films with it [Lin, 1993].

An improved micromachined indicator structure, inspired by Lin's work, was built by Ericson et al. (1995). By reading an integrated nonius scale in an SEM or an optical microscope, internal stress was measured with a resolution better than 0.5 MPa [Ericson et al., 1995; Benitez et al., 1995]. Both thick (10- $\mu\text{m}$ ) and thin (2- $\mu\text{m}$ ) poly-Si films were characterized this way.

**Lateral Resonators.** Biebl et al. (1995) extracted the Young's modulus of *in situ* phosphorus-doped polysilicon by measuring the mechanical response of poly-Si linear lateral comb-drive resonators (see Figure 16.88). The results reveal a value of  $130 \pm 5$  GPa for the Young's modulus of highly phosphorus-doped films deposited at 610°C with a phosphine-to-silane mole ratio of  $1.0 \times 10^{-2}$  and annealing at 1050°C. For a deposition at 560°C with a phosphine to silane ratio of  $1.6 \times 10^{-3}$ , a Young's modulus of  $147 \pm 6$  GPa was extracted.

### **Stress Nonuniformity Measurement by Cantilever Beams and Cantilever Spirals**

The uniformity of stress through the depth of a film introduces an extremely important property to control. Variations in the magnitude and direction of the stress in the vertical direction can cause cantilevered

**FIGURE 16.82** (A) Micro-cantilever deflection for measuring stress non-uniformity. (a) No gradient; (b) high tensile stress near the surface; and (c) lower tensile stress near the surface. (B) Topographical contour map of polysilicon cantilever array. (From Core, T.A., W.K. Tsang, and S.J. Sherman, *Solid State Technol.*, 36, 39–47, 1993. With permission.)

structures to curl toward or away from the substrate. Stress gradients present in the polysilicon film must thus be controlled to ensure predictable behavior of designed structures when released from the substrate. To determine the thickness variation in residual stress, noncontact surface profilometer measurements on an array of simple cantilever beams [Core et al., 1993; Chu et al., 1992] or cantilever spirals can be used [Fan et al., 1990].

**Cantilever Beams.** The deflections resulting from stress variation through the thickness of simple cantilever beams after their release from the substrate is shown in [Figure 16.82A](#). The bending moment causing deflection of a cantilever beam follows out of pre-release residual stress and is given by (see [Figure 16.82A](#)):

$$M = \int_{-t/2}^{t/2} zb\sigma(z) dZ \quad (16.56)$$

where  $\sigma(z)$  represents the residual stress in the film as a function of thickness and  $b$  stands for cantilever width. Assuming a linear strain gradient  $\Gamma$  (physical dimensions 1/length) such that  $\sigma(z) = E\Gamma z$ , Eq. (16.56) converts to:

$$\Gamma = \frac{M(12)}{Ebt^3} = \frac{M}{EI} \quad (16.57)$$

where the moment of inertia,  $I$ , for a rectangular cross section is given by  $I = bt^3/12$ . The measured deflection  $z$ , i.e., the vertical deflection of the cantilever's endpoint, from beam theory for a cantilever with an applied end moment, is given as:

$$z = \frac{ML^2}{2EI} = \frac{\Gamma L^2}{2} \quad (16.58)$$

Figure 16.82B represents topographical contour map of an array of polysilicon cantilevers. The cantilevers vary in length from 25 to 300  $\mu\text{m}$  by 25- $\mu\text{m}$  increments. Notice that the tip of the longest cantilever resides at a lower height (approximately 0.9  $\mu\text{m}$  closer to the substrate) than the anchored support, indicating a downward bending moment [Core et al., 1993]. The gradients can be reduced or eliminated with a high-temperature anneal. With integrated electronics on the same chip, long high-temperature processing must be avoided. Therefore, stress gradients can limit the length of cantilevered structures used in surface-micromachined designs.

**Cantilever Spirals.** Residual stress gradients can also be measured by Fan's cantilever spiral as shown in Figure 16.83A [Fan et al., 1990]. Spirals anchored at the inside spring upwards, rotate, and contract with positive strain gradient (tending to curl a cantilever upwards), while spirals anchored at the outside deflect in a similar manner in response to a negative gradient. Theoretically, positive and negative gradients produce spirals with mirror symmetry [Fan et al., 1990]. The strain gradient can be determined from spiral structures by measuring the amount of lateral contraction, the change in height, or the amount of rotation. Krulevitch presented the computer code for the spiral simulation in his doctoral thesis [Krulevitch, 1994]. Figure 16.83B shows a simulated spiral with a bending moment of  $\Gamma = \pm 3.0 \text{ mm}^{-1}$  after release.

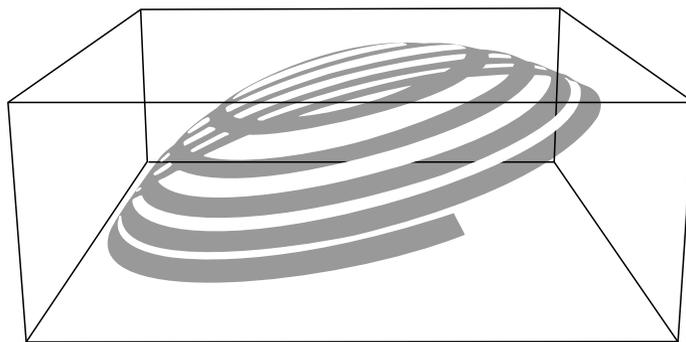

Krulevitch compared all the above surface micromachined structures for stress and stress gradient measurements on poly-Si films. His comments are summarized in Table 16.12 [Krulevitch, 1994]. Krulevitch found that the fixed-fixed beam structures for determining compressive stress from the buckling criterion produced remarkably self-consistent and repeatable results. Wafer curvature stress profiling proved reliable for determining average stress and the true stress gradient as compared with micromachined spirals. Measurements of curled cantilevers could not be used much as the strain gradients mainly were negative for poly-Si, leading to cantilevers contacting the substrate. The strain gauge dial structures were useful over a rather limited strain-gradient range. With too large a strain gradient curling of the long beams overshadows expansion effects and makes the vernier indicator unreadable.

#### 16.12.4 Strength of Thin Films

Due to the high activation energy for dislocation motion in silicon (2.2 eV), hardly any plastic flow occurs in single crystalline silicon for temperatures lower than 673°C. Grain boundaries in poly-Si block dislocation motion; hence, polysilicon films can be treated as an ideal brittle material at room temperature [Biebl et al., 1995]. High yield strengths often are obtained in thin films with values up to 200 times as large as those found in the corresponding bulk material [Campbell, 1970]. In this light, the earlier quoted fracture stresses of poly-Si, between two and ten times smaller than that of bulk single crystal, are

**TABLE 16.12** Summary of Various Techniques for Measuring Residual Film Stress

Measurement Technique	Measurable Stress State	Remarks
Wafer curvature	Stress gradient, average stress	Average stress over entire wafer; provides true stress gradient; approx. 5 MPa resolution
Vernier strain gauges	Average stress	Local stress; small dynamic range; resolution = 2 MPa
Spiral cantilevers	Stress gradient	Local stress, provides equivalent linear gradient
Curling beam cantilevers	Large positive stress gradient	Local stress, provides equivalent linear gradient
Fixed-fixed beams	Average compressive stress	Local stress measurement

surprising. Greek et al. (1995) explain this deviation by pointing at the high surface roughness of poly-Si films compared to single crystal Si. They believe that a reduction in surface roughness would improve the tensile fracture strength considerably.

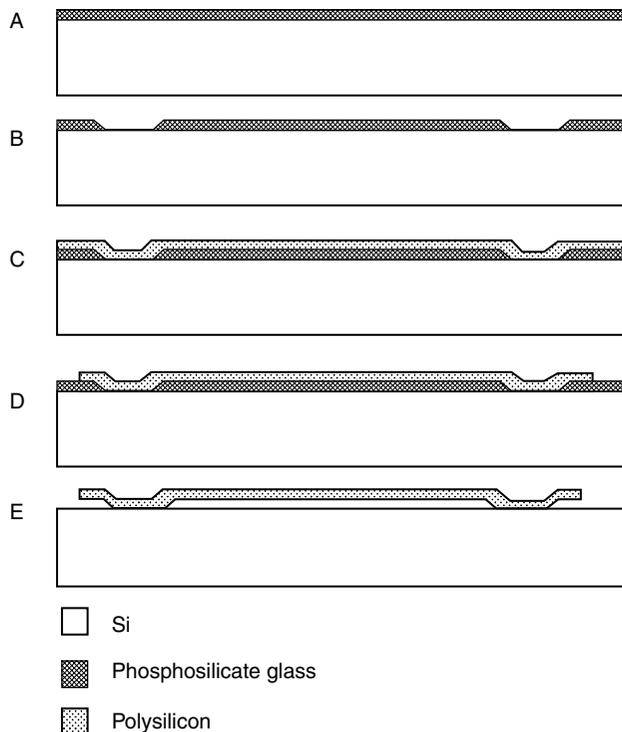

Indentation (hardness) testing is very common for bulk materials where the direct relationship between bulk hardness and yield strength is well known. It can be measured by pressing a hard, specially shaped point into the surface and observing indentation. This type of measurement is of little use for measuring thin films

below  $5 \times 10^4 \text{ \AA}$ . Consequently, very little is known about the hardness of thin films. Recently, specialized instruments have been constructed (e.g., the Nanoindenter) in which load and displacement data are collected while the indentation is being introduced in a thin film. This eliminates the errors associated with later measurement of indentation size and provides continuous monitoring of load/displacement data similar to a standard tensile test. Load resolution may be  $0.25 \text{ \mu N}$ , displacement resolution 0.2 to 0.4 nm, and x-y sample position accuracy  $0.5 \text{ \mu m}$ . Empirical relations have correlated hardness with Young's modulus and with uniaxial strength of thin films. Hardness calculations must include both plastic and long-distance elastic deformation. If the indentation is deeper than 10% of the film, corrections for elastic hardness contribution of the substrate must also be included [Vinci and Braveman, 1991]. Mechanical properties such as hardness and modulus of elasticity can be determined on the micro- to picoscales using AFM [Bushan, 1996]. Bushan provides an excellent introduction to this field in *Handbook of Micro/Nanotribology* [Bushan, 1995].

## 16.13 Surface Micromachining Processes

### 16.13.1 Basic Process Sequence

A surface micromachining process sequence for the creation of a simple free-standing poly-Si bridge is illustrated in Figure 16.84 [Howe and Muller, 1983; Howe, 1985]. A sacrificial layer, also called a spacer layer or base, is deposited on a silicon substrate coated with a dielectric layer as the buffer/isolation layer (Figure 16.84A). Phosphosilicate glass (PSG) deposited by LPCVD stands out as the best material for the sacrificial layer because it etches even more rapidly in HF than  $\text{SiO}_2$ . In order to obtain a uniform etch rate, the PSG film must be densified by heating the wafer to  $950\text{--}1100^\circ\text{C}$  in a furnace or a rapid

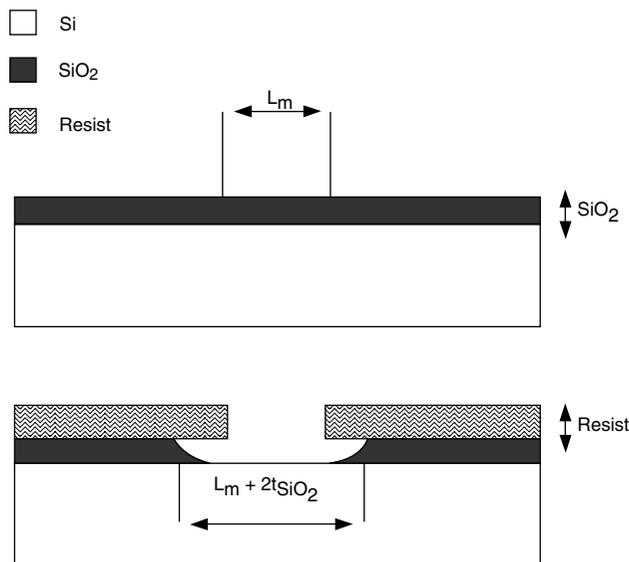

**FIGURE 16.84** Basic surface micromachining process sequence. (A) Spacer layer deposition (the thin dielectric insulator layer is not shown). (B) Base patterning with mask 1. (C) Microstructure layer deposition. (D) Pattern microstructure with mask 2. (E) Selective etching of spacer layer.

thermal annealer (RTA) [Yun, 1992]. With a first mask the base is patterned as shown in Figure 16.84B. Windows are opened up in the sacrificial layer and a microstructural thin film, whether consisting of polysilicon, metal, alloy or a dielectric material, is conformably deposited over the patterned sacrificial layer (Figure 16.84C). Furnace annealing, in the case of polysilicon at 1050°C in nitrogen for one hour, reduces stress stemming from thermal expansion coefficient mismatch and nucleation and growth of the film. Rapid thermal annealing has been found effective for reducing stress in polysilicon as well [Yun, 1992]. With a second mask, the microstructure layer is patterned, usually by dry etching in a  $\text{CF}_4 + \text{O}_2$  or a  $\text{CF}_3\text{Cl} + \text{Cl}_2$  plasma (Figure 16.84D) [Adams, 1988]. Finally, selective wet etching of the sacrificial layer, say in 49% HF, leaves a free-standing micromechanical structure (Figure 16.84E). The surface micromachining technique is applicable to combinations of thin films and lateral dimensions where the sacrificial layer can be etched without significant etching or attack of the microstructure, the dielectric or the substrate.

## 16.13.2 Fabrication Step Details

### 16.13.2.1 Pattern Transfer to $\text{SiO}_2$ Buffer/Isolation Layer

A blanket  $n^+$  diffusion of the Si substrate, defining a ground plane, often outlines the very first step in surface micromachining, followed by a passivation step of the substrate, for example, with 0.15- $\mu\text{m}$ -thick LPCVD nitride on a 0.5- $\mu\text{m}$  thermal oxide. Suppose the buffer/isolation passivation layer as illustrated in Figure 16.85 itself needs to be patterned, perhaps to make a metal contact pad onto the Si substrate. Then, the appropriate fabrication step is a pattern transfer to the thin isolation film as shown in Figure 16.85, illustrating a wet pattern transfer to a 1- $\mu\text{m}$ -thick thermal  $\text{SiO}_2$  film with a 1- $\mu\text{m}$  resist layer. Typically, an isotropic etch such as buffered HF, e.g., BHF (5:1), which is 5 parts  $\text{NH}_4\text{F}$  and 1 part conc. HF, is used (unbuffered HF attacks the photoresist). This solution etches  $\text{SiO}_2$  at a rate of 100 nm/min, and the creation of the opening to the underlying substrate takes about 10 min. The etch progress may be monitored optically (color change) or by observing the hydrophobic/hydrophilic behavior [Hermansson et al., 1991] of the etched layer. With a resist opening,  $L_m$ , the undercut typically measures the same thickness as the oxide thickness,  $t_{\text{SiO}_2}$ . In other words, the contact pad will have a size of  $L_m + 2t_{\text{SiO}_2}$ . The undercut worsens with loss of photoresist adhesion during etching. Using an adhesion promoter such

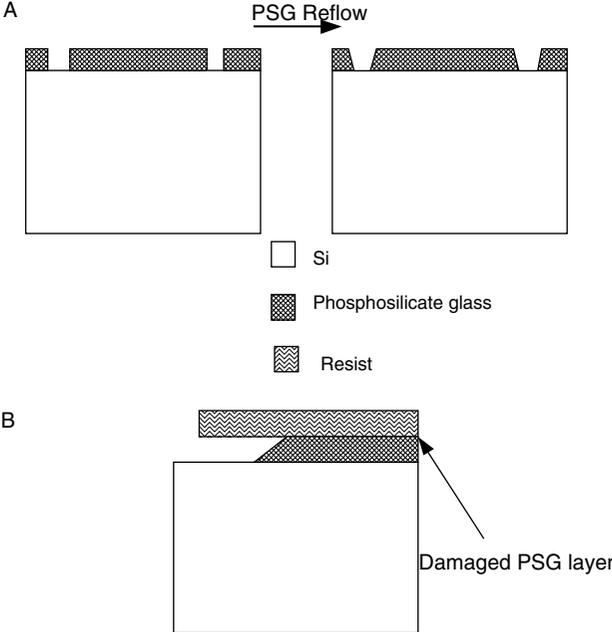

**FIGURE 16.85** Wet etch pattern transfer to a thin thermal  $\text{SiO}_2$  film for the fabrication of a contact pad to the Si substrate.

as HMDS (hexamethyldisilazane) prove useful in such case. A new bake after 5 min of etching is a good procedure to maintain the resist integrity. After the isotropic etch, the resist is stripped in a piranha etch bath. This strong oxidizer grows about 3 nm of oxide back in the cleared window. To remove the oxide resulting from the piranha, a dip in diluted BHF suffices. After cleaning and drying, the substrate is ready for contact metal and base material deposition. Applying a dry etch (say, a  $\text{CF}_4\text{-H}_2$  plasma) to open up the window in the oxide would eliminate undercutting of the resist, but requires a longer set-up time. With an LPCVD low stress nitride on top of a thermal  $\text{SiO}_2$ , an often-used combination for etching the buffer/isolation layer is a dry etch (say, a  $\text{SF}_6$  plasma) followed by a 5:1 BHF [Tang, 1990].

**16.13.2.2 Base Layer (also Spacer or Sacrificial Layer) Deposition and Etching**

A thin LPCVD phosphosilicate glass (PSG) layer (say, 2  $\mu\text{m}$  thick) is a preferred base, spacer, or sacrificial layer material. Adding phosphorous to  $\text{SiO}_2$  to produce PSG enhances the etch rate in HF [Monk et al., 1992; Tenney and Ghezzi, 1973]. Other advantages to using doped  $\text{SiO}_2$  include its utility as a solid state diffusion dopant source to make subsequent polysilicon layers electrically conductive and helping to control window taper (see below). As deposited phosphosilicate displays a nonuniform etch rate in HF and must be densified, typically carried out in a furnace at 950°C for 30 min to 1 hr in a wet oxygen ambient. The etch rate in BHF can be used as the measure of the densification quality. The base window etching stops at the buffer isolation layer, often a  $\text{Si}_3\text{N}_4/\text{SiO}_2$  layer which also forms the permanent passivation of the device. Windows in the base layer are used to make anchors onto the buffer/isolation layer for mechanical structures.

The edges of the etched windows in the base may need to be tapered to minimize coverage problems with subsequent structural layers, especially if these layers are deposited with a line-of-sight deposition technique. An edge taper is introduced through an optimization of the plasma etch conditions (see Madou [1997, chap. 2]), through the introduction of a gradient of the etch rate, or by reflow of the etched spacer. In Figure 16.86A we depict the reflow process of a PSG spacer after patterning in a dry etch. Viscous flow at higher temperature smooths the edge taper. The ability of PSG to undergo viscous deformation at a given temperature primarily is a function of the phosphorous content in the glass; reflow profiles get progressively smoother the higher the phosphorous concentration—reflecting the corresponding

**FIGURE 16.86** Edge taper of spacer layer. (A) Taper by reflow of PSG. (B) Taper by ion implantation of PSG.

enhancement in viscous flow [Levy and Nassau, 1986]. In [Figure 16.86B](#), ion implantation of PSG has created a rapidly etching, damaged PSG layer [North et al., 1978; Goetzlich and Ryssel, 1981; White, 1980]. The steady-state taper is a function of the etch rate in PSG etchants (e.g., BHF).

### 16.13.2.3 Deposition of Structural Material

For the best step coverage of a structural material over the base window, chemical vapor deposition is preferred. If a physical deposition method must be used, sputtering is preferred over line-of-sight deposition techniques which lead to the poorest step coverage (see Madou [1997, chap. 3]). In the latter case, edge taper could be introduced advantageously.

The most widely used structural material in surface micromachining is polysilicon (poly-Si or simply poly). Polysilicon is deposited by low pressure (25 to 150 Pa) chemical vapor deposition in a furnace (a poly chamber) at about 600°C. The undoped material is usually deposited from pure silane, which thermally decomposes according to the reaction:

Typical process conditions may consist of a temperature of 605°C, a pressure of 550 mTorr (73 Pa), and a silane flow rate of 125 sccm. Under those conditions a normal deposition rate is 100 Å/min. To deposit a 1-μm film will take about 90 min. Sometimes the silane is diluted by 70 to 80% nitrogen. The silicon is deposited at temperatures ranging from 570 to 580°C for fine-grained poly-Si to 620 to 650°C for coarse-grained poly-Si. The characteristics of these two types of poly-Si materials will be compared in the case studies presented below. Furnace annealing of the poly-Si film at 1050°C in nitrogen for one hour is employed commonly to reduce stress stemming from thermal expansion coefficient mismatch and nucleation and growth of the polysilicon film.

To make parts of the microstructure conductive, dopants can be introduced in the poly-Si film by adding dopant gases to the silane gas stream, by drive-in from a solid dopant source or by ion implantation. When doping from the gas phase, the dopant can be readily controlled in the range of  $10^{19}$  to  $10^{21}/\text{cm}^3$ . Polysilicon deposition rates, in the case of gas phase doping (*in situ* doping), may be significantly impacted. For example, decreases in poly-Si deposition rate by as much as a factor of 25 have been reported in phosphine and arsine doping. The effect is associated with the poisoning of reaction sites by phosphine and arsine [Adams, 1988]. The lower deposition rate of *in situ* phosphine doping can be mitigated by reducing the ratio of phosphine to silane flow by one third [Howe, 1995]. With the latter flow regime, deposition at 585°C (for a 2-μm-thick film), followed by 900°C rapid thermal annealing for 7 min, results in a polysilicon with low residual stress, negligible stress gradient and low resistivity [Howe, 1995; Biebl et al., 1995]. *In situ* boron doping, in contrast to arsine and phosphine doping, accelerates the polysilicon deposition rate through an enhancement of silane adsorption induced by the boron presence [Fresquet et al., 1995]. Film thickness uniformity for doped films typically is less than 1% and sheet resistance uniformity less than 2%. Alternatively, poly-Si may be doped from PSG films sandwiching the undoped poly-Si film. By annealing such a sandwich at 1050°C in  $\text{N}_2$  for one hour, the polysilicon is symmetrically doped by diffusion of dopant from the top and the bottom layers of PSG. Symmetric doping results in a polysilicon film with a moderate compressive stress. The resulting uniform grain texture avoids gradients in the residual stress which would cause bending moments warping microstructures upon release. Finally, ion implantation of undoped polysilicon, followed by high temperature dopant drive-in, also leads to conductive polysilicon. This polysilicon has a moderate tensile stress, with a strain gradient that causes cantilevers to deflect toward the substrate [Core et al., 1993]. The poly-Si is now ready for patterning by RIE in, say, a  $\text{CF}_4\text{-O}_2$  plasma.

Although the mechanical properties still are not well understood, microstructures based on poly-Si as a mechanical member have been commercialized [Editor, 1991; Core et al., 1993]. Other structural materials used in surface micromachining include single crystal Si (epi-Si or etched back, fusion bonded Si),  $\text{SiO}_2$ , silicon nitride, silicon oxynitride, polyimide, diamond, SiC, GaAs, tungsten,  $\alpha\text{-Si:H}$ , Ni, W, Al etc. A few words about the merit of some of these materials as structural components follow.

Silicon nitride and silicon oxide also can be deposited by CVD methods but usually exhibit too much residual stress which hampers their use as mechanical components. However, CVD of mixed silicon oxynitride can produce substantially stress-free components.

Amorphous Si ( $\alpha$ -Si) can be stress annealed at temperatures as low as 400°C [Chang et al., 1991]. This low-temperature anneal makes the material compatible with almost any active electronic component. Unfortunately, very little is known about the mechanical properties of amorphous Si.

Hydrogenated amorphous Si ( $\alpha$ -Si:H), with its interesting electronic properties, is even less understood in terms of its mechanical properties. If the mechanical properties of hydrogenated amorphous Si were found as good as those of poly-Si, the material might make a better choice than poly-Si as a MEMS material given its better electronic characteristics.

Tungsten CVD deposition is IC compatible. The material has some unique mechanical properties (see Madou [1997, chap. 8, Table 8.4]). Moreover, the material can be applied selectively. Selective CVD tungsten has the unique property that tungsten will only nucleate on silicon or metal surfaces but does not deposit on dielectrics such as oxides and nitrides [Chen and MacDonald, 1991].

Metals and polyimides, because they are easily deformed, usually do not qualify as mechanical members but have been used, for example, in plastically deformable hinges [Suzuki et al., 1994; Hoffman et al., 1995]. Aluminum constitutes the mirror material in Texas Instruments' flexure-beam micromirror devices (FBMDs). The metal is used both for the L-shaped flexure hinges and the mirror itself [Lin, 1996]. Polycrystalline diamond films, deposited by CVD, are potential high-temperature, harsh environment MEMS candidates [Herb et al., 1990]. Problems include oxidation above 500°C for nonpassivated films, difficulty of making reliable ohmic contact to the material, and the reproducibility and surface roughness of the films [Obermeier, 1995]. Poly-SiC films have been deposited by an APCVD process on 4-in. polysilicon-coated, silicon wafers. A surface micromachining process using the underlying polysilicon film as the sacrificial layer was developed. Poly-SiC is projected for use as structural material for high temperatures and harsh environments, and to reduce friction and wear between moving components [Fleischman et al., 1996]. Surface micromachining of thin single crystalline Si layers in SOI and with polyimides is discussed separately below.

### 16.13.2.4 Selective Etching of Spacer Layer

#### Selective Etching

To create movable micromachines the microstructures must be freed from the spacer layers. The challenge in freeing microstructures by undercutting is evident from Figure 16.87. After patterning the poly-Si by

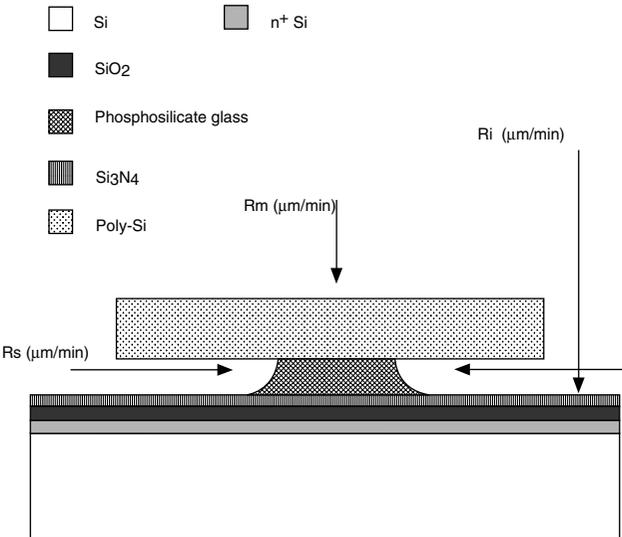

FIGURE 16.87 Selective etching of spacer layer.

RIE in, say, a SF<sub>6</sub> plasma, it is immersed in an HF solution to remove the underlying sacrificial layer, releasing the structure from the substrate. Commonly, a layer of sacrificial phosphosilicate glass, between 1 and 2000 μm long and 0.1 to 5 μm thick, is etched in concentrated, dilute or buffered HF. The spacer etch rate, R<sub>s</sub>, should be faster than the attack on the microstructural element, R<sub>m</sub>, and that of the insulator layer, R<sub>i</sub>. For this type of complete undercutting, only wet etchants can be used. Etching narrow gaps and undercutting wide areas with BHF can take hours. To shorten the etch time, extra apertures in the microstructures sometimes are provided for additional access to the spacer layer. The etch rate of PSG, the most common spacer material, increases monotonically with dopant concentration, and thicker sacrificial layers etch faster than thinner layers [Monk et al., 1994].

The selectivity ratios for spacer layer, microstructure and buffer layer are not infinite [Lober and Howe, 1998], and in some instances even silicon substrate attack by BHF was observed under polysilicon/spacer regions [Fan et al., 1988; Mehregany et al., 1988]. Heavily phosphorous-doped polysilicon is especially prone to attack by BHF. Silicon nitride deposited by LPCVD etches much more slowly in HF than oxide films, making it a more desirable isolation film. When depositing this film with a silicon-rich composition, the etch rate is even slower (15 nm/min) [Tang, 1990]. Eaton et al. (1995) compared oxide and nitride etching in a 1:1 HF:H<sub>2</sub>O and in a 1:1 HF:HCl solution and concluded that the HCl-based etch yielded both faster oxide etch rates (617 nm/min vs. 330 nm/min) and slower nitride etch rates (2 nm/min vs. 3.6 nm/min), providing a much greater selectivity of the oxide to silicon nitride (310 vs. 91!). The same authors also studied the optimum composition of a sacrificial oxide for the fastest possible etching in their most selective 1:1 HF:HCl etch. The faster sacrificial layer etch limited the damage to nitride structural elements. Their results are summarized in Table 16.13. A densified CVD SiO<sub>2</sub> was used as a control, and a 5%/5% borophosphosilicate glass (BPSG) was found to etch the fastest.

Watanabe et al. (1995) using low pressure vapor HF, found high etch ratios of PSG and BPSG to thermal oxides of over 2000, with the BPSG etching slightly faster than the PSG. We will see further that low pressure vapor HF also leads to less stiction of structural elements to the substrate. In Table 16.14 we present etch rate and etch ratios for R<sub>i</sub> and R<sub>s</sub> in BHF (7:1) for a few selected materials.

Detailed studies on the etching mechanism of oxide spacer layers were undertaken by Monk et al. (1994a; 1994b) They found that the etching reaction shifts from kinetic controlled to diffusion controlled as the etch channel becomes longer. This affects mainly large-area structures, as diffusion limitations were observed only after approximately 200 μm of channel etching or 15 min in concentrated HF. Eaton and Smith (1996) developed a release etch model which is an extension of the work done by Monk et al. (1994a; 1994b) and Liu et al. (1993).

Etching is followed by rinsing and drying. Extended rinsing causes a native oxide to form on the surface of the polysilicon structure. Such a passivation layer often is desirable and can be formed more easily by a short dip in 30% H<sub>2</sub>O<sub>2</sub>.

#### ***Etchant-Spacer-Microstructure Combinations***

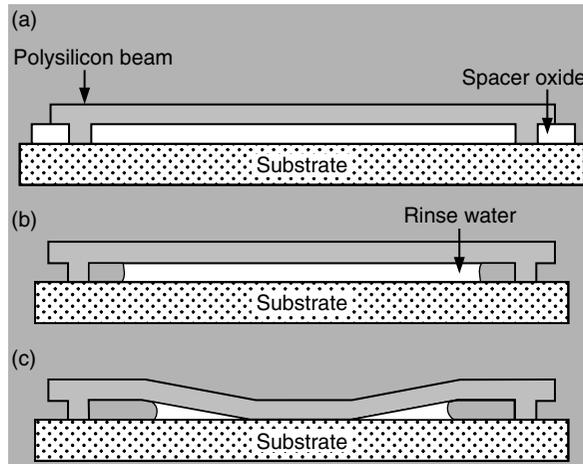

A wide variety of etchant, spacer, and structural material combinations have been used; a limited listing is presented in Table 16.15. One interesting case concerns poly-Si as the sacrificial layer. This was used, for example, in the fabrication of a vibration sensor at Nissan Motor Co [Nakamura et al., 1985]. In this case poly-Si is etched in KOH from underneath a nitride/polysilicon/nitride sandwich cantilever. Also, a solution of HNO<sub>3</sub> and BHF can be used to etch poly-Si, but it proves difficult to control. Using aqueous solutions of NR<sub>4</sub>OH, where R is an alkyl group, provides a better etching solution for poly-Si, with greater selectivity with respect to silicon dioxide and phosphosilicate glass. The relatively slow etch rate enables better process control [Bassous and Liu, 1978] and the etchant does not contain alkali ions, making it more CMOS compatible. With tetramethylammonium hydroxide (TMAH) the etch rate of CVD poly-Si, deposited at 600°C from SiH<sub>4</sub>, follows the rates of the (100) face of single crystal Si and is dopant dependent. The selectivity of Si/SiO<sub>2</sub> and Si/PSG, at temperatures below 45°C are measured to be about 1000. Hence, a layer of 500-Å PSG can be used as the etch mask for 10,000 Å of poly-Si.

### **16.13.2.5 Stiction**

#### ***Stiction During Release***

The use of sacrificial layers enables the creation of very intricate movable polysilicon surface structures. An important limitation of such polysilicon shapes is that large-area structures tend to deflect through stress gradients or surface tension induced by trapped liquids and attach to the substrate/isolation layer during the final rinsing and drying step, a stiction phenomenon that may be related to hydrogen bonding or residual contamination. Recently, great strides were made towards a better understanding and prevention of stiction.

The sacrificial layer removal with a buffered oxide etch followed by a long, thorough rinse in deionized water and drying under an infrared lamp typically represent the last steps in the surface micromachining sequence. As the wafer dries, the surface tension of the rinse water pulls the delicate microstructure to the substrate where a combination of forces, probably van der Waals forces and hydrogen bonding, keeps it firmly attached (see Figure 16.88) [Core et al., 1993]. Once the structure is attached to the substrate by stiction, the mechanical force needed to dislodge it usually is large enough to damage the micromechanical structure [Lober and Howe, 1988; Guckel et al., 1987; Alley et al., 1988]. Basically, the same phenomena are thought to be involved in room temperature wafer bonding [Madou, 1997, chap. 8]. We will not further dwell upon the mechanics of the stiction process here, but the reader should refer to the theoretical and experimental analysis of the mechanical stability and adhesion of microstructures under capillary forces by Mastrangelo et al. (1993a; 1993b).

**FIGURE 16.88** Stiction phenomenon in surface micromachining and the effect of surface tension on micromechanical structures. (a) Unreleased beam. (b) Released beam before drying. (c) Released beam pulled to the substrate by capillary forces as the wafer dries [conc].

Creating stand-off bumps on the underside of a poly-Si plate [Tang, 1990; Fan, 1989] or adding meniscus-shaping microstructures to the perimeter of the microstructure are mechanical means to help reduce sticking [Abe et al., 1995]. Fedder et al. (1992) used another mechanical approach to avoid stiction by temporarily stiffening the microstructures with polysilicon links. These very stiff structures are not affected by liquid surface tension forces and the links are severed afterward with a high current pulse once the potentially destructive processing is complete. Yet another mechanical approach to avoid stiction involves the use of sacrificial supporting polymer columns. A portion of the sacrificial layer is substituted by polymer spacer material, spun-on after partial etch of the oxide glass. After completion of the oxide etch, the polymer spacer prevents stiction during evaporative drying. Finally, an isotropic oxygen plasma etches the polymer to release the structure [Mastrangelo and Saloka, 1993].

Ideally, to ensure high yields, one should avoid contact between structural elements and the substrate during processing. In a liquid environment, however, this may become impossible due to the large surface tension effects. Consequently, most solutions to the stiction problem involve reducing the surface tension of the final rinse solution by physico-chemical means. Lober et al. (1988), for example, tried HF vapor and Guckel et al. (1989; 1990) used freeze-drying of water/methanol mixtures. Freezing and sublimating the rinse fluid in a low-pressure environment gives improved results by circumventing the liquid phase. Takeshima et al. (1991) used t-butyl alcohol freeze-drying. Since the freezing point of this alcohol lies at 25.6°C, it is possible to perform freeze-drying without special cooling equipment. More recently, attempts at supercritical drying resulted in high microstructure yields [Mulhern et al., 1993]. With this technique, the rinse fluid is displaced with a liquid that can be driven into a supercritical phase under high pressure. This supercritical phase does not exhibit surface tension. Typically, CO<sub>2</sub> under about 75 atm is used (see also Madou [1997, chap. 1 under Cleaning]).

Kozlowski et al. (1995) substituted HF in successive exchange steps by the monomer divinylbenzene to fabricate very thin (500 nm) micromachined polysilicon bridges and cantilevers. The monomer was polymerized under UV light at room temperature and was removed in an oxygen plasma. Analog Devices applied a proprietary technique involving only standard IC process technology in the fabrication of a micro-accelerometer to eliminate yield losses due to stiction [Core et al., 1993].

#### ***Stiction After Release, i.e., In-Use Stiction***

Stiction remains a fundamental reliability issue due to contact with adjacent surfaces after release. Stiction free passivation that can survive the packaging temperature cycle is not known at present [Howe, 1995]. Attempted solutions are summarized below.

Adhesive energy may be minimized in a variety of ways, for example, by forming bumps on surfaces (see above) or roughening of opposite surface plates [Alley et al., 1993]. Also, self-assembled monolayer coatings have been shown to reduce surface adhesion and to be effective at friction reduction in bearings at the same time [Alley et al., 1992]. Making the silicon surface very hydrophobic or coating it with diamond-like carbon are other potential solutions for preventing postrelease stiction of polysilicon microstructures. Man et al. (1996) eliminate post-release adhesion in microstructures by using a thin conformal fluorocarbon film. The film eliminates the adhesion of polysilicon beams up to 230  $\mu\text{m}$  long even after direct immersion in water. The film withstands temperatures as high as 400°C and wear tests show that the film remains effective after  $10^8$  contact cycles. Along the same line, ammonium fluoride-treated Si surfaces are thought to be superior to the HF-treated surfaces due to a more complete hydrogen termination, leading to a cleaner hydrophobic surface [Houston et al., 1995]. Gogoi and Mastrangelo (1995) introduced electromagnetic pulses for postprocessing release of stuck microstructures.

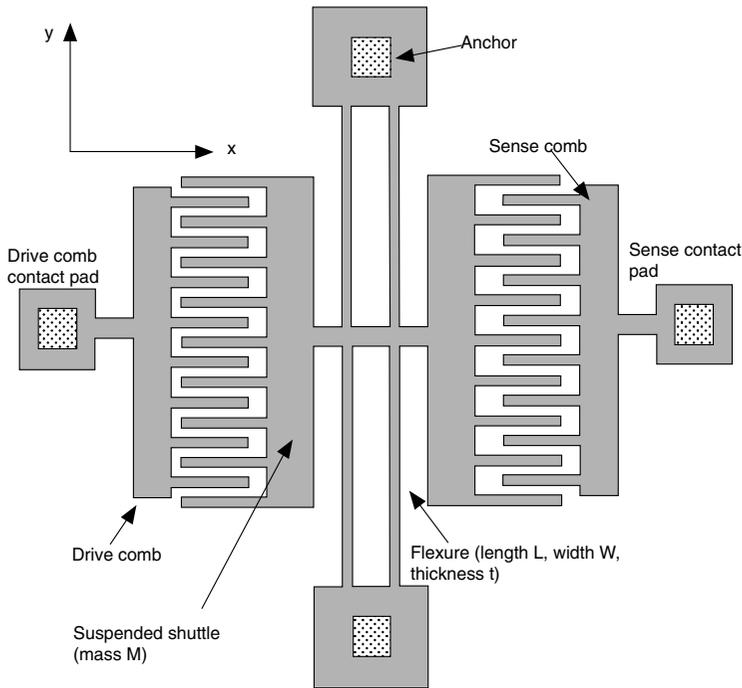

### 16.13.3 Control of Film Stress

After reviewing typical surface micromachining process sequences we are ready to investigate some of the mechanical properties of the fabricated mechanical members. Consider a lateral resonator as shown in Figure 16.89A. Electrostatic force is applied by a drive comb to a suspended shuttle. Its motion is detected capacitively by a sense comb. For many applications a tight control over the resonant frequency,  $f_0$ , is required. A simple analytical approximation for  $f_0$  of this type of resonator can be deduced from Rayleigh's method [Howe, 1987]:

$$f_0 \approx \frac{1}{2\pi\sqrt{ML^3}} \sqrt{4EtW^3 + \frac{24\sigma_r tW}{5ML}} \quad (16.59)$$

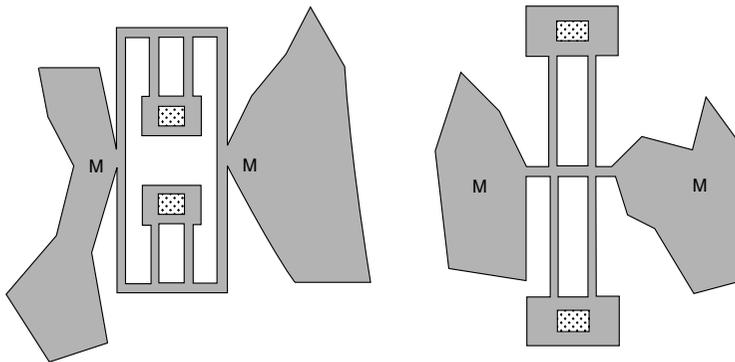

where  $E$  represents the Young's modulus of polysilicon;  $L$ ,  $W$  and  $t$  are the length, width and thickness of the flexures; and  $M$  stands for the mass of the suspended shuttle (of the order of  $10^{-9}$  kg, or less). For typical values ( $L = 150 \mu\text{m}$  and  $W = t = 2 \mu\text{m}$ ) and a small tensile residual stress, the resonant frequency  $f_0$  is between 10 and 100 kHz [Howe, 1995]. For typical values of  $L/W$  the stress term in Eq. (16.59) dominates the bending term. Any residual stress,  $\sigma_r$ , obviously will affect the resonant frequency. Consequently, stress and stress gradients represent critical stages for microstructural design. One of the many challenges of any surface-micromachining process is to control the intrinsic stresses in the deposited films. Several techniques can be used to control film stress. Some we detailed before, but we list them again for completeness:

- Large-grained poly-Si films, deposited around 625°C, have a columnar structure and are always compressive. Compressive stress can cause buckling in constrained structures. Annealing at high temperatures, between 900 and 1150°C, in nitrogen significantly reduces the compressive stress in as-deposited poly-Si [Guckel et al., 1985; Howe and Muller, 1983] and can eliminate stress gradients. No significant structural changes occur when annealing a columnar poly-Si film. The annealing process is not without danger in cases where active electronics are integrated on the same chip. Rapid thermal annealing might provide a solution (see IC Compatibility, below).
- Undoped poly-Si films are in an amorphous state when deposited at 580°C or lower. The stress and the structure of this low-temperature material depend on temperature and partial pressure of the silane. A low-temperature anneal leads to a fine-grained poly-Si with low tensile stress and very smooth surface texture [Guckel et al., 1989]. Tensile rather than compressive films are a necessity if lateral dimensions of clamped structures are not to be restricted by compressive buckling. Conducting regions are formed in this case by ion implantation. Fine-grained and large-grained poly-Si are compared in more detail further below.

■ Polysilicon

A

B

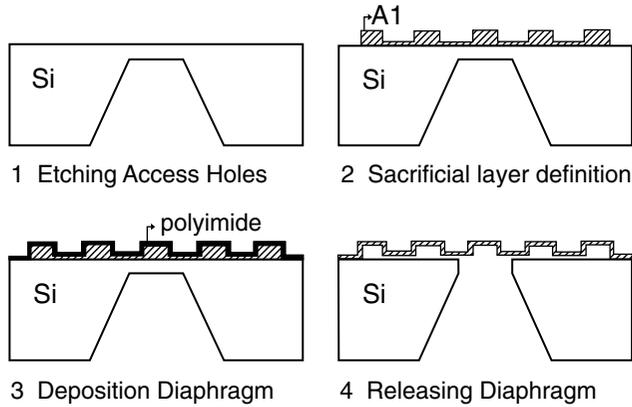

**FIGURE 16.89** Layout of a lateral resonator with straight flexures. (A) Folded flexures (left) to release stress are compared with straight flexures (right). (B) M is shuttle mass.

- Phosphorus [Murarka and Retajczyk, 1983; Orpana and Korhonen, 1991; Lin et al., 1993], boron [Orpana and Korhonen, 1991; Choi and Hearn, 1984; Ding and Ko, 1991], arsenic [Orpana and Korhonen, 1991] and carbon [Hendriks et al., 1983] doping have all been shown to affect the state of residual stress in poly-Si films. In the case of single crystal Si, to compensate for strain induced by dopants, one can implant with atoms with the opposite atomic radius vs. silicon. Similar approaches would most likely be effective for poly-Si as well.
- Tang et al. (1990; 1989) developed a technique that sandwiches a poly-Si structural layer between a top and bottom layer of PSG and lets the high temperature anneal drive in the phosphorus symmetrically, producing low stress poly-Si with a negligible stress gradient.

- Another stress reduction method is to vary the materials composition, something readily done in CVD processes. An example of this method is the Si enrichment of  $\text{Si}_3\text{N}_4$  which reduces the tensile stress [Sekimoto et al., 1982; Guckel et al., 1986].
- During plasma-assisted film deposition processes, one can influence stress dramatically. In a physical deposition process such as sputtering, stress control involves varying gas pressure and substrate bias. In plasma-enhanced chemical vapor deposition (PECVD) the RF power, through increased ion-bombardment, influences stress. In this way, the stress in a thin film starts out tensile, decreases as the power increases and finally becomes compressive with further RF power increase. PECVD equipment manufacturers also are working to build stress control capabilities into new equipment by controlling plasma frequency (see also Madou [1997, chap. 3]). In CVD, stress control involves all types of temperature treatment programs.
- A clever mechanical design might facilitate structural stress relief [Tang et al., 1989]. By folding the flexures in the lateral resonator in [Figure 16.89B](#), and by the overall structural symmetry, the relaxation of residual polysilicon stress is possible without structural distortion. By folding the flexures, the resonant frequency,  $f_0$ , becomes independent of  $\sigma_r$  (see Eq. (16.59)). The springs in the resonator structure provide freedom of travel along the direction of the comb-finger motions ( $x$ ) while restraining the structure from moving sideways ( $y$ ), thus preventing the comb fingers from shorting out the drive electrodes. In this design, the spring constant along the  $y$  direction must be higher than along the  $x$  direction, i.e.,  $k_y \gg k_x$ . The suspension should allow for the relief of the built-in stress of the polysilicon film and the axial stress induced by large vibrational amplitudes. The folded-beam suspensions meet both criteria. They enable large deflections in the  $x$  direction (perpendicular to the length of the beams) while providing stiffness in the  $y$  direction (along the length of the beams). Furthermore, the only anchor points (see [Figure 16.89B](#)) for the whole structure reside near the center, thus allowing the parallel beams to expand or contract in the  $y$  direction, relieving most of the built-in and induced stress [Tang, 1990]. Tang also modeled and built spiral and serpentine springs supporting torsional resonant plates. An advantage of the torsional resonant structures is that they are anchored only at the center, enabling radial relaxation of the built-in stress in the polysilicon film [Tang, 1990]. For some applications, the design approach with folded flexures is an attractive way to eliminate residual stress. However, a penalty for using flexures is increased susceptibility to out-of-plane warpage from residual stress gradients through the thickness of the polysilicon microstructure [Howe, 1995].
- Corrugated structural members, invented by Jerman for bulk micromachined sensors [Jerman, 1990], also reduce stress effectively. In the case of a single crystal Si membrane, stress may be reduced by a factor of 1000 to 10,000 [Spiering et al., 1991]. One of the applications of such corrugated structures is the decoupling of a mechanical sensor of its encapsulation, by reducing the influence of temperature changes and packaging stress [Spiering et al., 1991; Offereins et al., 1991]. Thermal stress alone can be reduced by a factor of 120 [Spiering et al., 1993]. Besides stress release, corrugated structures enable much larger deflections than do similar planar structures. This type of structural stress release was studied in some detail for single crystal Si [Zhang and Wise, 1994] (see also earlier in this chapter), polyimide [van Mullem et al. 1991] and LPCVD silicon nitride membranes [Scheeper et al., 1994]; but the quantitative influence of corrugated poly-Si structures still requires investigation. [Figure 16.90](#) illustrates a fabrication sequence for a polyimide corrugated structure. The sacrificial Al in step 4 may be etched away by a mixture of phosphoric acid: acetic acid: nitric acid (PAN, see [Table 16.15](#)).

### 16.13.4 Dimensional Uncertainties

The often-expressed concerns about run-to-run variability in material properties of polysilicon or other surface micromachined materials are somewhat misplaced, Howe points out [Howe, 1995]. He contrasts the relatively large dimensional uncertainties inherent to any lithography technique with poly-Si quality factors of up to 100,000 and long-term (>3 years) resonator frequency variation of less than 0.02 Hz.

**FIGURE 16.90** Schematic view of the fabrication process of a polyimide corrugated diaphragm. (From van Mullem, C.J. et al., Large Deflection Performance of Surface Micromachined Corrugated Diaphragms, presented at Transducers '91, San Francisco, CA, 1991. With permission.)

We follow his calculations here to prove the relative importance of the dimensional uncertainties. The shuttle mass  $M$  of a resonator as shown in Figure 16.89 is proportional to the thickness ( $t$ ) of the polysilicon film, and neglecting the residual stress term, Eq. (16.59) reduces to:

$$f_0 \propto \left(\frac{W}{L}\right)^{\frac{3}{2}} \quad (16.60)$$

In case the residual stress term dominates in Eq. (16.59), the resonant frequency is expressed as:

$$f_0 \propto \left(\frac{W}{L}\right)^{\frac{1}{2}} \quad (16.61)$$

The width-to-length ratio is affected by systematic and random variations in the masking and etching of the microstructural polysilicon. For 2- $\mu\text{m}$ -thick structural polysilicon, patterned by a wafer stepper and etched with a reactive-ion etcher, a reasonable estimate for the variation in linear dimension of etched features,  $\Delta$  is about 0.2  $\mu\text{m}$  (10% relative tolerance).

From Eq. (16.60) the variation  $\Delta$  in lateral dimensions will result in an uncertainty  $\delta f_0$  in the lateral frequency of:

$$\frac{\delta f_0}{f_0} \approx \frac{3}{2} \left(\frac{\Delta}{W}\right) \quad (16.62)$$

for a case where the residual stress can be ignored. With a nominal flexure width of  $W = 2 \mu\text{m}$ , the resulting uncertainty in resonant frequency is 15%. For the stress-dominated case, Eq. (16.61) indicates that the uncertainty is

$$\frac{\delta f_0}{f_0} \approx \frac{1}{2} \left(\frac{\Delta}{W}\right) \quad (16.63)$$

The same 2- $\mu\text{m}$ -wide flexure would then lead to a 5% uncertainty in resonant frequency.

Interestingly, the stress-free case exhibits the most significant variation in the resonant frequency. In either case, resonant frequencies must be set by some postfabrication frequency trimming or other adjustment.

In Chapter 7 of Madou (1997) we draw further attention to the increasing loss of relative manufacturing tolerance with decreasing structure size (see Figure 7.1 in Madou [1997]).

### 16.13.5 Sealing Processes in Surface Micromachining

Sealing cavities to hermetically enclose sensor structures is a significant attribute of surface micromachining. Sealing cavities often embodies an integral part of the overall fabrication process and presents a desirable chip level, batch packaging technique. The resulting surface packages (microshells) are much smaller than typical bulk micromachined ones (see Madou [1997, chap. 8 on Packaging]).

### 16.13.6 IC Compatibility

Putting detection and signal conditioning circuits right next to the sensing element enhances the performance of the sensing system, especially when dealing with high impedance sensors. A key benefit of surface micromachining, besides small device size and single-sided wafer processing, is its compatibility with CMOS processing. IC compatibility implies simplicity and economy of manufacturing. In the examples at the end of this chapter we will discuss how Analog Devices used a mature 4- $\mu\text{m}$  BICMOS process to integrate electronics with a surface micromachined accelerometer.

To develop an appreciation of integration issues involved in combining a CMOS line with surface micromachining, we highlight Yun's [Yun, 1992] comparison of CMOS circuitry and surface micromachining processes in Table 16.16A. Surface micromachining processes are similar to IC processes in several aspects. Both processes use similar materials, lithography and etching techniques. CMOS processes involve at least ten lithography steps where lateral small feature size plays an important role. Some processing steps, such as gate and contact patterning, are critical to the functionality and performance of the CMOS circuits. Furthermore, each processing step is strongly correlated with other steps. Change in any one of the processing steps will lead to modifications in a number of other steps in the process. In contrast, surface micromachining is relatively simple. It usually consists of two to six masks, and the feature sizes are much larger. The critical processing steps, such as structural poly-Si,

**TABLE 16.16** Surface Micromachining and CMOS

A. Comparison of CMOS and Surface Micromachining		
	CMOS	Surface Micromachining
Common features	Silicon-based processes; same materials, same etching principles	
Process flow	Standard	Application specific
Vertical dimension	$\sim 1 \mu\text{m}$	$\sim 1\text{--}5 \mu\text{m}$
Lateral dimension	$< 1 \mu\text{m}$	$2\text{--}10 \mu\text{m}$
Complexity (# masks)	$> 10$	$2\text{--}6$
B. Critical Process Temperatures for Microstructures		
	Temperature ( $^{\circ}\text{C}$ )	Material
LPCVD deposition	450	Low temperature oxide (LTO)/PSG
LPCVD deposition	610	Low stress poly-Si
LPCVD deposition	650	Doped poly-Si
LPCVD deposition	800	Nitride
Annealing	950	PSG densification
Annealing	1050	Poly-Si stress annealing

(After Yun, W., A Surface Micromachined Accelerometer with Integrated CMOS Detection Circuitry, Ph.D. Thesis, U.C. Berkeley, 1992.)

often are self-aligned which eliminates lithographic alignment. The CMOS process is mature, quite generic and fine-tuned, while surface micromachining strongly depends on the application and still needs maturing.

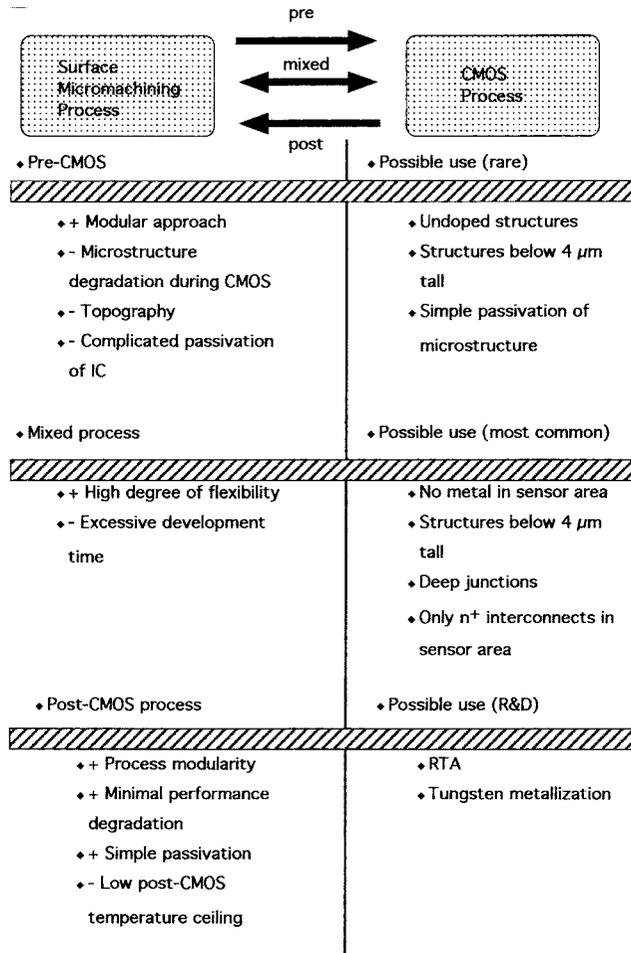

Table 16.16B presents the critical temperatures associated with the LPCVD deposition of a variety of frequently used materials in surface micromachining. Polysilicon is used for structural layers and thermal SiO<sub>2</sub>, LPCVD SiO<sub>2</sub> and PSG are used as sacrificial layers; silicon nitride is used for passivation. The highest temperature process in Table 16.16B is 1050°C and is associated with the annealing step to release stress in the polysilicon layers. Doped polysilicon films deposited by LPCVD under conventional IC conditions usually are in a state of compression that can cause mechanically constrained structures such as bridges and diaphragms to buckle. The annealing step above about 1000°C promotes crystallite growth and reduces the strain. If one wants to build polysilicon microstructures after the CMOS active electronics have been implemented (a so-called post-CMOS procedure), one has to avoid temperatures above 950°C, as junction migration will take place at those temperatures. This is especially true with devices incorporating shallow junctions where migration might be a problem at temperatures as low as 800°C. The degradation of the aluminum metallization presents yet a bigger problem. Aluminum typically is used as the interconnect material in the conventional CMOS process. At temperatures of 400 to 450°C, the aluminum metallization will start suffering. Anneal temperatures (densification of the PSG and stress anneal of the poly-Si) only account for some of the concerns; in general, several compatibility issues must be considered: (1) deposition and anneal temperatures, (2) passivation during micromachining etching steps and (3) surface topography.

Yun (1992) compared three possible approaches to build integrated microdynamic systems: pre-, mixed and post-CMOS microstructural processes as shown in Figure 16.91. He concluded that building up the microstructures after implementation of the active electronics offers the best results.

In a post-CMOS process, the electronic circuitry is passivated to protect it from the subsequent micromachining processes. The standard IC processing may be performed at a regular IC foundry, while the surface micromachining occurs as an add-on in a specialized sensor fabrication facility. LPCVD silicon nitride (deposited at 800°C, see Table 16.16B) is stable in HF solutions and is the preferred passivation layer for the IC during the long release etching step. PECVD nitride can be deposited at around 320°C, but it displays relatively poor step coverage, while pin holes in the film allow HF to diffuse through and react with the oxide underneath. LPCVD nitride is conformably deposited. While it shows fewer pin holes, circuitry needs to be able to survive the 800°C deposition temperature.

Aluminum metallization must be replaced by another interconnect scheme in order to raise the post-CMOS temperature ceiling higher than 450°C. Tungsten, which is refractory, shows low resistivity and has a thermal expansion coefficient matching that of Si, is an obvious choice. One problem with tungsten metallization is that tungsten reacts with silicon at about 600°C to form WSi<sub>2</sub>, implying the need for a diffusion barrier. The process sequence for the tungsten metallization developed at Berkeley is shown in Figure 16.92. A diffusion barrier consisting of TiSi<sub>2</sub> and TiN is used. The TiN film forms during a 30-sec sintering step to 600°C in N<sub>2</sub>. Rapid thermal annealing with its reduced time at high temperatures (10 sec to 2 min) and high ramp rates (~150°C/sec) allows very precise process control as well as a dramatic reduction of thermal budgets, reducing duress for the active on-chip electronics. Titanium silicide is formed at the interface of titanium and silicon while titanium nitride forms simultaneously at the exposed surface of the titanium film. The TiSi<sub>2</sub>/TiN forms a good diffusion barrier against the formation of WSi<sub>2</sub> and at the same time provides an adhesion and contact layer for the W metallization.

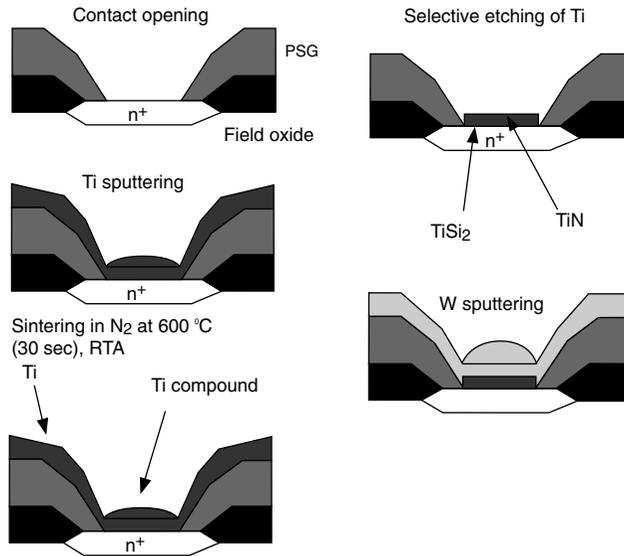

To avoid the junction migration in a post-CMOS process, rapid thermal annealing is used for both the PSG densification and polysilicon stress anneal: 950°C for 30 sec for the PSG densification and 1000°C for 60 sec for the stress anneal of the poly-Si. Alternatively, one could consider the use of fine-grained polysilicon which can yield a controlled tensile strain with low-temperature annealing [Guckel et al., 1988].

**FIGURE 16.91** Comparison of various options for process integration. (Adapted from Yun, W., A Surface Micromachined Accelerometer with Integrated CMOS Detection Circuitry, Ph.D. thesis, University of California, Berkeley, 1992. With permission.)

Despite some advantages the post-CMOS process with tungsten metallization is not the preferred implementation. Hillock formation in the W lines during annealing and high contact resistance remain problems [Howe, 1995]. Moreover, the finely tuned CMOS fabrication sequence may also be affected by the heavily doped structural and sacrificial layers.

The mixed CMOS/micromachining approach implements a processing sequence which puts the processes in a sequence to minimize performance degradation for both electronic and mechanical components. According to Yun this requires significant modifications to the CMOS fabrication sequence. Nevertheless, Analog Devices relied on such an interleaved process sequence to build the first commercially available integrated micro-accelerometer (see Example 1). The modifications required on a standard BICMOS line were minimal: to facilitate integration of the IC and to surface micromachine the thickness of deposited microstructural films the line was limited to 1 to 4 μm. Relatively deep junctions permitted thermal processing for the sensor poly-Si anneal and interconnections to the sensor were made only via n<sup>+</sup> underpasses. No metallization is present in the sensor area. This industrial solution remains truer to the traditional IC process experience than the post-CMOS procedure. Howe recently detailed another example of such a mixed process [Howe, 1995]. In Howe's scenario, the micromachining sequence is inserted after the completion of the electronic

- ◆ Self-aligned process
- ◆ No peeling of W up to 1050 °C in Ar
- ◆ Thin layer of nitride forms during RTA in N<sub>2</sub>

structures, but prior to contact etching or aluminum metallization. By limiting the polysilicon annealing to 7 min at 900°C, only minor dopant redistribution is expected. Contact and metallization lithography and etching become more complex now due to the severe topography of the poly-Si microstructural elements.

The pre-CMOS approach is to fabricate microstructural elements before any CMOS process steps. At first glance this seems like an attractive approach as no major modifications would be needed for process integration. However, due to the vertical dimensions of microstructures, step coverage is a problem for the interconnection between the sensor and the circuitry (the latest approach introduced by Howe faces the same dilemma). Passivation of the microstructure during the CMOS process can also become problematic. Furthermore, the fine-tuned CMOS fabrication sequence, such as gate oxidation, can be affected by the heavily doped structural layers. Consequently, this approach is only used for some special applications [Yun, 1992].

A unique pre-CMOS process was developed at Sandia National Labs [Smith et al., 1995]. In this approach, micromechanical devices are fabricated in a trench etched in a Si epilayer. After the mechanical components are complete, the trench is filled with oxide, planarized using chemical-mechanical polishing (CMP) (see Madou [1994, chap. 3]) and sealed with a nitride membrane. The flat wafer with the embedded micromechanical devices is then processed by means of conventional CMOS processing. Additional steps are added at the end of the CMOS process in order to expose and release the embedded micromechanical devices.

The SPIE “Smart Structures and Materials 1996” meeting in San Diego, CA, had two complete sessions dedicated to the crucial issue of integrating electronics with polysilicon surface micromachining [Varadan and McWhorter, 1996].

## 16.14 Poly-Si Surface Micromachining Modifications

### 16.14.1 Porous Poly-Si

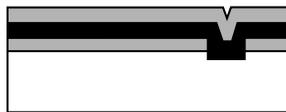

In the first part of this chapter we discussed the transformation of single crystal Si into a porous material with porosity and pore sizes determined by the current density, type and concentration of the dopant and the hydrofluoric acid concentration. A transition from pore formation to electropolishing is reached by raising the current density and/or by lowering the hydrofluoric acid concentration [Memming and Schwandt, 1966; Zhang et al., 1989]. Porous silicon can also be formed under similar conditions from LPCVD poly-Si [Anderson et al., 1994]. In this case pores roughly follow the grain boundaries of the polysilicon. Figure 16.93 illustrates the masking and process sequence to prepare a wafer to make thin layers of porous Si between two insulating layers of low stress silicon nitride [Field, 1987]. The wafer, after the process steps outlined in Figure 16.93, is put in a Teflon test fixture, protecting the back from HF attack. An electrical contact is established on the back of the wafer and a potential is applied with respect to a Pt-wire counterelectrode immersed in the same HF solution. Electrolytes consisting of 5 to 49% HF (wt) and current densities from 0.1 to 50 A cm<sup>-2</sup> are used. The advance of a pore-etching front, growing parallel to the wafer surface, may be monitored using a line-width measurement tool. The highest observed rate of porous-silicon formation is 15 μm min<sup>-1</sup> (in 25%, wt HF). In the electro-polishing regime, at the highest currents, the etch rate is diffusion limited but the reaction is controlled by surface reaction kinetics in the porous Si growth regime.

By changing the conditions from pore formation to electropolishing and back to porous Si, an enclosed chamber may be formed with porous poly-Si walls (plugs) and 'floor and ceiling' silicon nitride layers. Sealing of the cavities by clogging the microporous poly-Si was attempted by room temperature oxidation in air and in a H<sub>2</sub>O<sub>2</sub> solution. Leakage through the porous plug persisted after those room temperature oxidation treatments, but with a Ag deposition from a 400-mM AgNO<sub>3</sub> solution and subsequent atmospheric tarnishing (48 h, Ag<sub>2</sub>S) the chambers appeared to be sealed, as determined from the lack of

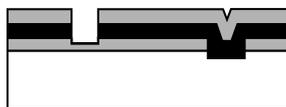

1. Deposit CVD silicon nitride on silicon wafer.
2. Pattern and plasma-etch silicon nitride.

3. Deposit CVD polysilicon.
4. Deposit CVD silicon nitride.

2. Pattern and plasma-etch nitride and polysilicon.

**FIGURE 16.93** Masking and process sequence preparing a wafer for laterally grown porous polysilicon. (From Field, L., *Low-Stress Nitrides for Use in Electronic Devices* (University of California, Berkeley, 1987), pp. 42 and 43. With permission.)

penetration by methanol. This technology might open up possibilities for filling cavities with liquids and gases under low-temperature conditions. The chamber provided with a porous plug might also make a suitable on-chip electrochemical reference electrolyte reservoir.

Hydrofluoric acid can penetrate thin layers of poly-Si either at foreign particle inclusion sites, or at other critical film defects such as grain boundaries (see above). This way the HF can etch underlying oxide layers, creating, for example, circular regions of free-standing poly-Si, so-called 'blisters.' The poly-Si permeability associated with blistering of poly-Si films has been applied successfully by Judy and Howe (1993a; 1993b) to produce thin-shelled hollow beam electrostatic resonators from thin poly-Si films deposited onto PSG. The possible advantage of using these hollowed structures is to obtain a yet higher resonator quality factor  $Q$ . The devices were made in such a way that the 0.3- $\mu\text{m}$ -thick undoped poly-Si completely encased a PSG core. After annealing, the structures were placed in HF which penetrated the poly-Si shell and dissolved away the PSG, eliminating the need for etch windows. It was not possible to discern the actual pathways through the poly-Si using TEM.

Leboutitz et al. (1995) apply permeable polysilicon etch-access windows to increase the speed of creating microshells for packaging surface micromachined components. After etching the PSG through the many permeable Si windows, the shell is sealed with 0.8  $\mu\text{m}$  of low stress LPCVD nitride.

## 16.14.2 Hinged Polysilicon

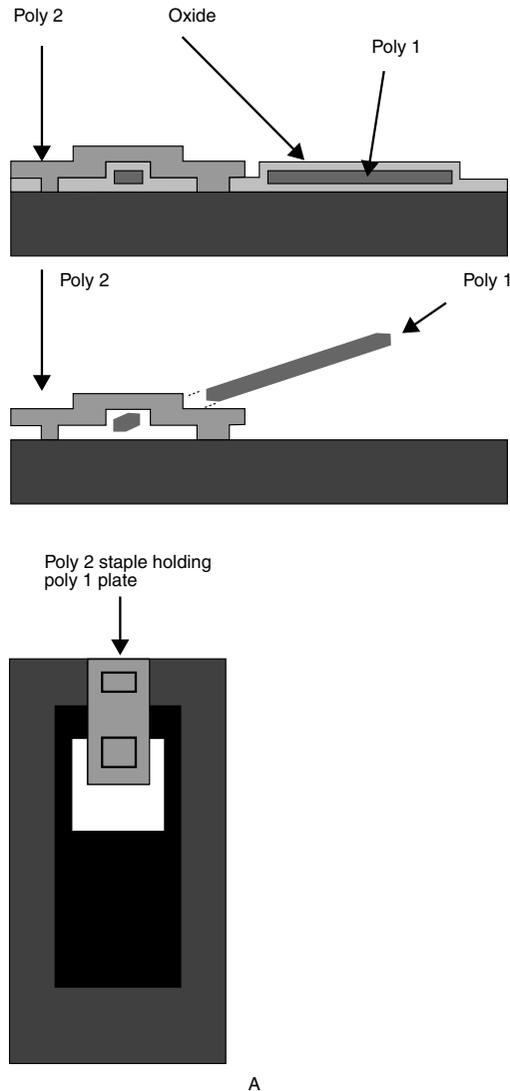

One way to achieve high vertical structures with surface micromachining is building large flat structures horizontally and then rotating them on a hinge to an upright position. Pister et al. [Burgett et al., 1992; Ross and Pister, 1994; Lin et al., 1995; Yeh et al., 1994; Lin et al., 1996] developed the poly-Si hinges shown in [Figure 16.94A](#); on these hinges, long structural poly-Si features (1 mm and beyond) can be rotated out of the plane of a substrate. To make the hinged structures, a 2- $\mu\text{m}$ -thick PSG layer (PSG-1) is deposited on the Si substrate as the sacrificial material, followed by the deposition of the first polysilicon layer (2- $\mu\text{m}$ -thick poly-1). This structural layer of polysilicon is patterned by photolithography and dry etching to form the desired structural elements, including hinge pins to rotate them. Following the deposition and patterning of poly-1, another layer of sacrificial material (PSG-2) of 0.5- $\mu\text{m}$  thickness is deposited. Contacts are made through both PSG layers to the Si substrate, and a second layer of polysilicon is deposited and patterned (poly-2), forming a staple to hold the first polysilicon layer hinge to the surface. The first and second layers of poly are separated everywhere by PSG-2 in order for the first polysilicon layer to freely rotate off the wafer surface when the PSG is removed in a sacrificial etch. After the sacrificial etch, the structures are rotated in their respective positions. This is accomplished in an electrical probe station by skillfully manipulating the movable parts with the probe needles. Once the components are in position, high friction in the hinges tends to keep them in the same position. To obtain more precise and stable control of position, additional hinges and supports are incorporated. To provide electrical contact to the vertical poly-Si structures one can rely on the mechanical contact in the hinges, or poly-Si beams (cables) can be attached from the vertical structure to the substrate.

Pister's research team made a wide variety of hinged microstructures, including hot wire anemometers, a box dynamometer to measure forces exerted by embryonic tissue, a parallel plate gripper [Burgett et al., 1992], a micro-windmill [Ross and Pister, 1994], a micro-optical bench for free-space integrated optics [Lin et al., 1995] and a standard CMOS single piezoresistive sensor to quantify rat single heart cell contractile forces [Lin et al., 1996]. One example from this group's efforts is illustrated in [Figure 16.94B](#), showing an SEM photograph of an edge-emitting laser diode shining light onto a collimating micro-Fresnel lens [Lin et al., 1995]. The micro-Fresnel lens in the SEM photo is surface micromachined in the plane and erected on a polysilicon hinge. The lens has a diameter of 280  $\mu\text{m}$ . Alignment plates at the front and the back sides of the laser are used for height adjustment of the laser spot so that the emitting spot falls exactly onto the optical axis of the micro-Fresnel lens. After assembly, the laser is electrically contacted by silver epoxy. Although this hardly outlines standard IC manufacturing practices, excellent collimating ability for the Fresnel lenses has been achieved. The eventual goal of this work is a micro-optical bench (MOB) in which microlenses, mirrors, gratings and other optical components are pre-aligned in the mask

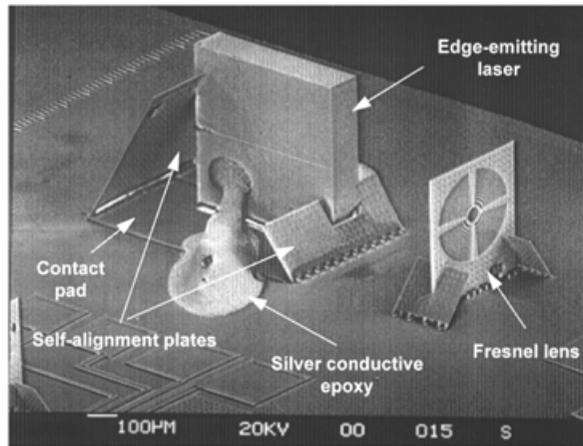

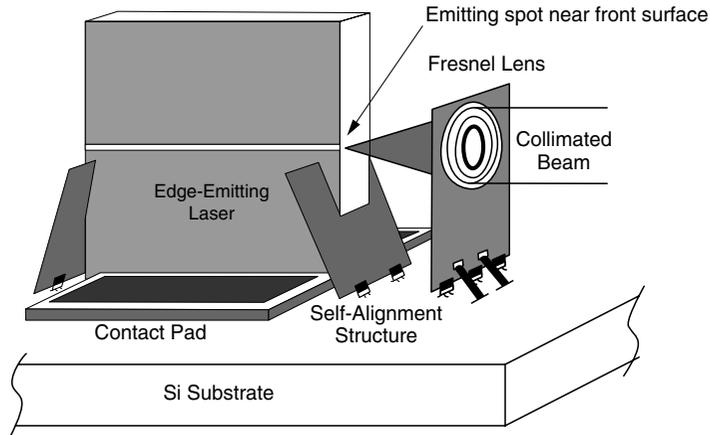

layout stage using computer-aided design. Additional fine adjustment would be achieved by on-chip micro-actuators and micropositioners such as rotational and translational stages.

Today, erecting these poly-Si structures with the probes of an electrical probe station or, occasionally, assembly by chance in the HF etch or deionized water rinse represent too complicated or too unreliable postrelease assembly methods for commercial acceptance.

Friction in poly-Si joints, as made by Pister, is high because friction is proportional to the surface area ( $s^2$ ) and becomes dominant over inertial forces ( $s^3$ ) in the microdomain (see Madou [1997, chap. 9]). Such joints are not suitable for microrobotic applications. Although attempts have been made to incorporate poly-Si hinges in such applications [Yeh et al., 1994], plastically deformable hinges make more sense for microrobot machinery involving rotation of rigid components. Noting that the external skeleton of insects incorporates hard cuticles connected by elastic hinges, Suzuki et al. (1994) fabricated rigid

poly-Si plates ( $E = 140$  GPa) connected by elastic polyimide hinges ( $E = 3$  GPa) as shown in Figure 16.95 (see also section below on Polyimide Surface Structures). Holes in the poly-Si plates shorten the PSG etch time compared to plates without holes. The plates without holes remain attached to the substrate while the ones with holes are completely freed. Using electrostatic actuators, a structure as shown in Figure 16.95 can be made to flap like the wing of a butterfly. By applying an AC voltage of 10 kHz, resonant vibration of such a flapping wing was observed [Suzuki et al., 1994].

More recently, Hoffman et al. (1995) demonstrated aluminum plastically deformable hinges on oxide movable thin plates. Oxide plates and Al hinges were etched free from a Si substrate by using  $\text{XeF}_2$ , a vapor phase etchant exhibiting excellent selectivity of Si over Al and oxide. According to the authors, this process, due to its excellent CMOS compatibility, might open the way to designing and fabricating sophisticated integrated CMOS-based sensors with rapid turnaround time (see also Madou [1997, chap. 2]).

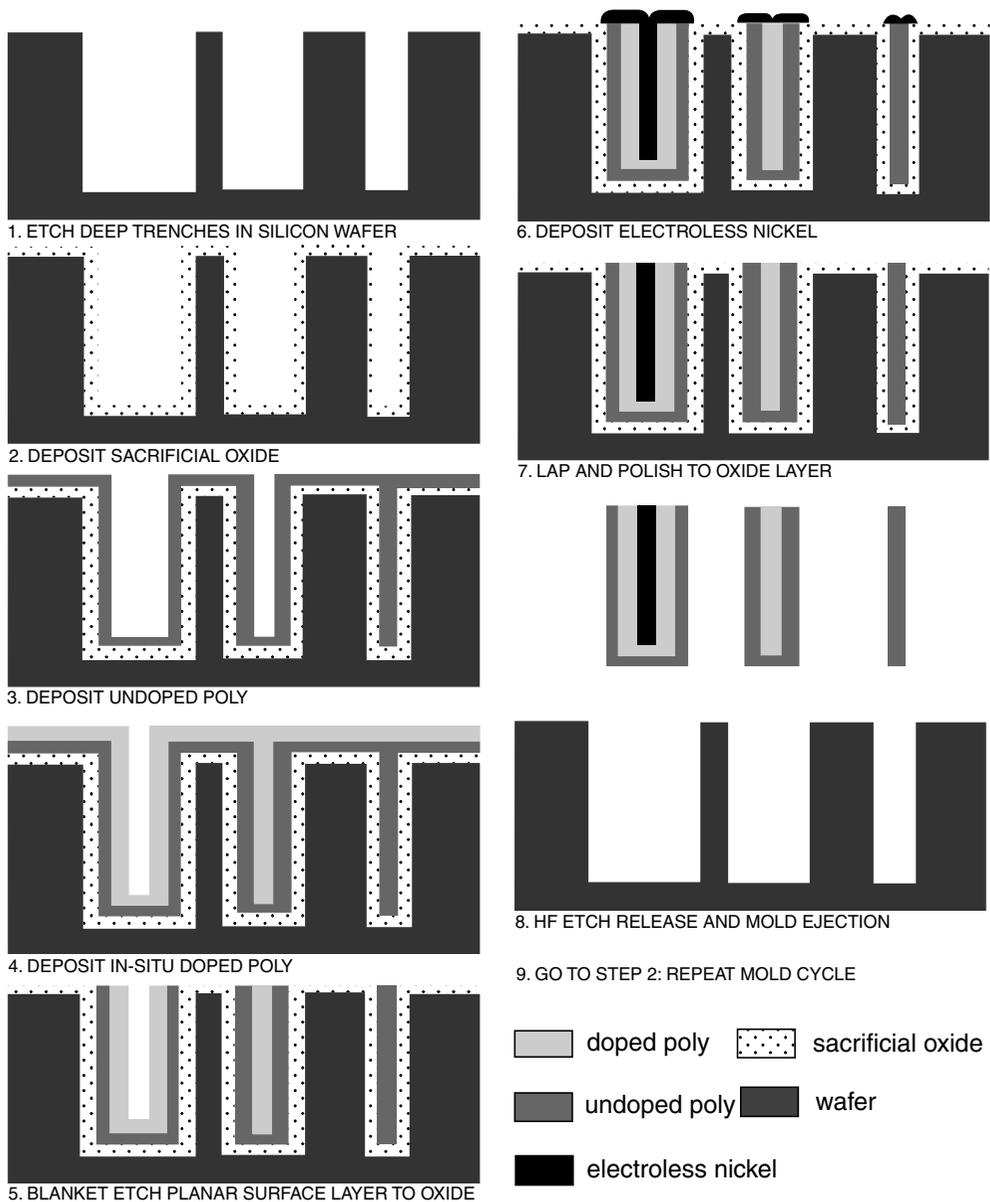

### 16.14.3 Thick Polysilicon

Applying classical LPCVD to obtain poly-Si deposition is a slow process. For example, a layer of 10  $\mu\text{m}$  typically requires a deposition time of 10 hr. Consequently, most micromachined structures are based on layer thicknesses in the 2- to 5- $\mu\text{m}$  range. Basing their process on dichlorosilane ( $\text{SiH}_2\text{Cl}_2$ ) chemistry, Lange et al. (1995) developed a CVD process in a vertical epitaxy batch reactor with deposition rates as high as 0.55  $\mu\text{m}/\text{min}$  at 1000°C. The process yields acceptable deposition times for thicknesses in the 10- $\mu\text{m}$  range (20 min). The highly columnar poly-Si films are deposited on sacrificial  $\text{SiO}_2$  layers and exhibit low internal tensile stress making them suitable for surface micromachining. The surface roughness comprises about 3% of the thickness, which might preclude some applications.

Kahn et al. (1996) made mechanical property test structures from thick undoped and *in situ* B-doped polysilicon films. The elastic modulus of the B-doped polysilicon films was determined as  $150 \pm 30$  GPa. The residual stress of as-deposited undoped thick polysilicon was determined as  $200 \pm 10$  MPa.

### 16.14.4 Milli-Scale Molded Polysilicon Structures

The assembly of tall three-dimensional features in the described hinged polysilicon approach is complicated by the manual assembly of the fabricated microparts resembling building a miniature boat in a bottle. Keller at University of California, Berkeley, came up with an elegant alternative for building tall, high-aspect-ratio microstructures in a process that does not require postrelease assembly steps [Keller and Ferrari, 1994]. The technique involves deep dry etching of trenches in a Si substrate, deposition of sacrificial and structural materials in those trenches, and demolding of the deposited structural materials by etching away the sacrificial materials. CVD processes can typically only deposit thin films ( $\sim 1$  to 2  $\mu\text{m}$ ) on flat surfaces. If, however, these surfaces are the opposing faces of deep narrow trenches, the growing films will merge to form solid beams. In this fashion, high-aspect-ratio structures that would normally be associated with LIGA now also can be made of CVD polysilicon. The procedure is illustrated in Figure 16.96 [Keller and Ferrari, 1994; Keller and Howe, 1995]. The first step is to etch deep trenches into a silicon wafer. The depth of the trenches equals the height of the desired beams and is limited to about 100  $\mu\text{m}$  with aspect ratios of about 10 (say, a 10- $\mu\text{m}$ -diameter hole with a depth of 100  $\mu\text{m}$ ). For trench etching, Keller uses a  $\text{Cl}_2$  plasma etch with the following approximate etching conditions: flow rates of 200 sccm for He and 180 sccm for  $\text{Cl}_2$ , a working pressure of 425 mTorr, a power setting of 400 W and an electrode gap of 0.8 cm. The etch rate for Si in this mode equals 1  $\mu\text{m}/\text{min}$ . Thermal oxide and CVD oxide act as masks with 1  $\mu\text{m}$  of oxide needed for each 20  $\mu\text{m}$  of etch depth. Before the  $\text{Cl}_2$  etch a short 7-sec  $\text{SF}_6$  pre-etch removes any remaining native oxide in the mask openings. During the chlorine etch a white sidewall passivating layer must be controlled to maintain perfect vertical sidewalls. After every 30 min of plasma etching, the wafers are submerged in a silicon isotropic etch long enough to remove the residue [Keller and Howe, 1995]. Beyond 100  $\mu\text{m}$ , severe undercutting occurs and the trench cross section becomes sufficiently ellipsoidal to prevent molded parts from being pulled out. Advances in dry cryogenic etching are continually improving attainable etch depths, trench profiles and minimum trench diameter. We can expect continuous improvements in the tolerances of this novel technique. After plasma etching, an additional 1  $\mu\text{m}$  of silicon is removed by an isotropic wet etch to obtain a smoother trench wall surface. Alternatively, to smooth sidewalls and bottom of the trenches a thermal wet oxide is grown and etched away. The sacrificial oxide in step 2 is made by CVD phosphosilicate glass (PSG)

**FIGURE 16.96** Schematic illustration of HEXSIL process. The mold wafer may be part of an infinite loop. (From Keller and Ferrari [1994]. Courtesy of Mr. C. Keller.)

at 450°C, 140 Å/min), CVD low-temperature oxide (LTO at 450°C) or CVD polysilicon (580°C, 65 Å/min). The latter is completely converted to SiO<sub>2</sub> by wet thermal oxidation at 1100°C. The PSG needs an additional reflowing and densifying anneal at 1000°C in nitrogen for 1 hr. This results in an etching rate of the sacrificial layer of ~20 μm/min in 49% HF. The mold shown in Figure 16.96 displays three different trench widths and can be used to build integrated micromachines incorporating doped and undoped poly-Si parts as well as metal parts. The remaining volume of the narrowest trench after oxide deposition is filled completely with the first deposition of undoped polysilicon (poly 1) in step 3. The undoped poly will constitute the insulating regions in the micromachine. Undoped CVD polysilicon was formed in this case at 580°C, with a 100 SCCM silane flow rate, and

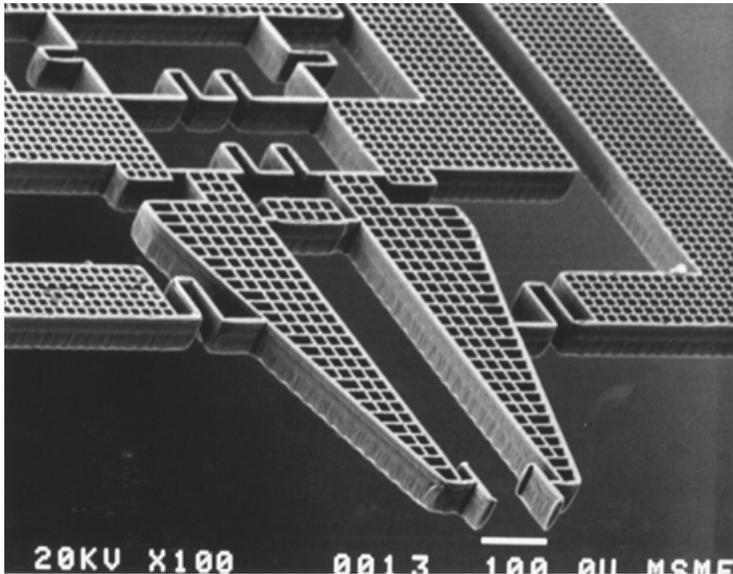

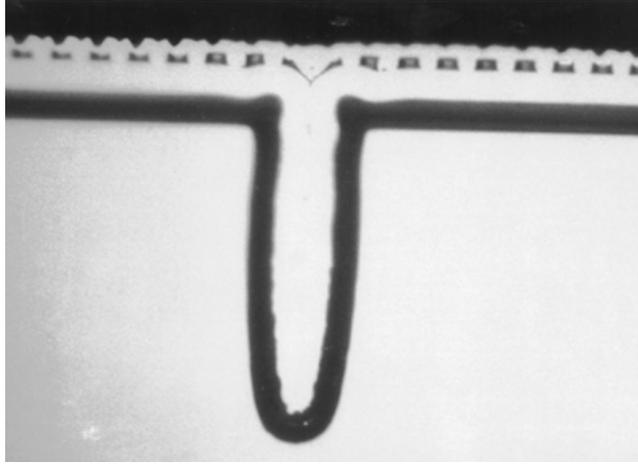

FIGURE 16.97 SEM micrograph of HEXSIL tweezers: 4 mm long, 2 mm wide and 80  $\mu\text{m}$  tall. Lead wires for current supply are made from Ni-filled poly-Si beams; *in situ* phosphorus-doped polysilicon provides the resistor part for actuation. The width of the beam is 8  $\mu\text{m}$ : 2  $\mu\text{m}$  poly-Si, 4  $\mu\text{m}$  Ni, and 2  $\mu\text{m}$  poly-Si. (Courtesy of Mr. C. Keller.)

a 300-mTorr reactor pressure, resulting in a deposition rate of 0.39  $\mu\text{m}/\text{hr}$ . The deposited film under these conditions is amorphous or very fine-grained. Since the narrowest trenches are completely filled in by the first deposition, they cannot accept material from later depositions. The trenches of intermediate width are lined with the first material and then completely filled in by the second deposition. In the case illustrated the second deposition (step 4) consists of *in situ* doped poly-Si and forms the resistive region in the micromachine under construction. To prevent diffusion of P from the doped poly deposited on top of the narrow undoped beams, a blanket etch in step 5 is used to remove the doped surface layer prior to the anneal of the doped poly. The third deposition, in step 6 of the example case, consists of electroless nickel plating on poly-Si surfaces but not on oxides surfaces and results in the conducting parts of the micromachine. By depositing structural layers in order of increasing conductivity, as done here, regions of different conductivity can be separated by regions of narrow trenches containing only nonconducting material. Lapping and polishing in step 7 with a 1- $\mu\text{m}$  diamond abrasive in oil planarizes the top surface, readying it for HF etch release and mold ejection in step 8. Annealing of the polysilicon is required to relieve the stress before removing the parts from the wafer so they remain straight and flat. In step 8 the sacrificial oxide is dissolved in 49% HF. A surfactant such as Triton X100 is added to the etch solution to facilitate part ejection by reducing surface adhesion between the part and the mold. The parts are removed from the wafer, and the wafer may be returned to step 2 for another mold cycle. An example micromachine, resulting from the described process, is the thermally actuated tweezers shown in Figure 16.97. These HEXSIL tweezers measure 4 mm long, 2 mm wide and 80  $\mu\text{m}$  tall. The thermal expansion beam to actuate the tweezers consists of the *in situ* doped poly-Si; the insulating parts are made from the undoped poly-Si material. Ni-filled poly-Si beams are used for the current supply leads. It is possible to combine the HEXSIL process with classical poly-Si micromachining, as illustrated in Figure 16.98, where HEXSIL forms a stiffening rib for a membrane filter fashioned by surface micromachining of a surface poly-Si layer. The surface poly-Si is deposited after HEXSIL. A critical need in HEXSIL technology is controlled mold ejection. Keller and Howe (1995) have experimented with HEXSIL-produced bimorphs, making the structure spring up after release.

**FIGURE 16.98** SEM micrograph of surface micromachined membrane filter with a stiffening rib (50  $\mu\text{m}$  high). Original magnification 1000 $\times$ . (Courtesy of Mr. C. Keller.)

## 16.15 Non-Poly-Si Surface Micromachining Modifications

---

### 16.15.1 Silicon on Insulator Surface Micromachining

#### 16.15.1.1 Introduction

A major sensor use of silicon on insulator wafers is established in the production of high-temperature sensors. Compared to p-n junction isolation, which is limited to about 125°C, much higher temperature devices are possible based on the dielectric insulation of SOI. Recently, a wide variety of SOI surface micromachined structures have been explored, including pressure sensors, accelerometers, torsional micromirrors, light sources, optical choppers etc. [Diem et al., 1993; Noworolski et al., 1995]

Three major techniques currently are applied to produce *SOI* wafers (see also under Epitaxy in Madou [1997, chap. 3]): *SIMOX* (Separated by IMplanted OXYgen), the Si fusion bonded (SFB) wafer technique and zone-melt recrystallized (ZMR) polysilicon. With SIMOX, standard Si wafers are implanted with oxygen ions and then annealed at high temperatures (1300°C). The oxygen and silicon combine to form a silicon oxide layer beneath the silicon surface. The oxide layer's thickness and depth are controlled by varying the energy and dose of the implant and the anneal temperature. In some cases, a CVD process deposits additional epitaxial silicon on the top silicon layer. Attempts have also been made to implant nitrogen in Si to create abrupt etch stops. At high enough energies the implanted nitrogen is buried 1/2 to 1  $\mu\text{m}$  deep. At a high enough dose, the etching in that region stops. It is not necessary to implant the stoichiometric amount of nitrogen concentration; a dose lower by a factor of 2 to 3 suffices. After implantation, it is necessary to anneal the wafer because the implantation destroys the crystal structure at the surface of the wafer.

The bonded wafer process starts with an oxide layer grown (typically about 1  $\mu\text{m}$ ) on a standard Si wafer. That wafer is then bonded to another wafer, with the oxide sandwiched between. For the bonding no mechanical pressure or other forces are applied. The sandwich is annealed at 1100°C for 2 hr in a nitrogen ambient leading to a strong binding between the two wafers. One of the wafers is then ground to a thickness of a few microns using mechanical and CMP.

A third process for making SOI structures is to recrystallize polysilicon (e.g., with a laser, an electron-beam or a narrow strip heater) deposited on an oxidized silicon wafer. This process is called zone melting recrystallization (ZMR). This technique is used primarily for local recrystallization and has not yet been explored much in micromachining applications.

## How SOI wafers are made.

Many different silicon-on-insulator materials have been developed over the years, but two are currently being used for IC production: SIMOX (Separated by Implanted Oxygen) and bonded wafers.

In the SIMOX process, a standard silicon wafer is implanted with oxygen ions, and then annealed at high temperatures; the oxygen and silicon combine to form a silicon oxide layer beneath the wafer surface. To minimize wafer damage, the oxygen is sometimes implanted in two or more passes, each followed by an anneal.

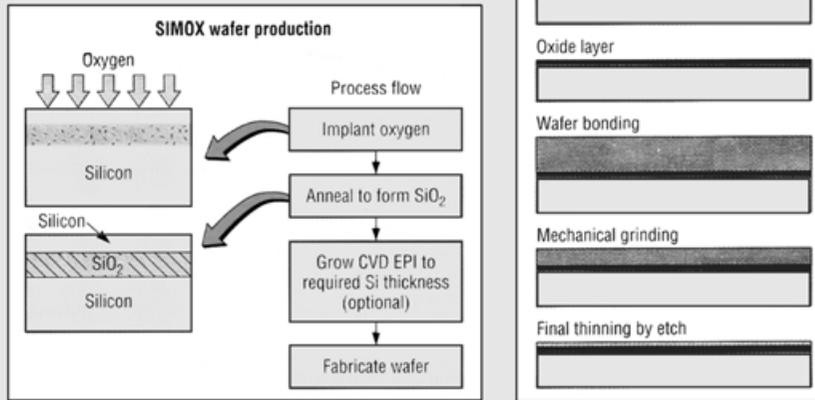

The oxide layer's thickness and depth are controlled by varying the energy and dose of the implant and the anneal temperature. In some cases, a CVD process is used to deposit additional silicon on the top layer.

The bonded wafer process starts with an oxide layer of the desired thickness (typically 0.25 to 2 microns) being grown on a stan-

dard silicon wafer. That wafer is then bonded at high temperatures to another wafer, with the oxide sandwiched between. One of the wafers is then ground to a thickness of a few microns using a mechanical tool.

Because advanced devices require an even thinner layer, more silicon must be removed. In Hughes Danbury's AcuThin process, the wafer is etched with a confined plasma, between 3 and 30 mm wide, which is stepped across the wafer surface. A film thickness map is made

for each wafer, and used to compute the dwell time for the plasma etcher at each stop. The process can be repeated for additional precision; Hughes Danbury offers silicon thicknesses of as little as 1000 to 3000 angstroms, with total thickness variation of 200 angstroms. IBM has also developed an etch-back process for bonded wafers. ■

From Dunn, P.N., *Solid State Technol.*, October, 32–35 (1993). With permission.

The crystalline perfection of conventional silicon wafers in SFB and ZMR is completely maintained in the SOI layer as the wafers do not suffer from implant-induced defects. By using plasma etching, wafers with a top Si layer thickness of as little as 1000 to 3000 Å with total thickness variations of less than 200 Å can be made [Dunn, 1993]. SOI layers of 2 μm thick are more standard [Abe and Matlock, 1990].

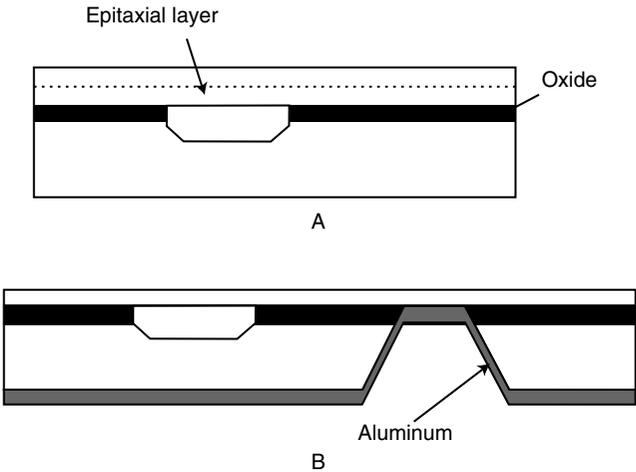

Kanda (1991) reviews different types of SOI wafers in terms of their micromachining and IC applications. Working with SOI wafers offers several advantages over bulk Si wafers: fewer process steps are needed for feature isolation, parasitic capacitance is reduced, and power consumption is lowered. In the IC industry these wafers are used for high-speed CMOS ICs, smart power ICs, three-dimensional ICs, and radiation-hardened devices [Kuhn and Rhee, 1973]. In micromachining, SOI wafers are employed to produce an etch stop in such mechanical devices as pressure and acceleration sensors and in high-temperature sensors, and ISFETs. Etched-back fusion-bonded Si wafers and SIMOX are already employed extensively to build micromachines. The two types of SOI wafers are commercially available. A tremendous amount of effort is spent in the IC industry on controlling the SOI thin Si layer thickness which will benefit any narrow tolerance micromachine. The silicon fusion bonded (SFB) method offers the more versatile MEMS approach due to the associated potential for thicker single crystal layers and the option of incorporating buried cavities, facilitating micromachine packaging. Sensors manufactured by means of SFB now are commercially available [Pourahmadi et al., 1992]. The SIMOX approach is less labor intensive and holds better membrane thickness control. An important expansion of the SOI technique is selective epitaxy. The latter enables a wide range of new mechanical structures (see Madou [1997, chap. 3]) and enables novel etch-stop methods [Gennissen et al., 1995], as well as electrical and/or thermal separation and independent

optimization of active sensor and readout electronics [Bartek et al., 1995]. In all cases SOI machining involves dry anisotropic etching to etch a pattern into the Si layer on top of the insulator. These structures then become free by etching the sacrificial buried SiO<sub>2</sub> insulator layer, which displays a thickness with very high reproducibility (400 ± 5 nm) and uniformity (<±5 nm), especially in the case of SIMOX. Etched free cantilevers and membranes consist of single crystalline silicon with thicknesses ranging from microns and submicrons (SIMOX) up to hundreds of microns (SFB). Below we review three implementations of SOI techniques that may be crucial for future MEMS development.

**16.15.1.2 Silicon Fusion Bonded Micromachining**

Silicon fusion bonding enables the formation of thick single crystal layers with cavities built in. An example is shown in Figure 16.99 [Noworolski et al., 1995]. The device pictured involves two 4-in. <100> wafers: a handle wafer and a wafer used for the SOI surface. The p-type (3 to 7 Ωcm) handle wafer is thermally oxidized at 1100°C to obtain a 1-μm-thick oxide. Thermal oxidation enables thicker oxides than the ones formed in SIMOX by ion implantation and avoids the potential implantation damage in the working material. To make a buried cavity, the oxide is patterned and etched. To produce yet deeper cavities, the Si handle wafer may be etched as well (as in Figure 16.99). In the case shown, the top wafer consists of the same p-type substrate material as the handle wafer with a 2- to 30-μm-thick n-type epitaxial layer. The epitaxial layer determines the thickness of the final mechanical material. The epitaxial layer is fusion bonded to the cavity side of the handle wafer (2 hr at 1100°C). The top wafer is then partially thinned by grinding and polishing (Figure 16.99A). An insulator is deposited and patterned on the back side of the handle wafer to etch access holes to the insulator. After the insulator at the bottom of the etch hole is removed by a buffered oxide etch (BOE), aluminum is sputtered and sintered to make contact to the n-type epilayer for the electrochemical etch back of the remaining p-type material (Figure 16.99B). The final single crystal silicon thickness is uniform to within ±0.05 μm (std. dev.) and does not require a costly, high accuracy polish step.

Draper Laboratory is using SOI processes in the development of inertial sensors, gyros and accelerometers as an alternative to their current devices fabricated by the dissolved wafer process (see Example 1, Section 16.9). The main advantage is that the former consists of an all Si process rather than a Si/Pyrex sandwich [Greiff, 1995].

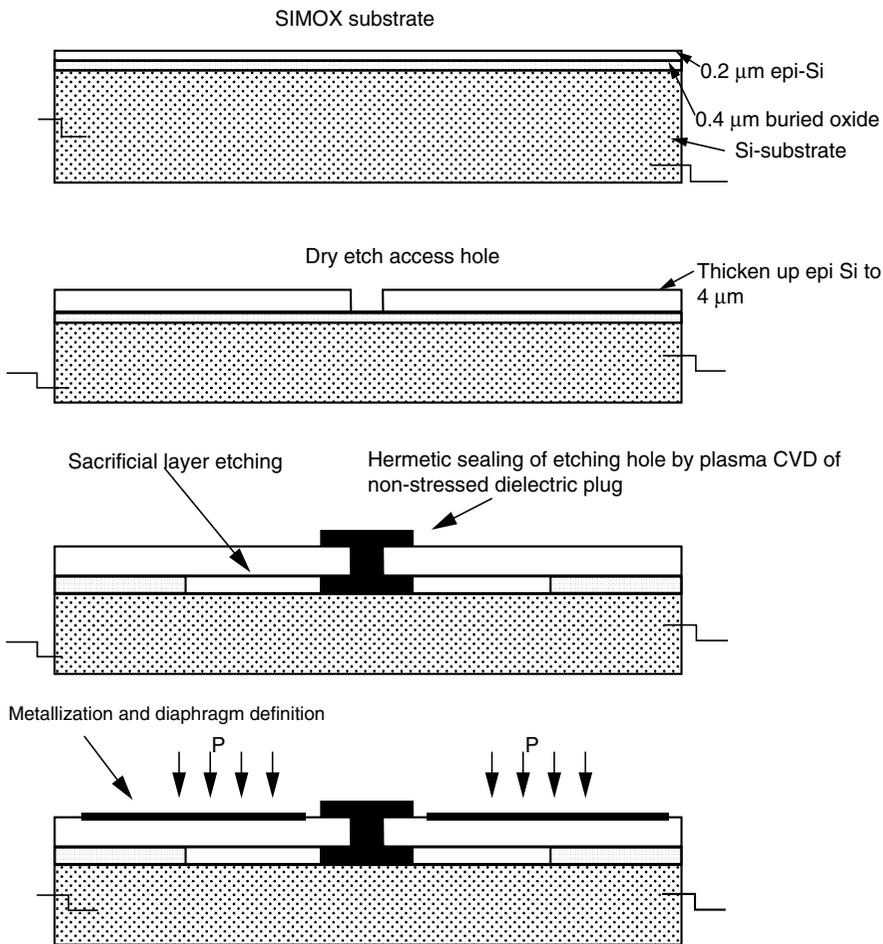

**FIGURE 16.99** (A) A wafer sandwich after grind-and-polish step. (B) A wafer after electrochemical etch-back in KOH, buried oxide removal and aluminum deposition. (From Noworolski, J.M. et al., Fabrication of SOI Wafers with Buried Cavities Using Silicon Fusion Bonding and Electrochemical Etchback, presented at Transducers '95, Stockholm, Sweden, 1995. With permission.)

### 16.15.1.3 SIMOX Surface Micromachining

Both capacitive and piezoresistive pressure sensors were microfabricated from SIMOX wafers [Diem et al., 1993]. Figure 16.100 illustrates the process sequence by Diem et al. (1993) for fabricating an absolute capacitive pressure sensor. The 0.2- $\mu\text{m}$  silicon surface layer of the SIMOX wafer is thickened with doped epi-Si to 4  $\mu\text{m}$ . An access hole is RIE etched in the Si layer, and vacuum cavity and electrode gap are obtained by etching the  $\text{SiO}_2$  buried layer. Since the buried thick oxide layer exhibits a very high reproducibility and homogeneity over the whole wafer ( $0.4 \mu\text{m} \pm 5 \text{ nm}$ ), the resulting vacuum cavity and electrode gap after etching also are very well controlled. The small gap results in relatively high capacitance values between the free membrane and bulk substrate ( $20 \text{ pf/mm}^2$ ). Diaphragm diameter, controlled by the  $\text{SiO}_2$  etching is up to several hundreds micrometers ( $\pm 2 \mu\text{m}$ ). The etching hole is hermetically sealed under vacuum by plasma CVD deposition of nonstressed dielectric layer plugs.

With the above scheme Diem et al. realized an absolute pressure sensor with a size of less than  $1.5 \text{ mm}^2$ . The temperature dependence of a capacitive sensor is mainly due to the temperature coefficient of the offset capacitance. Therefore, a temperature compensation is needed for high accuracy sensors. A drastic reduction of the temperature dependence is obtained by a differential measurement, especially if the reference capacitor resembles the sensing capacitor. A reference capacitor was designed with the mem-

**FIGURE 16.100** Process sequence of a SIMOX absolute capacitive pressure sensor by Diem et al. (From Diem, B. et al., SOI (SIMOX) as a Substrate for Surface Micromachining of Single Crystalline Silicon Sensors and Actuators, presented at Seventh Int. Conf. on Solid-State Sensors and Actuators, Yokohama, Japan, 1993. With permission.)

brane blocked by several plugs for pressure insensitivity. The localization and the number of plugs were modeled by finite element analysis (FEA) (ANSYS software was used) to get a deformation lower than 1% of the active sensor's deformation. Even without temperature calibration the high output of the differential signal resulted in an overall output error better than  $\pm 2\%$  over the whole temperature range ( $-40^\circ\text{C}$  to  $+125^\circ\text{C}$ ) compared to 10% for nondifferential measurements. The temperature coefficient of the sensitivity is about 100 ppm/ $^\circ\text{C}$  which agrees with the theoretical variation of the Young modulus of silicon. A piezoresistive sensor could be achieved by implanted strain gauges in the membrane. Although SIMOX wafers are more expensive than regular wafers, they come with several process steps embedded and they make packaging easier.

#### 16.15.1.4 Selective Epitaxy Surface Micromachining

In the discussion on epitaxy in Madou (1997, chap. 3) we drew attention to the potential of selective epitaxy for creating novel microstructures. The example in Figure 3.21 in Madou illustrates the selective deposition of epi-Si on a Si substrate through a  $\text{SiO}_2$  window. The same figure also demonstrates the simultaneous deposition of poly-Si on  $\text{SiO}_2$  and crystalline epi-Si on Si, creating the basis for a structure featuring an epi-Si anchor with poly-Si side arms.

Neudeck et al. (1990) and Schubert and Neudeck (1990) at Purdue and Gennissen et al. (1995) and Bartek et al. (1995) at Twente proved that selective epitaxy can also be applied for automatic etch stop on buried oxide islands. Figure 16.101 demonstrates how epitaxial lateral overgrowth (ELO) can bury oxide islands. After removal of the native oxides from the seed windows, epi is grown for 20 min at  $950^\circ\text{C}$  and at 60 torr using a  $\text{Si}_2\text{H}_2\text{Cl}_2\text{-HCl-H}_2$  gas system. The epi growth front moves parallel to the wafer surface while growing in the lateral direction, leaving a smooth planar surface. During epi growth the HCl prevents poly nucleation on the nonsilicon areas. The epi quality is strongly dependent on the orientation of the seed holes in the oxide. Seed holes oriented in the  $\langle 100 \rangle$  direction lead to the best epi material and surface quality. Selective epi's other big problem for fabrication remains sidewall defects [Bashir et al.]. The buried oxide islands stop the KOH etch of the substrate, enabling formation of beams and membranes as shown in Figure 16.101B. This technique might form the basis of many high performance microstructures. The Purdue and Twente groups also work on confined selective epitaxial growth (CSEG), a process pioneered by Schubert and Neudeck (1990). In this process a micromachined cavity is formed above a silicon substrate with a seed contact window to the silicon substrate and access windows for epi-Si (Figure 16.101C) [Bartek et al., 1995]. Low-stress, silicon-rich nitride layers act as structural layers to confine epitaxial growth; PSG is used as sacrificial material. This confined selective epitaxial growth technique allows electrical and/or thermal isolation separation, as well as independent optimization of active sensor and readout electronic areas.

#### 16.15.1.5 SOI vs. Poly-Si Surface Micromachining

The power of poly-Si surface micromachining mainly lays in its CMOS compatibility. When deposited on an insulator, both poly-Si and single crystal layers enable higher operating temperatures ( $>200^\circ\text{C}$ ) than bulk micromachined sensors featuring p-n junction isolation only ( $130^\circ\text{C}$  max) [Luder, 1986]. An additional benefit for SOI-based micromachining is IC compatibility combined with single crystal Si performance excellence. The maximum gauge factor (see Eq. (16.28)) of a poly-Si piezoresistor is about 30, roughly 15 times larger than that of a metal strain gauge but only one third of that of an indiffused resistor in single crystal Si [Obermeier and Kopystynski, 1992]. Higher piezoresistivity and fracture stress would seem to favor SOI for sensor manufacture. But there is an important counter argument: the piezoresistivity and fracture stress in poly-Si are isotropic, a major design simplification. Moreover, by laser recrystallization the gauge factor of poly-Si might increase to above 50 [Voronin et al., 1992], and by appropriate boron doping the temperature coefficient of resistance (TCR) can actually reach 0 vs. a TCR of, say,  $1.7 \times 10^{-3}\text{K}^{-1}$  for single crystal p-type Si. Neither technical nor cost issues will be the deciding factor in determining which technology will become dominant in the next few years. Micromachining is very much a hostage to trends in the IC industry: promising technologies such as GaAs and micromachining do not necessarily take off in no small part because of the invested capital in some limited sets of standard silicon technologies. On this basis SOI surface micromachining is the favored candidate:

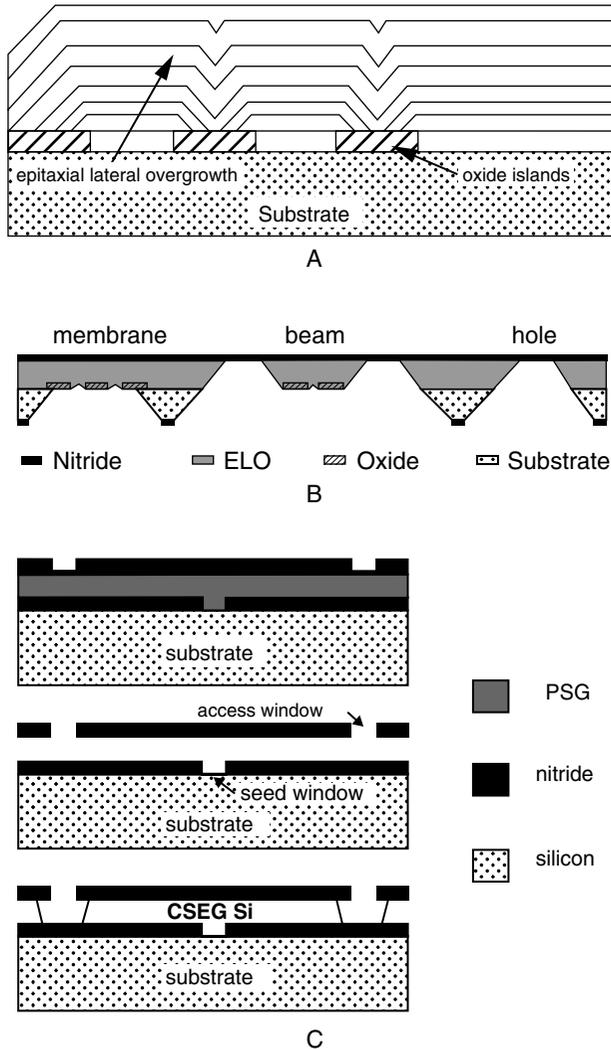

FIGURE 16.101 Micromachining with epi-Si. (A) Lateral overgrowth process of epi-Si (ELO, epitaxial lateral overgrowth) out of  $\langle 100 \rangle$ -oriented holes in an oxide mask. (B) KOH etch stop on buried oxide islands or front side nitride. (C) Principle of confined selective epitaxial growth. (From papers presented at Transducers '95, Stockholm, Sweden, 1995. With permission. )

SOI extends silicon's technological relevance and experiences increasing investment from the IC industry, benefiting SOI micromachining [Kanda, 1991].

Based on the above we believe that SOI micromachining not only introduces an improved method of making many simple micromachines, but it also will probably become the favored approach of the IC industry. A summary of SOI advantages is listed below:

- IC industry use in all types of applications such as MOS, bipolar digital, bipolar linear, power devices, BICMOS, CCDs, heterojunction bipolar [Burggraaf, 1991] etc.
- Batch packaging through embedded cavities
- CMOS compatibility
- Substrate industrially available at lower and lower cost (about \$200 today)
- Excellent mechanical properties of the single crystalline surface layer

- Freedom of shapes in the x-y dimensions and continually improving dry etching techniques, resulting in larger aspect ratios and higher features
- Freedom of choice of a very well-controlled range of thicknesses of epi surface layers
- SiO<sub>2</sub> buried layer as sacrificial and insulating layer and excellent etch stop
- Dramatic reduction of process steps as the SOI wafer comes with several 'embedded' process steps
- High temperature operation

## 16.16 Resists as Structural Elements and Molds in Surface Micromachining

---

### 16.16.1 Introduction

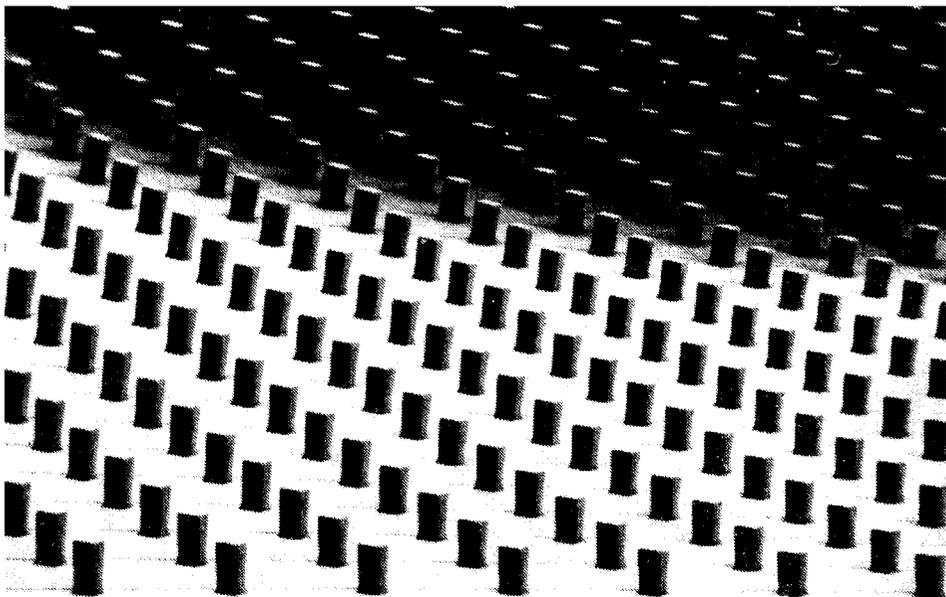

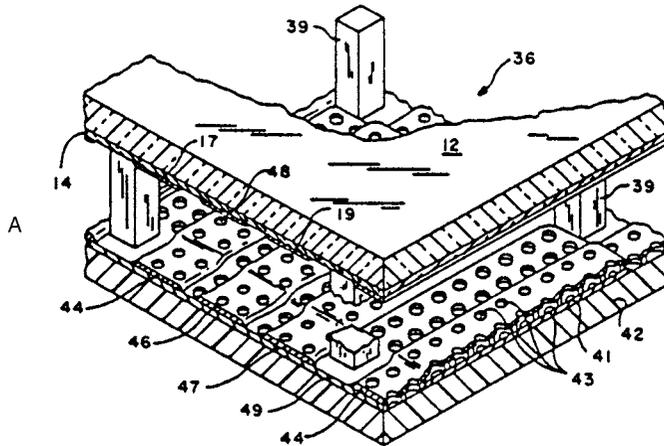

Polyimide and deep UV photoresists were covered already in Madou (1997, chap. 1 on lithography). We now reiterate some of the material covered there in the context of surface micromachining. Novel deep UV photoresists enable the molding of a wide variety of high aspect ratio microstructures in a wide variety of moldable materials or they are used directly as structural elements. LIGA (covered in Chapter 17), employing X-rays to pattern resists, is really just an extension of the same principles.

### 16.16.2 Polyimide Surface Structures

Polyimide surface structures, due to their transparency to exposing UV light, can be made very high and exhibit LIGA-like high aspect ratios. By using multiple coats of spun-on polyimide, thick suspended plates are possible. Moreover, composite polyimide plates can be made, depositing and patterning a metal film between polyimide coats. Polyimide surface microstructures are typically released from the substrate by selectively etching an aluminum sacrificial layer (see [Figure 16.90](#)), although Cu and PSG (e.g., in the butterfly wing in [Figure 16.95](#)) have been used as well (see [Table 16.15](#)).

An early result in this field was obtained at SRI International, where polyimide pillars (spacers) about 100 μm in height were used to separate a Si wafer, equipped with a field emitter array, from a display glass plate in a flat panel display [Bordie et al., 1990]. The flat panel display and an SEM picture of the pillars are shown in [Figure 16.102](#). The Probimide 348 FC formulation of Ciba-Geigy was used. This viscous precursor formulation (48% by weight of a polyamic ester, a surfactant for wetting and a sensitizer) with a 3500-cs viscosity was applied to the Si substrate and formed into a film of a 125-μm thickness by spinning. A 30- to 40-min prebake at about 100°C removed the organic solvents from the precursor. The mask with the pillar pattern was then aligned to the wafer coated with the precursor and subjected to about 20 min of UV radiation. After driving off moisture by another baking operation the coating, still warm, was spray developed (QZ 3301 from Ciba-Geigy), revealing the desired spacer matrix. By baking the polyimide at 100°C in a high vacuum (10<sup>-9</sup> Torr) the pillars shrunk to about 100 μm, while the polyimide became more dense and exhibited greater structural integrity.

More recently Frazier and Allen (1993) obtained a height-to-width aspect ratio of about 7 with polyimide structures. Ultraviolet was used to produce structures with heights in the range of 30 to 50 μm. At greater heights, the verticality of the sidewalls was relatively poor. Spun-on thickness in excess of 60 μm in a single coat was obtained for both Ciba-Geigy and Du Pont commercial UV-exposable, negative-tone polyimides. Using a G-line mask aligner, an exposure energy of 350 mJ/cm<sup>2</sup> was sufficient to develop a pattern with the Ciba-Geigy QZ 3301 developer. Allen and his team combined polyimide insert molds with electrodeposition to make a wide variety of metal structures [Ahn et al., 1993]. This polyimide application will be contrasted with LIGA in Chapter 17.

**FIGURE 16.102** Polyimide structural elements. (A) Micromachined flat panel display. Number 39 represents one of the spacer pillars in the matrix of polyimide pillars (100  $\mu\text{m}$  high). The spacer array separates the emitter plate from the front display plate. (B) SEM of the spacer matrix. (Courtesy of Dr. I. Brodie.) The height of the pillars is similar to what can be accomplished with LIGA. Since only a simple UV exposure was used, this polyimide is referred to as poor man's LIGA process, or pseudo-LIGA. (From Brodie, I. et al., U.S. Patent 4,923,421, 1990.)

### 16.16.3 UV Depth Lithography

Besides polyimides, research on novolak-type resists also is leading to higher three-dimensional features. Lochel et al. (1994; 1996a; 1996b) use novolak, positive tone resists of high viscosity (e.g., AZ 4000 series, Hoechst). They deposit in a multiple-coating process layers up to 200  $\mu\text{m}$  thick in a specially designed spin coater incorporating a co-rotating cover. The subsequent UV lithography yields patterns with aspect ratios up to 10, steep edges (more than  $88^\circ$ ) and a minimum feature size down to 3  $\mu\text{m}$ . By combining this

resist technology with sacrificial layers and electroplating, a wide variety of three-dimensional microstructures resulted.

Along the same line, researchers at IBM have started experimenting with Epon SU-8 (Shell Chemical), an epoxy-based, onium-sensitized, UV transparent negative photoresist used to produce high-aspect-ratio (>10:1) features as well as straight sidewalled images in thick film (>200  $\mu\text{m}$ ) using standard lithography [Acosta et al., 1995; LaBianca et al., 1995]. SU-8 imaged films were used as stencils to plate permalloy for magnetic motors [Acosta et al., 1995].

Patterns generated with these thick resist technologies should now be compared with LIGA-generated patterns, not only in terms of aspect ratio, where LIGA presumably still produces better results, but also in terms of sidewall roughness and sidewall run-out. Such a comparison will determine which surface machining technique to employ for the job at hand.

### 16.16.4 Comparison of Bulk Micromachining with Surface Micromachining

Surface and bulk micromachining have many processes in common. Both techniques rely heavily on photolithography; oxidation; diffusion and ion implantation; LPCVD and PECVD for oxide, nitride and oxynitride; plasma etching; use of polysilicon; metallizations with sputtered, evaporated and plated Al, Au, Ti, Pt, Cr and Ni. Where the techniques differ is in the use of anisotropic etchants, anodic and fusion bonding, (100) vs. (110) starting material,  $p^+$  etch stops, double-sided processing and electrochemical etching in bulk micromachining, and the use of dry etching in patterning and isotropic etchants in release steps for surface micromachines. Combinations of substrate and surface micromachining also frequently appear. The use of polysilicon avoids many challenging processing difficulties associated with bulk micromachining and offers new degrees of freedom for the design of integrated sensors and actuators. The technology combined with sacrificial layers also allows the nearly indispensable further advantage of *in situ* assembly of the tiny mechanical structures, because the structures are preassembled as a consequence of the fabrication sequence. Another advantage focuses on thermal and electrical isolation of polysilicon elements. Polycrystalline piezoresistors can be deposited and patterned on membranes of other materials, e.g., on a  $\text{SiO}_2$  dielectric. This configuration is particularly useful for high-temperature applications. The p-n junctions act as the only electrical insulation in the single crystal sensors, resulting in high leakage currents at high temperatures, whereas current leakage for the poly-Si/ $\text{SiO}_2$  structure virtually does not exist. The limits of surface micromachining are quite striking. CVD silicon usually caps at layers no thicker than 1 to 2  $\mu\text{m}$  because of residual stress in the films and the slow deposition process (thick poly-Si needs further investigation). A combination of a large variety of layers may produce complicated structures, but each layer is still limited in thickness. Also, the wet chemistry needed to remove the interleaved layers may require many hours of etching (except when using the porous Si option discussed above), and even then stiction often results.

The structures made from polycrystal silicon exhibit inferior electronic and slightly inferior mechanical properties compared to single crystal silicon. For example, poly-Si has a lower piezoresistive coefficient (resulting in a gauge factor of 30 vs. 90 for single crystal Si) and it has a somewhat lower mechanical fracture strength. Poly-Si also warps due to the difference of thermal expansion coefficient between polysilicon and single crystal silicon. Its mechanical properties strongly depend on processing procedures and parameters.

Table 16.17 extends a comparison of surface micromachining with polysilicon and wet bulk micromachining. The status depicted reflects the mid-1990s and only includes poly-Si surface micromachining. As discussed, SOI micromachining, thick poly-Si, hinged poly-Si, polyimide and millimeter-molded poly-Si structures have dramatically expanded the application bandwidth of surface micromachining. In Chapter 17 on LIGA we will see how X-ray lithography can further expand the z direction for new surface micromachined devices with unprecedented aspect ratios and extremely low surface roughness. In Table 16.18 we compare physical properties of single crystal Si with those of poly-Si.

Summarizing, although polysilicon can be an excellent mechanical material, it remains a poor electronic material. Reproducible mechanical characteristics are difficult and complex to consistently realize.

**TABLE 16.17** A Comparison of Bulk Micromachining with Surface Micromachining

Bulk Micromachining	Surface Micromachining
Large features with substantial mass and thickness	Small features with low thickness and mass
Utilizes both sides of the wafer	Multiple deposition and etching required to build up structures
Vertical dimensions: one or more wafer thicknesses	Vertical dimensions are limited to the thickness of the deposited layers (~2 $\mu\text{m}$ ), leading to compliant suspended structures with the tendency to stick to the support
Generally involves laminating Si wafer to Si or glass	Surface micromachined device has its built-in support and is more cost effective
Piezoresistive or capacitive sensing	Capacitive and resonant sensing mechanisms
Wafers may be fragile near the end of the production	Cleanliness critical near end of process
Sawing, packaging, testing are difficult	Sawing, packaging, testing are difficult
Some mature products and producers	No mature products or producers
Not very compatible with IC technology	Natural but complicated integration with circuitry; integration is often required due to the tiny capacitive signals

**TABLE 16.18** Comparison of Material Properties of Si Single Crystal with Crystalline Polysilicon

Material Property	Single Crystal Si	Poly-Si
Thermal conductivity ( $\text{W}/\text{cm}^\circ\text{K}$ )	1.57	0.34
Thermal expansion ( $10^{-6}/^\circ\text{K}$ )	2.33	2–2.8
Specific heat ( $\text{cal}/\text{g}^\circ\text{K}$ )	0.169	0.169
Piezoresistive coefficients	n-Si ( $\pi_{11} = -102.2$ ); p-Si ( $\pi_{44} = +138.1$ ); e.g., gauge factor of 90	Gauge factor of 30 (>50 with laser recrystallization)
Density ( $\text{cm}^3$ )	2.32	2.32
Fracture strength (GPa)	6	0.8 to 2.84 (undoped poly-Si)
Dielectric constant	11.9	Sharp maxima of 4.2 and 3.4 eV at 295 and 365 nm, respectively
Residual stress	None	Varies
Temperature resistivity coefficient (TCR) ( $^\circ\text{K}^{-1}$ )	0.0017 (p-type)	0.0012 nonlinear, + or – through selective doping, increases with decreasing doping level, can be made 0!
Poisson ratio	0.262 max for (111)	0.23
Young's modulus ( $10^{11}\text{N}/\text{m}^2$ )	1.90 (111)	1.61
Resistivity at room temperature (ohm.cm)	Depends on doping	$7.5 \cdot 10^{-4}$ (always higher than for single crystal silicone)

Source: Based on Lin (1993), Adams (1988), and Heuberger (1989). (See also Madou [1997, chap. 8, Table 8.5].)

Fortunately, SOI surface micromachining and other newly emerging surface micromachining techniques can alleviate many of the problems [Petersen et al., 1991].

## 16.17 Materials Case Studies

### 16.17.1 Introduction

Thin-film properties prove not only difficult to measure but also to reproduce, given the many influencing parameters. Dielectric and polysilicon films can be deposited by evaporation, sputtering and molecular

**TABLE 16.19** Comparison of Different Deposition Techniques

	Atmospheric Pressure CVD (APCVD)	Low Temperature LPCVD	Medium Temperature LPCVD	Plasma-Enhanced CVD (PECVD)
Temp (°C)	300–500	300–500	500–900	100–350
Materials	SiO <sub>2</sub> , P-glass	SiO <sub>2</sub> , P-glass, BP-glass	Poly-Si, SiO <sub>2</sub> , P-glass, BP-glass, Si <sub>3</sub> N <sub>4</sub> , SiON	SiN, SiO <sub>2</sub> , SiO <sub>2</sub> , SiON

beam techniques. In VLSI and surface micromachining, none of these techniques are as widely used as CVD techniques. The major problems associated with the former methods are defects caused by excessive wafer handling, low throughput, poor step coverage, and nonuniform depositions. From the comparison of CVD techniques in Table 16.19 we can conclude that LPCVD, at medium temperatures, prevails above all others. VLSI devices and integrated surface micromachines require low processing temperatures to prevent movement of shallow junctions uniform step coverage, few process-induced defects (mainly from particles generated during wafer handling and loading) and high wafer throughput to reduce cost. These requirements are best met by hot-wall, low-pressure depositions [Iscoff, 1991] (see also Madou [1997, chap. 3]). While depositing a material with LPCVD the following process parameters can be varied: deposition temperature, gas pressure, flow rate and deposition time.

Table 16.20 cites some approximate mechanical properties of microelectronic materials. The numbers for thin film materials must be approached as approximations; the various parameters affecting mechanical properties of thin films will become clear in the case studies below.

## 16.17.2 Polysilicon Deposition and Material Structure

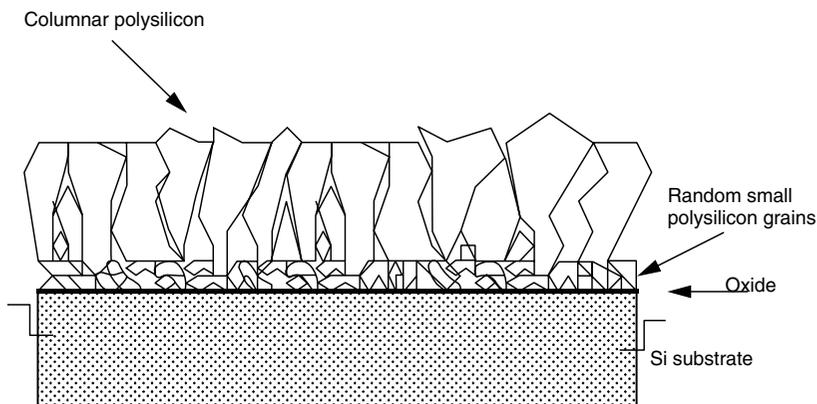

### 16.17.2.1 Introduction

The IC industry applies polysilicon in applications ranging from simple resistors, gates for MOS transistors, thin-film transistors (TFT) (with amorphous hydrogenated silicon:  $\alpha$ -Si:H), DRAM cell plates

and trench fills, as well as in emitters in bipolar transistors and conductors for interconnects. For the last application, highly doped polysilicon is especially suited; it is easy to establish ohmic contact, it is light insensitive, corrosion resistant, and its rough surface promotes adhesion of subsequent layers. Doping elements such as arsenic, phosphorous or boron reduce the resistivity of the polysilicon. Polysilicon also has emerged as the central structural/mechanical material in surface micromachining, and a closer look at the influence of deposition methodology on its materials characteristics is warranted.

### 16.17.2.2 Undoped Poly-Si

The properties of low-pressure chemical vapor deposited (LPCVD) undoped polysilicon films are determined by the nucleation and growth of the silicon grains. LPCVD Si films, grown slightly below the crystallization temperature (about 600°C for LPCVD), initially form an amorphous solid that subsequently may crystallize during the deposition process [Krulevitch, 1994; Lietoila et al., 1982]. The CVD method results in amorphous films when the deposition temperatures are well below the melting temperature of Si (1410°C). The subsequent transition from amorphous to crystalline depends on atomic surface mobility and deposition rate. At low temperatures, surface mobility is low, and nucleation and growth are limited. Newly deposited atoms become trapped in random positions and, once buried, require a substantial amount of time to crystallize as solid state diffusion is significantly lower than surface mobility. That is why, for low temperature deposition, amorphous layers only start to crystallize after sufficient time at temperature in the reactor. Working at temperatures between 580 and 591.5°C, Guckel et al. (1990) produced mostly amorphous films. But Krulevitch, working at only slightly higher temperatures (605°C) and probably leaving the films longer in the LPCVD set-up, produced crystallized films. Upon crossing the transition temperature between amorphous and crystalline growth (see Madou [1997, chap. 3, Figure 3.18]), crystalline growth immediately initiates at the substrate due to the increased surface mobility which allows adatoms to find low energy, crystalline positions from the start of the deposition process. The deposition temperature at which the transition from amorphous to a crystalline structure occurs depends on many parameters, such as deposition rate, partial pressure of hydrogen, total pressure, presence of dopants and presence of impurities (O, N or C) [Adams, 1988]. In the crystalline regime, numerous nucleation sites form, resulting in a transition zone of a multitude of small grains at the film/substrate interface to columnar crystallites on top, as shown in the schematic of a 620 to 650°C columnar film in Figure 16.103. In this figure, a transition zone of small, randomly oriented grains is sketched near the SiO<sub>2</sub> layer. The rate of crystallization is faster here than the deposition rate. Columnar grains ranging between 0.03 and 0.3 μm in diameter form on top of the small grains [Adams, 1988]. The columnar coarse grain structure arises from a process of growth competition among the small grains,

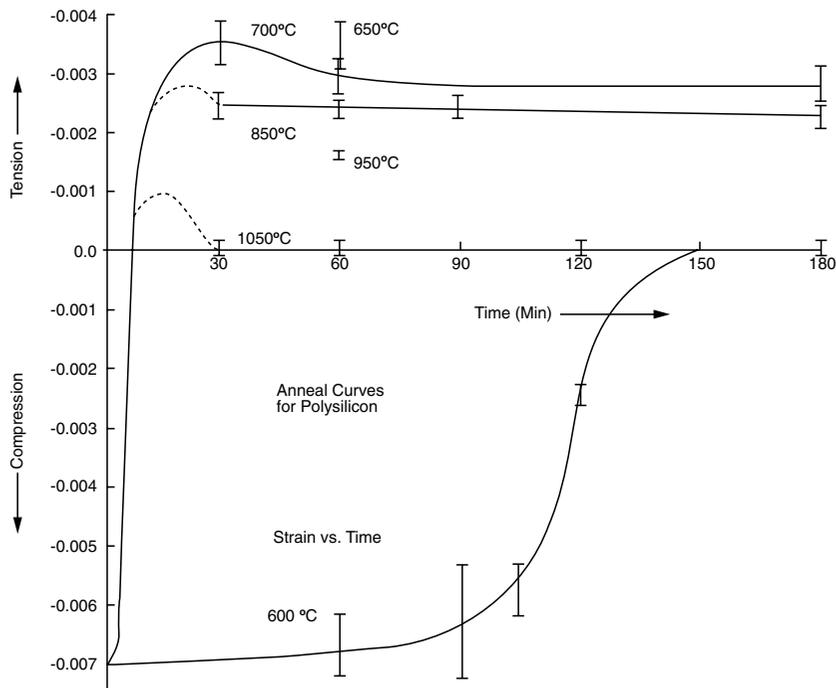

**FIGURE 16.103** Schematic of compressive poly-Si formed at 620 to 650°C. The columnar coarse-grain structure arises from a process of grain growth competition among the small grains, during which those grains preferentially oriented for fast vertical growth survive at the expense of misoriented, slowly growing grain. (After Krulevitch, P.A., *Micromechanical Investigations of Silicon and Ni-Ti-Cu Thin Films*, Ph.D. thesis, University of California, Berkeley, 1994.)

during which those grains preferentially oriented for fast vertical growth survive at the expense of misoriented, slowly growing grains [van der Drift, 1967; Matson and Polysakov, 1977]. The lower the deposition temperature, the smaller the initial grain size will be. At 700°C, films also are columnar; however, the grains are cylindrical extending through the thickness of the entire film and there is no transition zone near the SiO<sub>2</sub> interface [Krulevitch, 1994].

Stress in poly-Si films was found to vary significantly with deposition temperature and silane pressure. Guckel et al. (1990) found that their mainly amorphous films, deposited at temperatures below 600°C, proved highly compressive with strain levels as high as -0.67%. At temperatures barely above 600°C, Krulevitch reports tensile films, whereas for yet higher temperatures ( $\geq 620^\circ\text{C}$ ) the stress again turns compressive. While films deposited at temperatures greater than 630°C all turned out compressive, the magnitude of the compression decreased with increasing temperature. The stress gradient in the poly-Si films explains why compressive undoped and unannealed poly-Si beams tend to curl upward (positive stress gradient) when released from the substrate [Lober et al., 1988].

Using high resolution transmission electron microscopy, Guckel et al. (1990) and Krulevitch (1980) found a strong correlation between the material's microstructure and the exhibited stress. Guckel et al. found that in their mainly amorphous films, deposited at temperatures below 600°C, a region near the substrate interface crystallized during growth with grains between 100 and 4000 Å. Krulevitch found that tensile, low-temperature films (605°C) have Si grains dispersed throughout the film thickness. Krulevitch suggests that the compressive stress in the higher temperature compressive films ( $\geq 620^\circ\text{C}$ ) relates to the competitive growth mechanism of the columnar grains. The same author concluded that thermal sources of stress are insignificant.

Importantly, Guckel et al. discovered that annealing in nitrogen or under vacuum converts the low-temperature films with compressive built-in strain (-0.007) to a tensile strain with controllable strain levels between 0 and + 0.003 (see Figure 16.104). During anneal no grain size increase was noticed (100 to 4000 Å) but a slight increase in surface roughness was measured. This type of poly-Si is referred to as fine-grain

**FIGURE 16.104** Anneal curves for poly-Si. Strain versus anneal time. Upper curves: low-temperature film. Lower curve: high-temperature film. (From Guckel, H. et al., *IEEE Trans. Electron. Dev.*, 35, 800–801, 1988. With permission.)

poly-Si (also Wisconsin poly-Si). Guckel et al. explain this strain field reversal as follows: as the amorphous region of the film crystallizes, it attempts to contract, but due to the substrate constrained newly crystallized region, a tensile stress results. Higher temperature films, during an anneal, also become less strained, but the strain remains compressive (see lower curve in Figure 16.104). Moreover, in this case grain size does increase and the surface turns considerably rougher. The latter is called coarse-grain poly-Si. Fine-grain poly-Si with its tensile strain is preferable; however, it cannot be doped to as low a resistivity as coarse-grain polysilicon. Hence, fine-grain polysilicon should be considered as a structural material rather than an electronic material.

Summarizing stress in poly-Si depends on the material's microstructure, with tension arising from the amorphous to crystalline transformation during deposition and compression from the competitive grain growth mechanism.

Polysilicon deposited at 600 to 650°C has a {110}-preferred orientation. At higher temperatures, the {100} orientation dominates. Dopants, impurities and temperature influence this preferred orientation [Adams, 1988]. Drosd and Washburn (1982) introduced a model explaining the experimental observation that regrowth of amorphitized Si is faster for {100} surfaces, followed by {110} and {111} which are 2.3 and 20 times slower, respectively. Interestingly, the latter also pinpoints the order of fastest to slowest etching of the crystallographic planes in alkaline etchants. As discussed earlier in this chapter, Elwenspoek et al. (1994) used this observation of symmetry between etching and growing of Si planes as an important insight to develop a new theory explaining anisotropy in etching. In Table 16.21 we compare the discussed coarse- and fine-grain poly-Si forms.

The above picture might further be complicated by the controlling nature of the substrate. For example, depositing amorphous Si ( $\alpha$ -Si) at even lower temperatures of 480°C from disilane ( $\text{Si}_2\text{H}_6$ ) and crystallizing it by subsequent annealing at 600°C demonstrated a large dependency of crystallite size on the underlying  $\text{SiO}_2$  surface condition. Treating the surface with  $\text{HF}:\text{H}_2\text{O}$  or  $\text{NH}_4\text{OH}:\text{H}_2\text{O}_2:\text{H}_2\text{O}$  leads to poly-Si films with a large grain size, two or three times as large as without  $\text{SiO}_2$  treatment, believed to be the consequence of nucleation rate suppression [Shimizu and Ishihara, 1995].

T. Abe and M.L. Reed made low strain polysilicon thin film by DC-magnetics sputtering and post-annealing. The films showed very small regional stress and very smooth texture. The deposition rate was 193 Å/min and the substrate was neither cooled nor heated. The average roughness was found to be comparable to the surface roughness of polished, bare silicon substrates [Abe and Reed, 1996].

### 16.17.2.3 Doped Poly-Si

To produce micromachines, doped poly-Si is used far more frequently than undoped poly-Si. Dopants decrease the resistivity to produce conductors and control stress. Polysilicon can be doped by diffusion, implantation or the addition of dopant gases during deposition (*in situ* doping). We only detail material properties of *in situ* doped poly-Si here.

**TABLE 16.21** Comparison of Coarse-Grain and Fine-Grain Poly-Si

	Coarse-Grain Poly-Si	Fine-Grain Poly-Si
Temperature of deposition (°C)	620–650	570–591.5
Surface roughness	Rough, >50Å	Smooth, <15Å
Grain size	Undoped: 160–320 Å as deposited; <i>in situ</i> P-doped: 240–400 Å	Very small grains
As deposited strain	–0.007 (compressive)	–0.007 (compressive)
Effect of high-temperature anneal	Grains size increases, residual strain decreases but remains compressive, reduced bending moment	Grain size increases to 100 Å [Guckel et al., 1988]; others have found 700–900 Å; large variation in strain (see Figure 16.102) from compressive to tensile
Dry and wet etch rate	Higher for doped material; depends on dopant concentration	Higher for doped material; depends on dopant concentration
Texture	<110> as deposited, <311> <i>in situ</i> P-doped	No texture as deposited; depends on dopant concentration, <111> after 900–1000°C anneal [Harbeke et al., 1983]

Doping poly-Si films *in situ* reduces the number of processing steps required for producing doped micro-devices and also provides the potential for uniform doping through the film thickness. *In situ* doping of poly-Si with phosphorous is accomplished by maintaining a constant  $\text{PH}_3$  to  $\text{SiH}_4$  gas flow ratio of about 1 vol % in a hot-wall LPCVD set-up. At this ratio the phosphorus content in the film appears above the saturation limit and the excess dopant segregates at the grain boundaries [Adams, 1988]. *In situ* phosphorus-doped poly-Si undergoes the same amorphous to crystalline growth transformation observed in the undoped film, with the material's microstructure depending on deposition temperature as well as deposition pressure. The temperature of transformation is lower for the doped films than for the undoped poly-Si and occurs between 580 and 620°C [Mulder et al., 1990; Kinsbron et al., 1983]. Phosphorus doping thus enhances crystallization in amorphous silicon [Lietoila et al., 1982] and, due to passivation of the poly-Si surface by the phosphine gas, reduces the poly-Si deposition rate [Mulder et al., 1990]. Decreases in deposition rate by as much as a factor of 25 have been reported [Meyerson and Olbricht, 1984]. Slower deposition rates allow more time for adatoms to find crystalline sites, resulting in crystalline growth at lower temperatures. From Table 16.21 we read that the grain size of phosphorus-doped poly-Si tends to be larger (240 to 400 Å) than for the undoped material and that {311} planes show up as a texture facet in the doped material.

At lower deposition temperatures and higher pressures, the microstructure again consists of amorphous and crystalline regions, while at higher temperatures and lower pressures columnar films result and as deposited films exhibit compressive residual stress. The columnar films have a stress gradient that increases towards the film surface, as opposed to the gradient found in undoped columnar poly-Si. This gradient in stress most likely is due to nonuniform distribution of phosphorus throughout the film. Annealing at 950°C for 1 hour results in the same stress and stress gradient for initially columnar and initially amorphous/crystalline films (i.e.,  $\sigma_f = -45$  MPa and  $\Gamma = +0.2$  mm<sup>-1</sup>, respectively) [Krulvitch, 1994].

As with undoped poly-Si, phosphorus-doped poly-Si films with smooth surfaces (fine-grain) can be obtained by depositing *in situ* doped films in the amorphous state and then annealing [Harbeke et al., 1983; Hendriks and Maverio, 1991]. Phosphorus-doped poly-Si oxidizes faster than undoped poly-Si. The rate of oxidation is determined by the dopant concentration at the poly-Si surface [Adams, 1988].

Two drawbacks of *in situ* phosphorus doping are slower deposition rates [Kurokawa, 1982] and reduced film thickness uniformity [Meyerson and Olbricht, 1984], although uniformity can be improved by modifying the reactor geometry [Mulder et al., 1990]. As discussed before, the lower deposition rate of *in situ* phosphine doping can be mitigated by reducing the flow of phosphine/silane ratio by one third [Howe, 1995]. In contrast to *in situ* phosphine and arsine doping, which both decrease the deposition rate, diborane doping of poly-Si to make it p<sup>+</sup> accelerates the deposition rate [Adams, 1988].

The addition of oxygen to poly-Si increases the film's resistivity and the resulting coating, semi-insulating poly-Si (SIPOS) acts as a passivating coating for high voltage devices in the IC industry. The latter material does not seem to have emerged in surface micromachining yet.

The values for the fracture stress of boron-, arsenic- and phosphorus-doped polysilicon are  $2.77 \pm 0.08$  Gpa,  $2.70 \pm 0.09$  Gpa, and  $2.11 \pm 0.1$  Gpa, respectively, compared with  $2.84 \pm 0.09$  Gpa for undoped polysilicon. The lower value for phosphorus-doped material has been attributed to high surface roughness and with the large number of defects associated with extensive grain growth in highly phosphorus-doped films [Biebl and von Philipsborn, 1993].

The quest for low temperature poly-Si deposition makes the 320°C PECVD deposition method especially interesting. PECVD films, deposited in a 50-kHz parallel-plate diode reactor, can be doped *in situ* and crystallized by rapid thermal annealing (RTA: 1100°C, 100 seconds). It was shown that small-grained PECVD films annealed by RTA have good electrical properties and gauge factors between 20 and 30, i.e., similar to those reported for other alternative types of polycrystalline silicon [Compton, 1992].

### 16.17.3 Amorphous and Hydrogenated Amorphous Silicon

Amorphous silicon behaves quite different from either fine- or coarse-grain poly-Si. The amorphous material produces a high breakdown strength (7 to 9 MV/cm) oxide with low leakage currents (vs. a low

breakdown voltage and large leakage currents for polycrystalline Si oxides). Amorphous polysilicon also attains a broad maximum in its dielectric function without the characteristic sharp structures near 295 and 365 nm (4.2 and 3.4 eV) of crystalline poly-Si. Approximate refractive index values at a wavelength of 600 nm are 4.1 for crystalline polysilicon and 4.5 for amorphous material [Adams, 1988]. As deposited, the material is under compression, but an anneal at temperatures as low as 400°C reduces the stress significantly, even leading to tensile behavior [Chang et al., 1991].

Hydrogenated amorphous silicon ( $\alpha$ -Si:H) enables the fabrication of active semiconductor devices on foreign substrates at temperatures between 200 and 300°C. The technology, first applied primarily to the manufacturing of photovoltaic panels, now is quickly expanding into the field of large-area microelectronics such as active matrix liquid crystal displays (AMLCD). It is somehow surprising that micromachinists have not taken more advantage of this material either for powering surface micromachines or to implement electronics cheaply on non-Si substrates.

Spear and LeComber (1975) showed that, in contrast to  $\alpha$ -Si,  $\alpha$ -Si:H could be doped both n- and p-type. Singly bonded hydrogen, incorporated at the Si dangling bonds, reduces the electronic defect density from  $\sim 10^{19}/\text{cm}^3$  to  $\sim 10^{16}/\text{cm}^3$  (typical H concentrations are 5 to 10 atomic percent—several orders of magnitude higher than needed to passivate all the Si dangling bonds). The lower defect density results in a Fermi level that is free to move, unlike in ordinary amorphous Si, where it is pinned. Other interesting electronic properties are associated with  $\alpha$ -Si:H—exposure of  $\alpha$ -Si:H to light increases photoconductivity by four to six orders of magnitude, and its relatively high electron mobility ( $\sim 1 \text{ cm}^2/\text{V sec}^{-1}$ ) enables fabrication of useful thin-film transistors. Only recently did Lee et al. (1995) note that hydrogenated amorphous silicon solar cells are an attractive means to realize an on-board power supply for integrated micromechanical systems. They point out that the absorption coefficient of  $\alpha$ -Si:H is more than an order of magnitude larger than that of single crystal Si near the maximum solar photon energy region of 500 nm. Accordingly, the optimum thickness of the active layer in an  $\alpha$ -Si:H solar cell can measure 1  $\mu\text{m}$ , much smaller than that of single crystal Si solar cells. By interconnecting 100 individual solar cells in series, the measured open circuit potential reaches as high as 150 V under AM 1.5 conditions, a voltage high enough to drive on-board electrostatic actuators.

Hydrogenated amorphous silicon is manufactured by plasma-enhanced chemical vapor deposition from silane. Usually, planar RF-driven diode sources using  $\text{SiH}_4$  or  $\text{SiH}_4/\text{H}_2$  mixtures are used. Typical pressures of 75 mTorr and temperatures between 200 and 300°C allow silane decomposition with Si deposition as the dominant reaction. Decomposition occurs by electron impact ionization, producing many different neutral and ionic species [Crowley, 1992]. Deposition rates for usable device quality  $\alpha$ -Si:H generally do not exceed  $\sim 2$  to 5  $\text{\AA}/\text{sec}$ , due to the effects of temperature, pressure and discharge power. Table 16.22 gives state-of-the-art parameters for  $\alpha$ -Si:H prepared by PECVD. Although its semiconducting properties are inferior to single crystal Si, the material is finding more and more applications. Some examples are TFT switches for picture elements in AMLCDs [Holbrook and McKibben, 1992], page-wide TFT-addressed document scanners, high-voltage TFTs capable of switching up to 500 V etc. [Bohm, 1988]. An excellent source for further information on amorphous silicon is the book *Plasma Deposition of Amorphous Silicon-Based Materials* [Bruno et al., 1995].

#### 16.17.4 Silicon Nitride

Silicon nitride is a commonly used material in microcircuit and microsensors fabrication due to its many superior chemical, electrical, optical and mechanical properties. The material provides an extremely good barrier to the diffusion of water and to ions, particularly of  $\text{Na}^+$ . It also oxidizes slowly (about 30 times less than silicon) and has highly selective etch rates over  $\text{SiO}_2$  and Si in many etchants. Some applications of silicon nitride are optical waveguides (nitride/oxide), encapsulant (diffusion barrier to water and ions), insulator (high dielectric strength), mechanical protection layer, etch mask, oxidation barrier and ion implant mask (density is 1.4 times that of  $\text{SiO}_2$ ). Silicon nitride is also hard and can be used as, for example, a bearing material in micromotors [Pool, 1988].

**TABLE 16.22** Typical Opto-Electronic Parameters Obtained for PECVD  $\alpha$ -Si:H

	Symbol	Parameter
Undoped		
Hydrogen content		~10%
Dark conductivity at 300 K	$\sigma_D$	$\sim 10^{-10} (\Omega\text{-cm})^{-1}$
Activation energy	$E_\sigma$	0.8–0.9 eV
Pre-exponent conductivity factor	$\sigma_0$	$> 10^3 (\Omega\text{-cm})^{-1}$
Optical band gap at 300 K	$E_g$	1.7–1.8 eV
Temperature variation of band gap	$E_g(T)$	$2\text{--}4 \times 10^{-4} \text{ eV/K}$
Density of states at the minimum	$g_{\text{min}}$	$> 10^{15}\text{--}10^{17} \text{ cm}^3/\text{eV}$
Density of states at the conduction band edge		$\sim 10^{15}/\text{cm}^3$
ESR spin density	$N_s$	$\sim 10^{21}/\text{cm}^3\text{--eV}$
Infrared spectra		2000/640 $\text{cm}^{-1}$
Photoluminescence peak at 77K		~1.25 eV
Extended state mobility		
Electrons	$\mu_n$ or $\mu_e$	$> 10 \text{ cm}^2/\text{V-s}$
Holes	$\mu_p$ or $\mu_h$	$\sim 1 \text{ cm}^2/\text{V-s}$
Drift mobility		
Electrons	$\mu_n$ or $\mu_e$	$\sim 1 \text{ cm}^2/\text{V-s}$
Holes	$\mu_p$ or $\mu_h$	$\sim 10^{-2} \text{ cm}^2/\text{V-s}$
Conduction band tail slope		25 meV
Valence band tail slope		40 meV
Hole diffusion length		~1 $\mu\text{m}$
Doped amorphous		
n-Type <sup>a</sup>	$\sigma_D$	$10^{-2} (\Omega\text{-cm})^{-1}$
	$E_g$	~0.2 eV
p-Type <sup>b</sup>	$\sigma_D$	$10^{-3} (\Omega\text{-cm})^{-1}$
	$E_g$	~0.3 eV
Doped microcrystalline		
n-Type <sup>c</sup>	$\sigma_D$	$\geq 1 (\Omega\text{-cm})^{-1}$
	$E_g$	$\leq 0.05 \text{ eV}$

Silicon nitride can be deposited by a wide variety of CVD techniques: APCVD, LPCVD and PECVD. Nitride often is deposited from  $\text{SiH}_4$  or other Si containing gases and  $\text{NH}_3$  in a reaction such as:

In this CVD process, the stoichiometry of the resulting nitride can be moved toward a silicon-rich composition by providing excess silane or dichlorosilane compared to ammonia.

#### 16.17.4.1 PECVD Nitride

Plasma-deposited silicon nitride, also plasma nitride or SiN, is used as the encapsulating material for the final passivation of devices. The plasma-deposited nitride provides excellent scratch protection, serves as a moisture barrier and prevents sodium diffusion. Because of the low deposition temperature, 300 to 350°C, the nitride can be deposited over the final device metallization. Plasma-deposited nitride

**TABLE 16.23** Properties of Silicon Nitride<sup>a</sup>

Deposition	LPCVD	PECVD
Temperature (°C)	700–800	250–350
Density (g/cm <sup>3</sup> )	2.9–3.2	2.4–2.8
Pinholes	No	Yes
Throughput	High	Low
Step coverage	Conformable	Poor
Particles	Few	Many
Film quality	Excellent	Poor
Dielectric constant	6–7	6–9
Resistivity (Ωcm)	10 <sup>16</sup>	10 <sup>6</sup> –10 <sup>15</sup>
Refractive index	2.01	1.8–2.5
Atom % H	4–8	20–25
Energy gap	5	4–5
Dielectric strength (10 <sup>6</sup> V/cm)	10	5
Etch rate in conc. HF	200 Å/min	
Etch rate in BHF	5–10 Å/min	
Residual stress (10 <sup>9</sup> dyn/cm <sup>2</sup> )	1T	2 C–5T
Poisson ratio	0.27	
Young's modulus	270 GPa	
TCE	1.6 × 10 <sup>-6</sup> /°C	

Note: C = compressive; T = tensile.

<sup>a</sup> See Adams (1988), Sinha and Smith (1978) and Retajczyk and Sinha (1980).

and oxide both act as insulators between metallization levels, particularly useful when the bottom metal level is on aluminum or gold. The silicon nitride that results from PECVD in the gas mixture of Reaction 16.2 has two shortcomings: high hydrogen content (in the range of 20 to 30 atomic percent) and high stress. The high compressive stress (up to  $5 \times 10^9$  dyn/cm<sup>2</sup>) can cause wafer warping and voiding and cracking of underlying aluminum lines [Rosler, 1991]. The hydrogen in the nitride also leads to degraded MOSFET lifetimes. To avoid hydrogen incorporation, one may employ low or no hydrogen-containing source gases such as nitrogen instead of ammonia as the nitrogen source. Also, a reduced flow of SiH<sub>4</sub> results in less Si-H in the film. The hydrogen content and the amount of stress in the film are closely linked. Compressive stress, for example, changes toward tensile stress upon annealing to 490°C in proportion to the Si-H bond concentration. By adding N<sub>2</sub>O to the nitride deposition chemistry an oxynitride forms with lower stress characteristics; however, oxynitrides are somewhat less effective as moisture and ion barriers than nitrides.

We discussed the effect of RF frequency on nitride stress, hydrogen content, density and the wet etch rate in detail in Madou (1997, chap. 3). We can conclude that low frequency (high energy bombardment) results in films with low compressive stress, lower etch rates and higher density. The higher the ion bombardment during PECVD, the higher the stress is. Stress also is affected by moisture exposure and temperature cycling (for a good review, see Wu and Rosler [1992]). We compare properties of silicon nitride formed by LPCVD and PECVD in Tables 16.23 and 16.24. Table 16.24 highlights typical process parameters.

#### 16.17.4.2 LPCVD Nitride

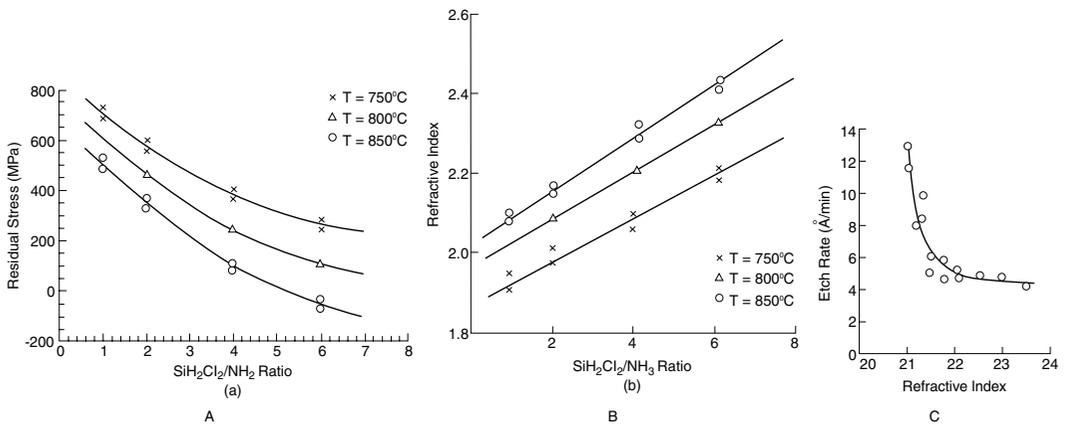

In the IC industry, stoichiometric silicon nitride (Si<sub>3</sub>N<sub>4</sub>) is LPCVD deposited at 700 to 900°C and functions as an oxidation mask and as a gate dielectric in combination with thermally grown SiO<sub>2</sub>. In micromachining, LPCVD nitride serves as an important mechanical membrane material and isolation/buffer layer. By increasing the Si content in silicon nitride the tensile film stress reduces (even to compressive), the film turns more transparent and the HF etch rate lowers. Such films result by increasing the dichlorosilane/ammonia ratio [Sakimoto et al., 1982].

Figure 16.105 illustrates the effect of gas flow ratio and deposition temperature on stress and the corresponding refractive index and HF etch rate [Sakimoto et al., 1982].

**TABLE 16.24** Silicon Nitride PECVD Process Conditions

Flow (sccm)	SiH <sub>4</sub>	190–270

BHF	25	5 to 10	1:200:±0
HF (40%)	25	200	1:>100:0.1

Silicon-rich or low-stress nitride emerges as an important micromechanical material. Low residual stress means that relatively thick films can be deposited and patterned without fracture. Low etch rate in HF means that films of silicon-rich nitride survive release etches better than stoichiometric silicon nitride. The etch characteristics of LPCVD SiN are summarized in Table 16.25. The properties of a LPCVD Si<sub>x</sub>N<sub>y</sub> film, deposited by reaction of SiCl<sub>2</sub>H<sub>2</sub> and NH<sub>3</sub> (5:1 by volume) at 850°C, were already summarized in Table 16.23.

### 16.17.5 CVD Silicon Dioxides

Silicon oxides, like other dielectrics, function as insulation between conducting layers, for diffusion and ion implementation masks, for diffusion from doped oxides, for capping doped oxides to prevent the

loss of dopants, for gettering impurities and for passivation to protect devices from impurities, moisture and scratches. In micromachining, silicon oxides serve the same purposes but also act as sacrificial material. Phosphorus-doped glass (PSG), also called P-glass or phosphosilicate glass, and borophosphosilicate glasses (BPSG) soften and flow at lower temperatures enabling the smoothing of topography. They etch much faster than  $\text{SiO}_2$ , which benefits their application as sacrificial material. The deposition of thermal  $\text{SiO}_2$  is covered in Madou (1997, chap. 3). Now we consider CVD techniques to deposit doped and undoped  $\text{SiO}_2$ .

#### 16.17.5.1 CVD Undoped $\text{SiO}_2$

Several CVD methods will deposit  $\text{SiO}_2$ . CVD silicon dioxide can be deposited on the wafer out of the vapor phase from the reaction of silane ( $\text{SiH}_4$ ) with oxygen at relative low temperatures (300 to 500°C) and low pressure. The silane/oxygen gas mixture has been applied at atmospheric pressure (AP) and plasma-enhanced conditions. The main advantage of silane/oxygen is the low deposition temperature; the main disadvantage is the poor step coverage.

In general, tetraethylorthosilicate (TEOS) brings about a better starting chemistry than the traditional silane-based CVD technologies. TEOS-based depositions lead to superior film quality in terms of step coverage and reflow properties. With an LPCVD reactor, the deposition temperature for TEOS is as high as 650 to 750°C, precluding its use over aluminum lines. In contrast, silicon dioxide is deposited by PECVD at 300 to 400°C from TEOS. CVD oxides in general feature porosity and low density. Low frequency (high energy) ion bombardment results in more compressive films, higher density and lower etch rates as well as better moisture resistance [Rosler, 1991]. Use of TEOS oxide, to replace  $\text{SiH}_4$ -based oxide in spin-on-glass (SOG) and photoresist planarization schemes, now has become commonplace for devices with small features.

Yet another promising silicon dioxide deposition technology is the subatmospheric pressure CVD (SACVD). Both undoped and borophosphosilicate glass have been deposited in this fashion. The process involves an ozone and TEOS reaction at a pressure of 600 Torr and at a temperature below 400°C. While offering the same good step coverage over submicron gaps, the films from the thermal reaction of ozone and TEOS exhibit relatively neutral stress and have a higher film density compared to low pressure processes. This increased density gives the oxide greater moisture resistance, lower wet etch rate and smaller thermal shrinkage. Compared to a 60-Torr process, the film density has increased from 2.09 to 2.15  $\text{g}/\text{cm}^3$ ; the wet etch rate decreased by more than 40%; and the thickness shrinkage changed from 12 to 4% after a 30-min anneal in dry  $\text{N}_2$  at 1000°C [Lee et al., 1992].

#### 16.17.5.2 CVD Phosphosilicate Glass Films

Adding a few percent of phosphine to the gas stream during deposition to obtain a lower melting point for the oxide ( $\text{PH}_3$ ) results in a phosphosilicate glass. Numerous applications of this material exist, such as:

1. Interlevel dielectric to insulate metallization levels
2. Gettering and flow capabilities
3. Passivation overcoat to provide mechanical protection for the chip from its environment
4. Solid diffusion source to dope silicon with phosphorus
5. Fast etching sacrificial material in surface micromachining

Both wet and dry etching rates of PSG are faster than the undoped material and depend on the dopant concentration. Profiles over steps get progressively smoother with higher phosphorous concentrations, reflecting the corresponding enhancement in viscous flow [Levy and Nassau, 1986]. Increased ion bombardment (energy or density) in a PECVD PSG results in more stable phosphosilicate glass film with compressive as-deposited stress. Table 16.26 summarizes typical PSG process conditions [Wu et al., 1992].

The addition of boron to P-glass further lowers its softening temperature. Flow occurs at temperatures between 850 and 950°C, even with phosphorous concentration as low as 4 wt%. A BPSG doped at 4% boron and 6% phosphorus is normal. BPSG deposition conditions are shown in Table 16.27 [Bonifield et al., 1993].

**TABLE 16.26** Typical PSG Process Conditions

Flow (sccm)	SiH <sub>4</sub>	150–230

## 16.18 Polysilicon Surface Micromachining Examples

### Example 1. Analog Devices Accelerometer

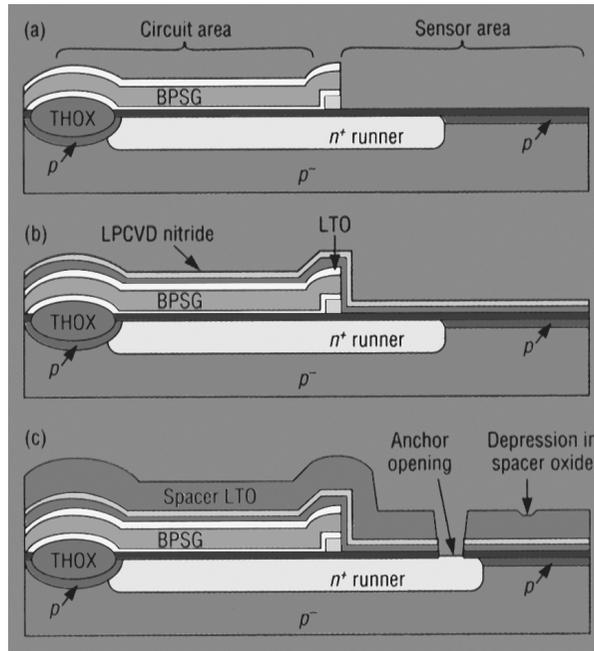

Accelerometers based on lateral resonators represent the main application of surface micromachining today. To facilitate integration of their 50-g surface micromachined accelerometer (ADXL-50) with on-board electronics, Analog Devices opted for a mature 4- $\mu$ m BICMOS process [Core et al., 1993]. Figure 16.106 presents a photograph of the finished capacitive sensor (center) with on-chip excitation, self-test and signal conditioning circuitry. The polysilicon-sensing element only occupies 5% of the total die area. The whole chip measures 500  $\times$  625  $\mu$ m and operates as an automotive airbag deployment sensor. The measurement accuracy is 5% over the  $\pm$ 50-g range. Deceleration in the axis of sensitivity exerts a force on the central mass that, in turn, displaces the interleaved capacitor plates, causing a fractional change in capacitance. In operation, the device has a force-balance electronic control loop to prevent the mass from actual movement. Straight flexures were used for the layout of the lateral resonator shuttle mass (see Figure 16.89B).

In the sensor design, n<sup>+</sup> underpasses connect the sensor area to the electronic circuitry, replacing the usual heat-sensitive aluminum connect lines. Most of the sensor processing is inserted into the BICMOS

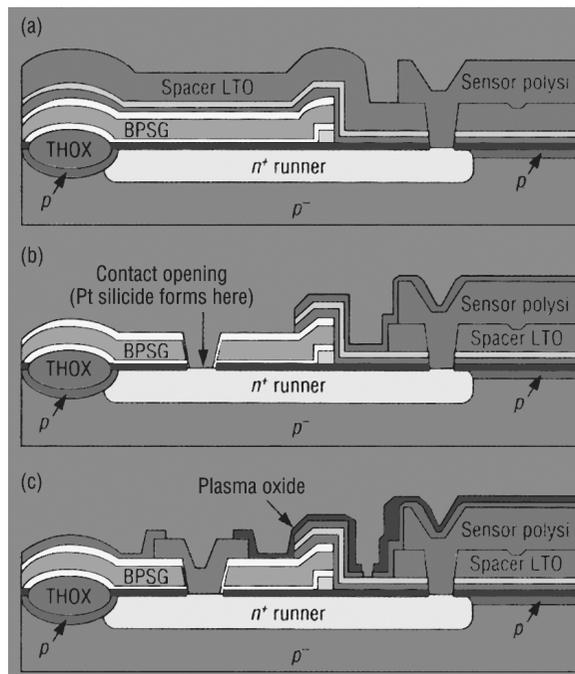

**FIGURE 16.106** Analog Devices' ADXL-50 accelerometer with a surface micromachined capacitive sensor (center), on-chip excitation, self-test, and signal-conditioning circuitry. (From Core, T.A. et al., *Solid State Technol.*, October, 39–47 (1993). With permission.)

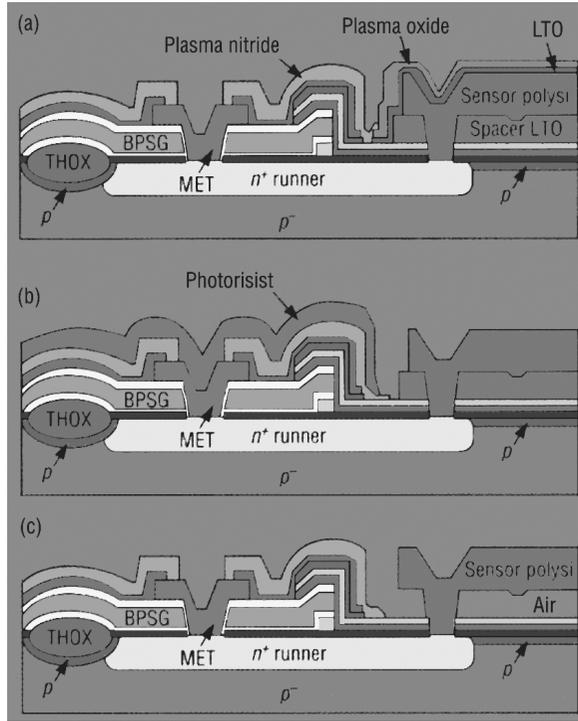

process right after the borophosphosilicate glass planarization. After planarization, a designated sensor region or moat is cleared in the center of the die (Figure 16.107a). A thin oxide is then deposited to passivate the  $n^+$  underpass connects, followed by a thin, low-pressure, vapor-deposited nitride to act as an etch stop (buffer layer) for the final poly-Si release etch (Figure 16.107b). The spacer or sacrificial oxide used is a 1.6- $\mu\text{m}$  densified low-temperature oxide (LTO) deposited over the whole die (Figure 16.107c). In a first timed etch, small depressions that will form bumps or dimples on the underside of the polysilicon sensor are created in the LTO layer. These will limit stiction in case the sensor comes in contact with the substrate. A subsequent etch cuts anchors into the spacer layer to provide regions of electrical and mechanical contact (Figure 16.107c). The 2- $\mu\text{m}$ -thick sensor poly-Si is then deposited, implanted, annealed and patterned (Figure 16.108a). The relatively deep junctions of the BICMOS process permit the polysilicon thermal anneal as well as brief dielectric densifications without resulting in degradation of the electronic functions. Next is the IC metallization which starts with the removal of the sacrificial spacer oxide from the circuit area along with the LPCVD nitride and LTO layer. A low-temperature oxide is deposited on the poly-Si sensor part and contact openings appear in the IC part of the die where platinum is deposited to form a platinum silicide (Figure 16.108b). The trimmable thin-film material, TiW barrier metal and Al/Cu interconnect metal are sputtered on and patterned in the IC area. The circuit area is then passivated in two separate deposition steps. First, plasma oxide is deposited and patterned (Figure 16.108c), followed by a plasma nitride to form a seal with the earlier deposited LPCVD nitride (Figure 16.109a). The nitride acts as an HF barrier in the subsequent long etch release. The plasma oxide left on the sensor acts as an etch stop for the removal of the plasma nitride (Figure 16.109a). Subsequently, the sensor area is prepared for the final release etch. The undensified dielectrics are removed from the sensor and the final protective resist mask is applied. The photoresist protects the circuit area from the long-term buffered oxide etch (Figure 16.109b). The final device cross section is shown in Figure 16.109c.

### Example 2. Polysilicon Stepping Slider

The principle of operation of the stepping slider is illustrated in Figure 16.110 [Akiyama, 1993; Akiyama and Shono, 1993]. Figure 16.110A shows a cross-sectional view of the polysilicon slider plate (length = 50  $\mu\text{m}$ , width = 30  $\mu\text{m}$ , height = 1.0  $\mu\text{m}$ ) and bushing (height = 1  $\mu\text{m}$ ) on an insulator film ( $\text{Si}_3\text{N}_4$ ) as it sets one step. Figure 16.110B displays a schematic of the complete slider. At the rise of an applied voltage pulse on the slider rail, the polysilicon plate is pulled down. Since one end of the plate, supported by the bushing, cannot move, the other part is pulled down to come into contact with the surface of the insulator. The warp of the plate causes the bushing to shift. At the fall of the pulse, the distortion is released and the

**FIGURE 16.110** Principle of operation of stepping slider. (A) Cross-sectional view of the polysilicon plate and bushing on an insulator ( $\text{Si}_3\text{N}_4$ ) on Si as the plate moves one step. (B) Schematic diagram of stepping slider.

plate snaps back to its original shape. If the size of the polysilicon step is  $\Delta x$ , the velocity of the polysilicon microstructure is given by:

$$v = \Delta x \cdot f \tag{16.64}$$

where  $f$  is the frequency of the pulse. The size of the step itself is given by:

$$\Delta x = \frac{h^2}{2(I - I')} \tag{16.65}$$

where  $I'$  stands for the length of the plate touching the insulator film.

Figure 16.111 illustrates the sequence of a stepping slider fabrication process. A layer of 0.3- $\mu\text{m}$  silicon nitride is deposited at 900°C by the reaction of  $\text{SiH}_4$  and  $\text{NH}_3$  in  $\text{N}_2$ . Next, *in situ* phosphorus-doped polysilicon is deposited and patterned in a  $\text{SF}_6$  plasma to form the sliding rail for the power supply of the slider (A) (mask 1). Thick sacrificial  $\text{SiO}_2$  is deposited at 610°C by CVD of  $\text{SiH}_4$  and  $\text{O}_2$  in  $\text{N}_2$ . The thickness of the oxide (1  $\mu\text{m}$ ) determines the future bushing height. The oxide is patterned with a second mask exposing the silicon nitride in the area of the bushing. Fifty nm of CVD PSG is then deposited over the whole wafer at 610°C from the thermal reaction of  $\text{SiH}_4$ ,  $\text{PH}_3$  and  $\text{O}_2$  in  $\text{N}_2$  (B). In step C, 1.4- $\mu\text{m}$

**FIGURE 16.112** SEM micrograph of the stepping slider (top) and scanned image (bottom). (From Akiyama, T., *J. Microelectromech. Syst.*, 2, 106–110, 1993. With permission.)

polysilicon is deposited at 610°C from  $\text{SiH}_4$ , coated with PSG and patterned with mask 3 to shape the slider plate. The silicon wafer is then heated in  $\text{N}_2$  at 1050°C for 60 min to release the residual strain in the polysilicon and at the same time to activate and diffuse phosphorus from the PSG into the polysilicon slider. The last step (D) in the fabrication process is the release of the polysilicon slider, by dipping the wafer into 50% HF to fully dissolve the sacrificial oxide. Finally, the wafer is rinsed in deionized water and IPA (isopropyl-alcohol) and dried in  $\text{N}_2$ . In the fabrication process, to avoid washing away the slider in the rinse, the slider is attached by polysilicon springs to the end of the rail. The springs are cut by the step motion of the slider and subsequently the sliders can move along the rail. The velocity at the peak voltage of 150 V is 30  $\mu\text{m}/\text{sec}$  with a 1200-Hz pulse. Figure 16.112 shows an SEM photo of the resulting slider (top). Components of the slider are named on the scanned image (bottom).
